formalism for Lagrangian perturbation theory (LPT).[3–6] Nonlinear PT is limited to weakly nonlinear scales, but it is nevertheless important because of the BAO and RSD effects are manifested in these scales. Non-linearities in MG show special features such as screening mechanisms due to the fifth force of the scalar degree of freedom present in these models.[7]

Since our goal is to test gravity at cosmic scales, one employs toy MG models, such as f(R) or Dvali-Gabadadze-Porrati (DGP) models to achieve a percent-level of precision in the power spectrum (PS) or two point correlation function, that will allow to describe the physics that new generation of stage IV experiments will be able to reach soon, such as DESI,[8] EUCLID[9] and LSST,[10] among others. Therefore, a whole machinery of tools are being developed, including precision theory, mocks, simulations, emulators, among other technical improvements, see for instance Alam et al.[11]

There are a few pieces to be understood to study LSS in PT, and that we tackle in the present work: description of the dynamics of density fields composed of dark matter particles, and here one has LPT and SPT; then, one has to deal with biased tracers; to understand how the RSD description is modelled in MG; to add the small-scale effective field theory (EFT) corrections coming from UV-cutoffs of PT; and finally, to apply a IR-resummation of modes to cancel out unwanted features in the power spectrum.

Our primer to PT for MG is organized as follows: We first explain, in section 2, how LPT is obtained and the role of growth functions is emphasized, and in section 3 we discuss their use to screen the fifth force. In section 4, we explain how LPT results can be used to obtain SPT ones, establishing a bridge between these two formalisms. In section 5, we present the power spectra for matter fields and in section 6 we introduce the bias parameter that contributes to power spectra for tracers. In section 7 we review recent results in which we modeled RSD for MG models. Finally, in section 8, EFT and IR-resummation explanations are shortly addressed, before we conclude in section 9.

2. LPT for MG

At the large scales we are working, baryons behave essentially as cold dark matter. So, from now on we consider the whole matter that follows trajectories with Eulerian comoving coordinates $\mathbf{x}$. The Lagrangian displacement vector field $\mathbf{\Psi}$ relates the initial (Lagrangian) $\mathbf{q}$ and Eulerian $\mathbf{x}$ positions of particles as $\mathbf{\Psi}(\mathbf{q},t) = \mathbf{x}(\mathbf{q},t) - \mathbf{q}$, chosen such that $\mathbf{x}(\mathbf{q}, t_{ini}) = \mathbf{q}$, with t_{ini} an early time where the evolution of all scales of interest remains linear and the overdensities are quite small, $\delta(\mathbf{x}, t_{ini}) = \delta(\mathbf{q}) \ll 1$. We consider $\mathbf{\Psi}$ a longitudinal field, since it is the only contribution to 1-loop. Using matter conservation,

$$(1 + \delta(\mathbf{x}, t))d^3x = (1 + \delta(\mathbf{q}))d^3q, \tag{1}$$

one gets the known relation between density and Lagrangian fields

$$\delta(\mathbf{x},t) = \frac{1+\delta(\mathbf{q})-J}{J} \simeq \frac{1-J}{J}, \tag{2}$$

where $J_{ij} = \partial x_i/\partial q^j = \delta_{ij} + \Psi_{i,j}$ is the Jacobian matrix of the coordinate transformation and J its determinant. Since $\mathbf{\Psi}$ is a potential field, the Jacobian matrix is symmetric.

The fundamental field in LPT is the displacement field, and its equation of motion is given by the geodesic equation,

$$\hat{\mathcal{T}}\mathbf{\Psi}(\mathbf{q},t) = -\frac{1}{a}\nabla_{\mathbf{x}}\psi(\mathbf{x},t)|_{\mathbf{x}=\mathbf{q}+\mathbf{\Psi}}. \tag{3}$$

where $\hat{\mathcal{T}} \equiv \frac{d^2}{dt^2} + 2H\frac{d}{dt}$. We use $\nabla_{\mathbf{x}} = \partial/\partial\mathbf{x}$ to denote partial differentiation with respect to Eulerian coordinates, and $\nabla = \partial/\partial\mathbf{q}$ for differentiation with respect to Lagrangian coordinates. The two scalar gravitational potentials of the metric are related by $\phi - \psi = \varphi/2$, assuming Newtonian gauge, where φ is the scalar field mediating the fifth force.

The gravity model can be set out in the Einstein frame, where the Ricci scalar in the Lagrangian is not coupled to the scalar field, but the couplings are given by the scalar field and the matter Lagrangian, such as in Symmetron gravity.[12] Another possibility is to lay out the theory in the Jordan frame, where explicit couplings exist between the Ricci and the scalar field, such as Brans-Dicke type of couplings, and in addition, couplings to matter may exist. For the sake of concreteness, we opt for the latter approach here, but we will show below some results for the former, as well. Then, the Poisson equation is

$$\frac{1}{a^2}\nabla^2_{\mathbf{x}}\psi = A_0\delta(\mathbf{x},t) - \frac{1}{2a^2}\nabla^2_{\mathbf{x}}\varphi. \tag{4}$$

clearly, the scalar field modifies the Newtonian potential (ψ), and then the force upon to test particles. The Klein-Gordon equation in the quasi-static limit takes the form[2]

$$(3+2\omega_{\rm BD})\frac{1}{a^2}\nabla^2_{\mathbf{x}}\varphi = -8\pi G\bar{\rho}\delta + \mathrm{NL}, \tag{5}$$

where NL contains all nonlinear terms to be defined next that will encode the mode couplings.

It is useful to consider PT in the Fourier space, in which modes are decoupled for LCDM and become simple for MG models at first order approximation. The full expansion for Klein-Gordon equation becomes

$$\begin{aligned} -\frac{k^2}{2a^2}\varphi(\mathbf{k}) = &-(A(k)-A_0)\tilde{\delta}(\mathbf{k}) + \frac{k^2/a^2}{6\Pi(k)}\delta I(\mathbf{k}) \\ &- \frac{(3+2\omega_{\rm BD})k^2/a^2}{3\Pi(k)}\frac{1}{2a^2}[(\nabla^2_{\mathbf{x}}\varphi - \nabla^2\varphi)](\mathbf{k}), \end{aligned} \tag{6}$$

where $[(\cdots)](\mathbf{k})$ means Fourier transform of $(\cdots)(\mathbf{q})$ and we defined

$$A(k) = A_0\left(1 + \frac{k^2/a^2}{3\Pi(k)}\right), \tag{7}$$

$$\Pi(k) = \frac{1}{3a^2}\big((3 + 2\omega_{\rm BD})k^2 + M_1 a^2\big), \tag{8}$$

$$A_0 = A(k = 0, t) = 4\pi G\bar{\rho}. \tag{9}$$

$A(k)$ is the gravitational strength in the MG cases, while A_0 is for GR. In Brans-Dicke type theories we identify $3 + 2\omega_{\rm BD} = 1/2\beta^2$, allowing us to recognize the β parameter as the strength of the matter to scalar field coupling.

There are two nonlinear terms in eq. (6), the second and third terms of the right hand side (r.h.s.). The second term encodes the nonlinear gravity model, given by

$$\begin{aligned}\delta I(\mathbf{k}) = {} & \frac{1}{2}\int \frac{d^3k_1 d^3k_2}{(2\pi)^3}\delta_{\rm D}(\mathbf{k} - \mathbf{k}_1 - \mathbf{k}_2)M_2(\mathbf{k}_1, \mathbf{k}_2)\varphi(\mathbf{k}_1)\varphi(\mathbf{k}_2) \\ & + \frac{1}{3}\int \frac{d^3k_1 d^3k_2 d^3k_3}{(2\pi)^6}\delta_{\rm D}(\mathbf{k} - \mathbf{k}_1 - \mathbf{k}_2 - \mathbf{k}_3)M_3(\mathbf{k}_1, \mathbf{k}_2, \mathbf{k}_3)\varphi(\mathbf{k}_1)\varphi(\mathbf{k}_2)\varphi(\mathbf{k}_3).\end{aligned} \tag{10}$$

The M_i functions carry the gravitational properties of particular MG models. It is convenient to insert eq. (6) into eq. (10) to obtain an equation in terms of δ expansions that is useful to find the final expression for the displacements.

The third term accounts for the difference of the Laplacian in x- and q- coordinates, the so called frame-lagging term:

$$\begin{aligned}[(\nabla^2_{\mathbf{x}}\varphi - \nabla^2\varphi)](\mathbf{k}) = {} & [-2\Psi_{i,j}\varphi_{,ij} - \Psi_{i,ij}\varphi_{,j} + 3\Psi_{i,j}\Psi_{j,k}\varphi_{,ki} + 2\Psi_{i,j}\Psi_{j,ik}\varphi_{,k} \\ & + \Psi_{l,li}\Psi_{i,j}\varphi_{,j}](\mathbf{k}),\end{aligned} \tag{11}$$

computed up to third-order PT. This term contributes at different scales, but it is more important at large scales, especially if the theory is expected to reduce to GR in that limit.

It is convenient to recast eq. (3) in terms of only Lagrangian coordinates, then by taking the $\mathbf{x}$-divergence and transforming to Lagrangian coordinates with the aid of $\nabla_{\mathbf{x}i} = (J^{-1})_{ji}\nabla_i$, we get in Fourier space

$$\big[(J^{-1})_{ij}\hat{\mathcal{T}}\Psi_{i,j}\big](\mathbf{k}) = -A(k)\tilde{\delta}(\mathbf{k}) + \frac{2\beta^2k^2}{k^2 + m^2a^2}\delta I(\mathbf{k}) + \frac{1}{2}\frac{m^2}{k^2 + m^2a^2}[(\nabla^2_{\mathbf{x}}\varphi - \nabla^2\varphi)](\mathbf{k}), \tag{12}$$

and

$$\tilde{\delta}(\mathbf{k}) = \int d^3q e^{-i\mathbf{q}\cdot\mathbf{k}}\delta(\mathbf{x}) = \left[\frac{1 - J(\mathbf{q})}{J(\mathbf{q})}\right](\mathbf{k}). \tag{13}$$

Eq. (12) is solved perturbatively using $(J^{-1})_{ij} = \delta_{ij} - \Psi_{i,j} + \Psi_{i,k}\Psi_{k,j} + \cdots$. One obtains the following equation for the displacement at third order PT:

$$\begin{aligned}(\hat{\mathcal{T}} - A(k))[\Psi_{i,i}](\mathbf{k}) = {} & [\Psi_{i,j}\hat{\mathcal{T}}\Psi_{j,i}](\mathbf{k}) - \frac{A(k)}{2}[\Psi_{i,j}\Psi_{j,i}](\mathbf{k}) - \frac{A(k)}{2}[(\Psi_{l,l})^2](\mathbf{k}) \\ & - [\Psi_{i,k}\Psi_{k,j}\hat{\mathcal{T}}\Psi_{j,i}](\mathbf{k}) + \frac{A(k)}{6}[(\Psi_{l,l})^3](\mathbf{k}) \\ & + \frac{A(k)}{2}[\Psi_{l,l}\Psi_{i,j}\Psi_{j,i}](\mathbf{k}) + \frac{A(k)}{3}[\Psi_{i,k}\Psi_{k,j}\Psi_{j,i}](\mathbf{k}) \\ & + \frac{k^2/a^2}{6\Pi(\mathbf{k})}\delta I(\mathbf{k}) + \frac{M_1}{6\Pi(k)}\frac{1}{a^2}[(\nabla^2_{\mathbf{x}}\varphi - \nabla^2\varphi)](\mathbf{k}). \end{aligned} \tag{14}$$

One then can analyze solutions at different PT orders. To linear order one has

$$(\hat{\mathcal{T}} - A(k,t))[\Psi^{(1)}_{i,i}] = 0, \tag{15}$$

which is the same equation for the linear matter overdensity. Hence, the first order solution is

$$\Psi^{(1)}_i(\mathbf{k},t) = i\frac{k_i}{k^2}\delta_L(\mathbf{k},t) = i\frac{k_i}{k^2}D_+(k,t)\delta_L(\mathbf{k},t_0), \tag{16}$$

where we notice the normalization is fixed by eq. (1), and we choose the growth function such that $D_+(k \to 0, t_0) = 1$, where t_0 denotes present time. More generally, Lagrangian displacements are expanded as

$$\Psi_i(\mathbf{k}) = \sum_{n=0}^{\infty}\Psi^{(n)} = \sum_{n=1}^{\infty}\frac{i}{n!}\int_{\mathbf{k}_{1\cdots n}=\mathbf{k}} L^{(n)}_i(\mathbf{k}_1,...,\mathbf{k}_n)\delta_L(\mathbf{k}_1)\cdots\delta_L(\mathbf{k}_n). \tag{17}$$

Hereafter we make use of the shorthand notation

$$\int_{\mathbf{k}_{1\cdots n}=\mathbf{k}} = \int\frac{d^3\mathbf{k}_1}{(2\pi)^3}\cdots\frac{d^3\mathbf{k}_n}{(2\pi)^3}(2\pi)^3\delta_{\rm D}(\mathbf{k}-\mathbf{k}_{1\cdots n}), \tag{18}$$

and $\mathbf{k}_{1\cdots n} = \mathbf{k}_1 + \cdots + \mathbf{k}_n$ denotes the sum of arbitrary number of momenta.

The LPT kernels $L^{(n)}_i$ are obtained order by order using eq. (12). At first order, reading eq. (16) above, we have

$$L^{(1)}_i(\mathbf{k}) = \frac{k_i}{k^2}, \tag{19}$$

while to second order we obtain[3]

$$L^{(2)}_i(\mathbf{k}_1,\mathbf{k}_2) = \frac{3}{7}\frac{k_i}{k^2}\left(\mathcal{A}(\mathbf{k}_1,\mathbf{k}_2) - \mathcal{B}(\mathbf{k}_1,\mathbf{k}_2)\frac{(\mathbf{k}_1\cdot\mathbf{k}_2)^2}{k_1^2k_2^2}\right), \tag{20}$$

with $\mathbf{k} = \mathbf{k}_1 + \mathbf{k}_2$,

$$\mathcal{A}(\mathbf{k}_1,\mathbf{k}_2) = \frac{7D^{(2)}_{\mathcal{A}}(\mathbf{k}_1,\mathbf{k}_2)}{3D_+(k_1)D_+(k_2)}, \qquad \mathcal{B}(\mathbf{k}_1,\mathbf{k}_2) = \frac{7D^{(2)}_{\mathcal{B}}(\mathbf{k}_1,\mathbf{k}_2)}{3D_+(k_1)D_+(k_2)}, \tag{21}$$

and the second order growth functions are the solutions to equations

$$(\hat{\mathcal{T}} - A(k))D_{\mathcal{A}}^{(2)} = \Bigg[A(k) + (A(k) - A(k_1))\frac{\mathbf{k}_1\cdot\mathbf{k}_2}{k_2^2} + (A(k) - A(k_2))\frac{\mathbf{k}_1\cdot\mathbf{k}_2}{k_1^2} - \left(\frac{2A_0}{3}\right)\frac{k^2}{a^2}\frac{M_2(\mathbf{k}_1\mathbf{k}_2)}{6\Pi(k)\Pi(k_1)\Pi(k_2)}\Bigg]D_+(k_1)D_+(k_2), \tag{22}$$

$$(\hat{\mathcal{T}} - A(k))D_{\mathcal{B}}^{(2)} = \Big[A(k_1) + A(k_2) - A(k)\Big]D_+(k_1)D_+(k_2), \tag{23}$$

with appropriate initial conditions. The second and third terms in the r.h.s. of eq. (22) stem from the frame-lagging contributions. The fourth term is the second order contribution of δI, which in MG is responsible of the screening mechanism. Since $\mathcal{A}$ and $\mathcal{B}$ depend on $\mathbf{k}_1$ and $\mathbf{k}_2$, the decomposition in eq. (20) is arbitrary and we adopt it because they take values of order unity and the connection to ΛCDM is direct. For this case we obtain

$$\begin{aligned} D_{\mathcal{A}}^{(2)}(t) = D_{\mathcal{B}}^{(2)}(t) &= (\hat{\mathcal{T}} - A_0)^{-1}\left[\frac{3}{2}\Omega_m H^2 D_+^2\right] \\ &= \frac{3}{7}D_+^2(t) + \frac{4}{7}(\hat{\mathcal{T}} - A_0)^{-1}\left[\frac{3}{2}\Omega_m H^2 D_+^2\left(1 - \frac{f^2}{\Omega_m}\right)\right], \end{aligned} \tag{24}$$

thus $\mathcal{A} = \mathcal{B}$ are only time dependent. For $f = \Omega_m^{1/2}$ we get $\mathcal{A}^{\rm EdS} = \mathcal{B}^{\rm EdS} = 1$ and the standard kernels in Einstein-de Sitter (EdS) are recovered.

The third order kernel $L_i^{(3)}(\mathbf{k}_1, \mathbf{k}_2, \mathbf{k}_3)$ and many more details are provided in Aviles & Cervantes,[3] therefore we do not reproduce them here.

3. Screenings by the growth functions

As explained above, MG models introduce a fifth force that changes the Newtonian collapse at cosmic scales. A known effect in nonlinear MG is that its spherical solutions show the screening of fifth force, to drive the solution to the Newtonian one. This happens in large density regions that produce an effective weak coupling that effectively cancels the fifth force; there are other screening mechanisms stemming from different theoretical reasons; see, e.g., K. Koyama.[13] Although screenings are more usually studied in the highly non-linear regime, they also leave imprints in quasi-linear scales that can be captured by cosmological PT.

3.1. *Einstein frame: Symmetron case*

The previous LPT formalism was done in the Jordan frame, but it can be equally well translated to the Einstein frame, for example to study PT within Symmetron fields.

The Symmetron achieves its screening through the coupling of the scalar field to the matter Lagrangian, generating an effective potential with two parameters

(using $\hat{n} = \hat{m} = 1/2$): the scalar field mass (m) and the strength of the coupling (β), see details in reference.[12]

To convert theories posed in the Einstein frame to the Jordan frame, it is convenient to define a rescaled field:

$$\chi(\mathbf{q}, t) \equiv -\frac{2\beta}{C}\frac{\varphi(\mathbf{q}, t)}{M_{\rm Pl}}, \tag{25}$$

hereafter we denote $C \equiv C(\bar{\varphi})$ unless otherwise is explicitly stated.And again, this new scalar field follows a similar Klein Gordon equation

$$\begin{aligned} -\frac{k^2}{2a^2}\chi(\mathbf{k}) = &-(A(k) - A_0)\tilde{\delta}(\mathbf{k}) + \frac{k^2/a^2}{6\Pi(k)}\delta\mathcal{I}(\chi) \\ &- \frac{C}{2\beta^2}\frac{k^2/a^2}{3\Pi(k)}\frac{1}{2a^2}[(\nabla^2_{\mathbf{x}}\chi - \nabla^2\chi)](\mathbf{k}), \end{aligned} \tag{26}$$

and the contribution from screenings is given by

$$\begin{aligned} \delta\mathcal{I}(\mathbf{k}) = &\sum_{n=2}^{\infty}\frac{(-1)^{n+1}}{2^n n!}\frac{C^n\kappa_{n+1}}{\beta^{n+1}}[\chi^n](\mathbf{k}) \\ &+ \sum_{n=1}^{\infty}\frac{(-1)^{n+1}}{2^n n!}\frac{2A_0C^n\beta_{n+1}}{\beta^{n+1}}[\chi^n\delta](\mathbf{k}), \end{aligned} \tag{27}$$

where $3 + 2\omega_{\rm BD}(a) = \frac{C}{2\beta^2}$.

Solutions to first order are formally the same as eq. (16). To second order one can write the solutions as:

$$\Psi^{i(2)}(\mathbf{k}) = \frac{ik^i}{2k^2}\int_{\mathbf{k}_{12}=\mathbf{k}}\frac{3}{7}\Big(\bar{D}^{(2)}_{\rm NS}(\mathbf{k}_1, \mathbf{k}_2) - \bar{D}^{(2)}_{\rm S}(\mathbf{k}_1, \mathbf{k}_2)\Big)\delta_1\delta_2, \tag{28}$$

where we denote $\delta_{1,2} \equiv \delta_L(\mathbf{k}_{1,2})$ and where we split the second order growth in non-screened (NS) and screening (S) pieces. These growth functions $D^{(2)}$ are solutions to the equations:

$$\begin{aligned} \big(\hat{\mathcal{T}} - A(k)\big)D^{(2)}_{\rm NS}(\mathbf{k}_1, \mathbf{k}_2) = &\left(A(k) - (A(k_1) + A(k_2) - A(k))\frac{(\mathbf{k}_1\cdot\mathbf{k}_2)^2}{k_1^2k_2^2}\right. \\ \left.+(A(k) - A(k_1))\frac{\mathbf{k}_1\cdot\mathbf{k}_2}{k_2^2} + (A(k) - A(k_2))\frac{\mathbf{k}_1\cdot\mathbf{k}_2}{k_1^2}\right)&D_+(k_1)D_+(k_2) \end{aligned} \tag{29}$$

$$\big(\hat{\mathcal{T}} - A(k)\big)D^{(2)}_{\rm S}(\mathbf{k}_1, \mathbf{k}_2) = \left(\frac{2A_0}{3}\right)^2\frac{k^2}{a^2}\frac{M_2(\mathbf{k}_1, \mathbf{k}_2)D_+(k_1)D_+(k_2)}{6\Pi(k)\Pi(k_1)\Pi(k_2)}, \tag{30}$$

and the normalized growth functions are defined as

$$\bar{D}^{(2)}_{\rm S,NS}(\mathbf{k}_1, \mathbf{k}_2, t) = \frac{7}{3}\frac{D^{(2)}_{\rm S,NS}(\mathbf{k}_1, \mathbf{k}_2, t)}{D_+(k_1)D_+(k_2)}. \tag{31}$$

In an EdS universe one obtains the well known result $\bar{D}^{(2)}_{\rm NS} = 1 - (\hat{\mathbf{k}}_1 \cdot \hat{\mathbf{k}}_2)^2$, while in ΛCDM one gets the same result multiplied by a function that varies slowly with time, such that nowadays $\bar{D}^{(2)\Lambda{\rm CDM}}_{\rm NS} \simeq 1.01 \bar{D}^{(2){\rm EdS}}_{\rm NS}$. As expected, the screening second order growth, $\bar{D}^{(2)}_{\rm S}$, is zero in both EdS and ΛCDM models.

The function $\bar{D}^{(2)}_{\rm S}$ encodes the non-linearities of the effective potential of the scalar field and it yields the second order screening effects that drive the theory to GR at small scales. The total second-order growth function, as can be read from eq. (28), is given by $D^{(2)} = D^{(2)}_{\rm NS} - D^{(2)}_{\rm S}$, such that negative values of $D^{(2)}_{\rm S}$ enhance the growth of perturbations (*anti-screening effects*), while positive values of it yield the standard suppression of the fifth force. In the Symmetron case there are configurations of interacting wave modes that instead of driving the theory towards GR, they drive the theory away from it. In fact, from eq. (30), all triangular configurations with

$$k_1^2 + k_2^2 < k_{AS}^2(a), \tag{32}$$

where the anti-screening wavenumber is defined as

$$k_{AS}^2(a) \equiv \frac{\kappa_3 \beta a^2}{\beta_2} - 2m^2 a^2, \tag{33}$$

will contribute with a negative source to the second order screening as long as the r.h.s. of the above equation is positive.

Analogously, each higher perturbative order carries its own screening and it is efficient over a certain k interval. We emphasize that $\bar{D}^{(2)}_{\rm S}$ and $\bar{D}^{(3)}_{\rm S}$ with positive values will screen the fifth force, while negative values will anti-screen it instead. Given this, the M_i MG functions of each model will determine their screening properties. We plot in Fig. 1 the normalized second and third order screening growth functions $\bar{D}^{(2)}_{\rm S}(\mathbf{k}_1, \mathbf{k}_2)$ and $\bar{D}^{(3)}_{\rm S}(\mathbf{k}_1, \mathbf{k}_2, \mathbf{k}_3)$ for the Symmetron, again for different triangle configurations.

The vertical lines correspond to the *screening wavenumber*

$$k_{M_1} = a\sqrt{M_1(a)}, \tag{34}$$

that characterizes the scale at which the screening is present; in fact it is close to the maximum screening growth of the largest triangular contribution (squeezed modes). This scale might serve to parametrize the nonlinear growth to eventually make (e.g. N-point statistics) computations more efficient.

3.2. *Jordan frame: the f(R) case*

As it is known, a f(R) Lagrangian can be transformed into the Jordan frame, and so we can use the formalism of section 2 and, in fact, also the screening/non-screened division of the previous subsection. Here we consider the HS n=1 model for different $f_{R0} = -10^{-4}, -10^{-8}, -10^{-12}$ corresponding to F4, F8, and F12 models. In the

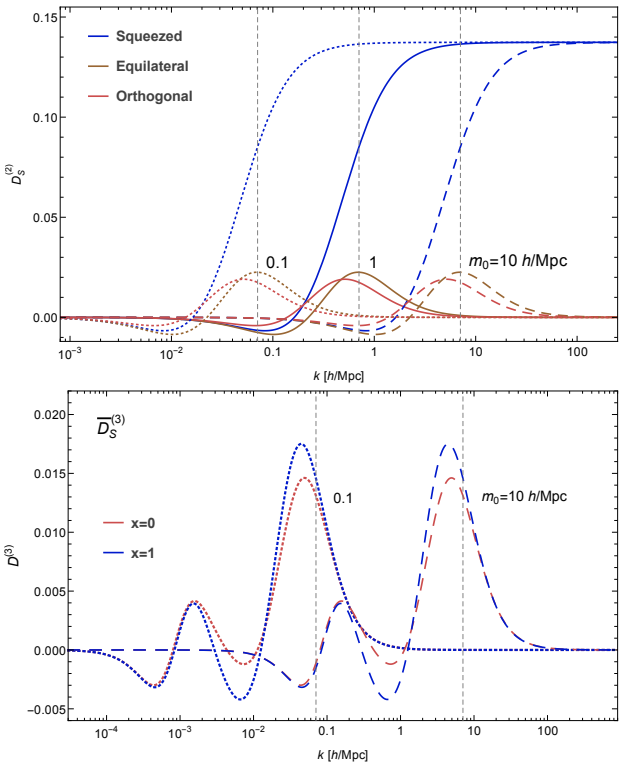

Fig. 1. We show the displacements at second and third order, for the Symmetron model with $a_{ssb} = 0.33$, $\beta_0 = 1$ and different values of m_0, and considering different triangle configurations; results are shown for $z = 0$. The vertical lines are located at $k = a\sqrt{M_1}$, showing the characteristic scale at which the screenings are present. In the upper plot we show the $\bar{D}_{\rm S}^{(2)}$ functions. The plot below shows $\bar{D}_{\rm S}^{(3)}(\mathbf{k}, -\mathbf{p}, \mathbf{p})$ for two values of cosine angle $\mathrm{x} = \hat{\mathbf{k}} \cdot \hat{\mathbf{p}}$. In both plots one observes regions of antiscreening behavior ($\bar{D}_{\rm S} < 0$).

upper panel of Fig. 2 we show plots for the second order screening growth functions, $\bar{D}_{\rm S}^{(2)}$, evaluated at redshift $z = 0$ and for different triangular configurations.

Note that in f(R) the screening scale, eq. (34), goes as $k_{M_1} \propto \sqrt{1/|f_{R0}|}$. The lower panel of Fig. 2 shows the growth $D_S^{(3)}(\mathbf{k}, -\mathbf{p}, \mathbf{p})$ for the double squeezed configuration with additionally $|\mathbf{k}| = |\mathbf{p}|$ and for different values of the cosine angle $x = \hat{\mathbf{k}} \cdot \hat{\mathbf{p}}$.

In order to study the effects of the background evolution on the screening growth, in Fig. 3 we show it for the F4 model at different redshifts $z = 0, 3$, and 10. The upper panel uses a ΛCDM background cosmology and the lower panel an EdS background evolution. In ΛCDM the screening curves are narrower and reach smaller maxima, this is expected because the cosmic acceleration attenuates the clustering of dark matter, and hence the nonlinear effects. Instead, in an EdS background the pattern of the growth is preserved. The vertical lines again denote the scale k_{M_1}, which are in ΛCDM slightly shifted in comparison with the EdS results.

It is worthy to observe that in f(R) the nonlinearities of the Klein-Gordon equation lead to screening for any configuration. This is manifested in Figs. 2 and 3 because the screening growth functions always take positive values.

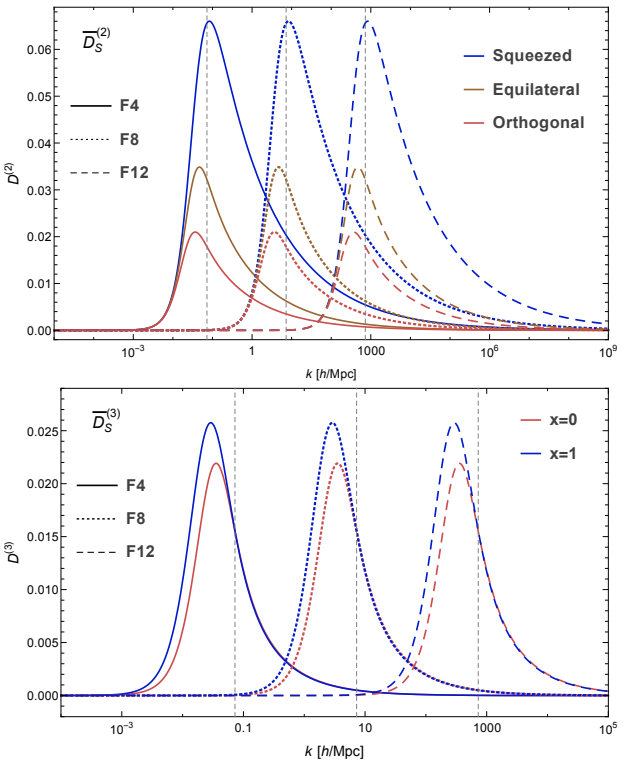

Fig. 2. The upper plot shows the $\bar{D}_{\rm S}^{(2)}$ functions for F4, F8, and F12 models, considering different triangle configurations. The vertical lines are located at $k = a\sqrt{M_1}$, showing the characteristic scale at which the screenings are present. The lower panel shows the third order growth $\bar{D}_{\rm S}^{(3)}$ for different angles $x = \hat{\mathbf{k}} \cdot \hat{\mathbf{p}}$ and with $k = p$. The f(R) n=1 shows no antiscreening.

We have considered other models that show different screening mechanisms, such as DGP based on the Vainshtein mechanism. In this case, the second and third order screening growths always act to attenuate the fifth force that modifies Newtonian gravity: no antiscreening is found. We refer to further details on the screening treatment to reference.[7]

4. From Lagrangian to standard PT

The formalism presented above was developed for LPT. However, one can demonstrate that from the kernel solutions of LPT one can obtain the kernels in SPT,

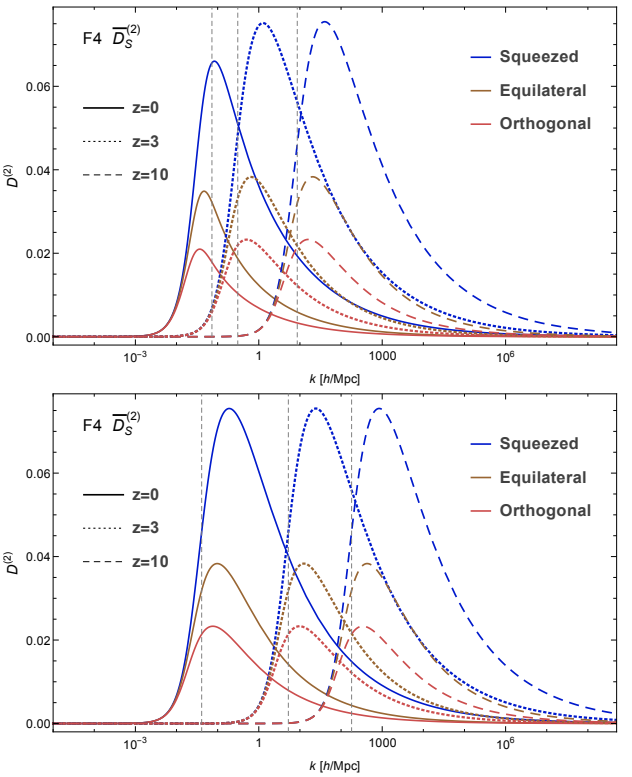

Fig. 3. $\bar{D}_{\rm S}^{(2)}$ functions for the F4 for redshifts $z = 0, 3, 10$, and considering different triangle configurations. The vertical lines are located at $k = a\sqrt{M_1}$, showing the characteristic scale at which the screenings are present. The upper panel shows a ΛCDM background evolution while the bottom panel an EdS background evolution.

so establishing a formal connection between these two formalisms. This was done for general cosmologies in reference,[4] where it is shown that the SPT power spectrum computed from the LPT formalism coincides with the Eulerean, SPT power spectrum. Here omit details that can be found in the above reference, where it is shown that one can express the overdensities as

$$\delta^{(n)}(\mathbf{k}) = \sum_{\ell=1}^{n} \sum_{m_1+\cdots+m_\ell=n} \frac{k_{i_1}\cdots k_{i_\ell}}{\ell! m_1! \cdots m_\ell!} \times \int_{\mathbf{p}_{1\cdots n}=\mathbf{k}} L_{i_1}^{(m_1)}(\mathbf{p}_1, ..., \mathbf{p}_{m_1}) \cdots L_{i_\ell}^{(m_\ell)}(\mathbf{p}_{m_{\ell-1}+1}, ..., \mathbf{p}_{m_\ell}) \times \delta_L(\mathbf{p}_1) \cdots \delta_L(\mathbf{p}_n). \tag{35}$$

This expression provides the SPT F_n kernels out of the LPT kernels (L_n):

$$F_n(\mathbf{k}_1,\ldots,\mathbf{k}_n) = \sum_{\ell=1}^{n} \sum_{m_1+\cdots+m_\ell=n} \frac{k_{i_1}\cdots k_{i_\ell}}{\ell! m_1!\cdots m_\ell!} \times L_{i_1}^{(m_1)}(\mathbf{k}_1,...,\mathbf{k}_{m_1})\cdots L_{i_\ell}^{(m_\ell)}(\mathbf{k}_{m_{\ell-1}+1},...,\mathbf{k}_{m_\ell}) \tag{36}$$

with $\mathbf{k} = \mathbf{k}_1 + \cdots + \mathbf{k}_n$.

As an example of these results here we show the $n = 2$ kernel:

$$F_2(\mathbf{k}_1,\mathbf{k}_2) = \frac{1}{2} + \frac{3}{14}\mathcal{A} + \left(\frac{1}{2} - \frac{3}{14}\mathcal{B}\right)\frac{(\mathbf{k}_1\cdot\mathbf{k}_2)^2}{\mathbf{k}_1^2\mathbf{k}_2^2} + \frac{\mathbf{k}_1\cdot\mathbf{k}_2}{2}\left(\frac{1}{k_1^2}+\frac{1}{k_2^2}\right). \tag{37}$$

and, analogously, for the velocity field kernels one finds a similar relation general relationship. For $n = 2$ we obtain:

$$G_2(\mathbf{k}_1,\mathbf{k}_2) = \frac{3}{14}\mathcal{A}(f_1+f_2) + \frac{3\dot{\mathcal{A}}}{14H} + \left(\frac{f_1+f_2}{2} - \frac{3}{14}\mathcal{B}(f_1+f_2) - \frac{3\dot{\mathcal{B}}}{14H}\right)\frac{(\mathbf{k}_1\cdot\mathbf{k}_2)^2}{\mathbf{k}_1^2\mathbf{k}_2^2} + \frac{\mathbf{k}_1\cdot\mathbf{k}_2}{2}\left(\frac{f_2}{k_1^2}+\frac{f_1}{k_2^2}\right), \tag{38}$$

where $f_{1,2} = f(k_{1,2})$ are growth rates for two arbitrary modes. $\mathcal{A}$ and $\mathcal{B}$ are given by eq. (21).

In Fig. 4 we plot the ratios of the SPT 1-loop to linear matter power spectra, for the ΛCDM model, as well as for HS n=1 F4, and the normal branch of DGP with crossover scale fixed by the Hubble constant, $r_c = H_0^{-1}$. We fixed the cosmological parameters to $\Omega_m = 0.281$, $\Omega_b = 0.046$, $h = 0.697$, $n_s = 0.971$, and $\sigma_8 = 0.82$, corresponding to WMAP 9 years best fit to ΛCDM.[14] For F4 model, the background cosmology is indistinguishable to that in ΛCDM. This is not the case for DGP. However, as it is usual in the literature, for DGP we fix to a ΛCDM background. In such a way we can compare the differences in the growth of perturbations due to the fifth force and not to a different Hubble flow. Despite this, the power spectrum in DGP suffers a scale independent shift because $A(k,t) = A(t) \neq A_0$. We plot the the power spectra with and without screenings; the later are achieved by setting $M_2 = M_3 = 0$ in eq. (10).

5. Matter power spectra

We now construct the power spectra for STP for general cosmologies. We follow the approach developed in Aviles et al.[15] As described in section 2, the Poisson equation is given by eq. (4), whereas the fluid equations are:

$$\partial_t\delta(\mathbf{x},t) + \frac{1}{a}\partial_i\left[(1+\delta)v^i\right] = 0, \tag{39}$$

$$\partial_t v^i(\mathbf{x},t) + \frac{1}{a}v^j\partial_j v^i + Hv^i + \frac{1}{a}\partial_i\psi = 0, \tag{40}$$

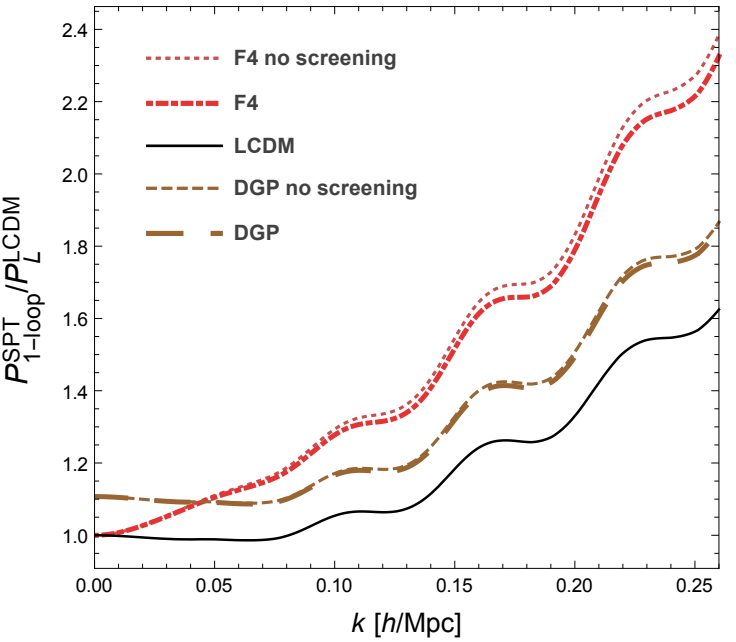

Fig. 4. Ratio of 1-loop SPT to ΛCDM linear matter power spectra for ΛCDM, F4, and DGP models at redshift $z = 0$. The role of screening is self evident at nonlinear scales. We fix cosmological parameters to the best fit of the WMAP Nine-year results.[14]

where $v^i(t) = \frac{dx^i(t)}{d\tau} = a\dot{x}^i(t)$ is the CDM fluid's element peculiar velocity; $\mathbf{x}$ is its comoving coordinate, t the cosmic time, and $d\tau = \frac{1}{a}dt$ the conformal time, such that the total velocity is $v^i_T = aHx^i + v^i$.

We use the (dimensionless) velocity divergence

$$\theta(\mathbf{x}, t) = -\frac{\partial_i v^i}{aHf_0}, \tag{41}$$

where $f_0(t)$ is an arbitrary function of time that will be fixed to be the logarithmic growth rate at a convenient scale. We assume the transverse piece of the velocity is negligible at large scales, hence it is a longitudinal field fully specified by θ.

In Fourier space the continuity and Euler equations can be written as

$$\frac{1}{H}\frac{\partial\delta(\mathbf{k})}{\partial t} - f_0\theta(\mathbf{k}) = f_0 \int_{\mathbf{k}_{12}=\mathbf{k}} \alpha(\mathbf{k}_1, \mathbf{k}_2)\theta(\mathbf{k}_1)\delta(\mathbf{k}_2), \tag{42}$$

$$\frac{1}{H}\frac{\partial f_0\theta(\mathbf{k})}{\partial t} + \left(2 + \frac{\dot{H}}{H^2}\right) f_0\theta(\mathbf{k}) - \frac{A(k)}{H^2}\delta(\mathbf{k}) - \frac{S(\mathbf{k})}{H^2} = f_0^2 \int_{\mathbf{k}_{12}=\mathbf{k}} \beta(\mathbf{k}_1, \mathbf{k}_2)\theta(\mathbf{k}_1)\theta(\mathbf{k}_2), \tag{43}$$

with

$$\alpha(\mathbf{k}_1,\mathbf{k}_2)=1+\frac{\mathbf{k}_1\cdot\mathbf{k}_2}{k_1^2},\qquad \beta(\mathbf{k}_1,\mathbf{k}_2)=\frac{k_{12}^2(\mathbf{k}_1\cdot\mathbf{k}_2)}{2k_1^2k_2^2}. \tag{44}$$

where $S(k)$ is related to eq. (10), see Aviles et al.[15] One finds perturbative solutions at the different orders according to eqs. (42, 43) and the nonlinear expansion (10). The solutions are same those given in eqs. (37) and (38), and so for higher orders.

Having found the kernels up to third order, we can now construct spectra and cross-spectra of the velocity and density fields. At 1-loop in PT, one can use the general expressions

$$P_{ab}(k)=P_{ab}^{L}(k)+P_{ab}^{22}(k)+P_{ab}^{13}(k), \tag{45}$$

where a and b refer to δ or θ fields, and linear power spectra $P_{ab}^{L}(k)$

$$P_{\delta\delta}^{L}(k)\equiv P_L(k),\quad P_{\delta\theta}^{L}(k)=\frac{f(k)}{f_0}P_L(k),\quad P_{\theta\theta}^{L}(k)=\left(\frac{f(k)}{f_0}\right)^2P_L(k), \tag{46}$$

and leading nonlinear contributions

$$P_{\delta\delta}^{22}(k)=2\int_{\mathbf{p}}\big[F_2(\mathbf{p},\mathbf{k}-\mathbf{p})\big]^2P_L(p)P_L(|\mathbf{k}-\mathbf{p}|), \tag{47}$$

$$P_{\delta\theta}^{22}(k)=2\int_{\mathbf{p}}F_2(\mathbf{p},\mathbf{k}-\mathbf{p})G_2(\mathbf{p},\mathbf{k}-\mathbf{p})P_L(p)P_L(|\mathbf{k}-\mathbf{p}|), \tag{48}$$

$$P_{\theta\theta}^{22}(k)=2\int_{\mathbf{p}}\big[G_2(\mathbf{p},\mathbf{k}-\mathbf{p})\big]^2P_L(p)P_L(|\mathbf{k}-\mathbf{p}|), \tag{49}$$

$$P_{\delta\delta}^{13}(k)=6P_L(k)\int_{\mathbf{p}}F_3(\mathbf{k},-\mathbf{p},\mathbf{p})P_L(p), \tag{50}$$

$$P_{\delta\theta}^{13}(k)=3P_L(k)\int_{\mathbf{p}}\big[F_3(\mathbf{k},-\mathbf{p},\mathbf{p})G_1(\mathbf{k})+G_3(\mathbf{k},-\mathbf{p},\mathbf{p})\big]P_L(p), \tag{51}$$

$$P_{\theta\theta}^{13}(k)=6P_L(k)\int_{\mathbf{p}}G_3(\mathbf{k},-\mathbf{p},\mathbf{p})G_1(\mathbf{k})P_L(p). \tag{52}$$

The above expressions are valid for any cosmological model such as MG models, dark energy, or massive neutrinos—in general, for models that introduce a new degree of freedom to the dynamics. For the different models, these expressions for power spectra and kernels are the same, the difference being the corresponding growth solutions through $\mathcal{A}$ and $\mathcal{B}$ (see e.g. eq. 37) that are inside the kernels.

6. Bias Expansion and tracer's power spectra

We now turn to the description of dark matter halos and galaxies, instead of only matter fields. That is, we go into tracers, that are more closely related to observations.

We expand the tracer densities in terms of a set of operators, including the leading curvature operators, labeled with "m" to make reference to matter fields,

in a manner similar to McDonald and Roy[16]:

$$\delta(\mathbf{x}) = c_\delta \delta_m + c_{\nabla^2\delta}\nabla^2\delta_m + \frac{1}{2}c_{\delta^2}\delta_m^2 + \frac{1}{2}c_{s^2}s^2 + \frac{1}{6}c_{\delta^3}\delta_m^3 + \frac{1}{2}c_{\delta s^2}\delta s^2 + c_\psi\psi + c_{st}st + \frac{1}{2}c_{s^3}s^3, \tag{53}$$

$$\theta(\mathbf{x}) = \theta_m + c_{\nabla^2\theta}\nabla^2\theta_m. \tag{54}$$

Since for MG models an additional scale shows up, the bias coefficients are re-scaled. The first order terms are:

$$\delta^{(1)}(\mathbf{k}) = (c_\delta - c_{\nabla^2\delta}k^2)\delta_m^{(1)}(\mathbf{k}), \text{ and} \tag{55}$$

$$\theta^{(1)}(\mathbf{k}) = (1 - c_{\nabla^2\theta}k^2)\theta_m^{(1)}(\mathbf{k}). \tag{56}$$

The expansion goes to third order that can be found in Aviles et al.[15]

One can now find the tracers' power spectra, that will be given in terms of the above biases and matter power spectra of the previous section. We obtain:

$$P_{\delta\delta}(k) = (b_1 - b_{\nabla^2\delta}k^2)^2 P_L(k) + b_1^2 P_{m,\delta\delta}^{\rm loop}(k) + 2b_1 b_2 P_{b_1 b_2}(k) + 2b_1 b_{s^2} P_{b_1 b_{s^2}}(k) + b_2^2 P_{b_2^2}(k) + 2b_2 b_{s^2} P_{b_2 b_{s^2}}(k) + b_{s^2}^2 P_{b_{s^2}^2}(k) + 2b_1 b_{3nl}\sigma_3^2(k)P_L(k), \tag{57}$$

$$P_{\delta\theta}(k) = (b_1 - b_{\nabla^2\delta}k^2)(1 - b_{\nabla^2\theta}k^2)\frac{f(k)}{f_0}P_L(k) + b_1 P_{m,\delta\theta}^{\rm loop}(k) + b_2 P_{b_2,\theta}(k) + b_{s^2}P_{b_{s^2},\theta}(k) + b_{3nl}\sigma_3^2(k)\frac{f(k)}{f_0}P_L(k), \tag{58}$$

$$P_{\theta\theta}(k) = (1 - b_{\nabla^2\theta}k^2)^2\left(\frac{f(k)}{f_0}\right)^2 P_L(k) + P_{m,\theta\theta}^{\rm loop}(k), \tag{59}$$

with

$$P_{b_1 b_2}(k) = \int_{\mathbf{k}_{12}=\mathbf{k}} F_2(\mathbf{k}_1,\mathbf{k}_2)P_L(\mathbf{k}_1)P_L(\mathbf{k}_2), \tag{60}$$

$$P_{b_1 b_{s^2}}(k) = \int_{\mathbf{k}_{12}=\mathbf{k}} F_2(\mathbf{k}_1,\mathbf{k}_2)S_2(\mathbf{k}_1,\mathbf{k}_2)P_L(\mathbf{k}_1)P_L(\mathbf{k}_2), \tag{61}$$

$$P_{b_2^2}(k) = \frac{1}{2}\int_{\mathbf{k}_{12}=\mathbf{k}} P_L(\mathbf{k}_1)\big[P_L(\mathbf{k}_2) - P_L(\mathbf{k}_1)\big], \tag{62}$$

$$P_{b_2 b_{s^2}}(k) = \frac{1}{2}\int_{\mathbf{k}_{12}=\mathbf{k}} P_L(\mathbf{k}_1)\left[P_L(\mathbf{k}_2)S_2(\mathbf{k}_1,\mathbf{k}_2) - \frac{2}{3}P_L(\mathbf{k}_1)\right], \tag{63}$$

$$P_{b_{s^2}^2}(k) = \frac{1}{2}\int_{\mathbf{k}_{12}=\mathbf{k}} P_L(\mathbf{k}_1)\left[P_L(\mathbf{k}_2)[S_2(\mathbf{k}_1,\mathbf{k}_2)]^2 - \frac{4}{9}P_L(\mathbf{k}_1)\right], \tag{64}$$

and

$$P_{b_2,\theta}(k) = \int_{\mathbf{k}_{12}=\mathbf{k}} G_2(\mathbf{k}_1,\mathbf{k}_2) P_L(\mathbf{k}_1) P_L(\mathbf{k}_2), \tag{65}$$

$$P_{b_{s^2},\theta}(k) = \int_{\mathbf{k}_{12}=\mathbf{k}} G_2(\mathbf{k}_1,\mathbf{k}_2) S_2(\mathbf{k}_1,\mathbf{k}_2) P_L(\mathbf{k}_1) P_L(\mathbf{k}_2), \tag{66}$$

with renormalized bias parameters

$$b_1 = c_\delta + \left[\frac{31}{24} c_{\delta^2}\mathcal{C}_{\delta^2} + \frac{1}{2} c_{\delta^3}\mathcal{C}_{\delta^3} + \frac{1}{3} c_{\delta s^2}\mathcal{C}_{\delta s^2} + \frac{68}{63} c_{s^2}\mathcal{C}_{s^2} - \frac{16}{63} c_{st}\mathcal{C}_{st}\right]\sigma^2, \tag{67}$$

with $\mathcal{C}_\mathcal{O}$ constants of order unity and they are required in cosmologies beyond EdS, as we have seen for $\mathcal{C}_{s^2}$ and $\mathcal{C}_{st}$. At 1-loop in the PS the rest of biasing parameters remain equal after renormalization: $b_2 = c_{\delta^2}$ and $b_{s^2} = c_{s^2}$.

7. Redshift space distortions in MG

We now introduce a model for RSD in alternative cosmologies. An object located at a comoving distance $\mathbf{x}$ is observed to be at an apparent position $\mathbf{s}$, such that the map between real and redshift space positions is given by the non-relativistic, longitudinal Doppler effect,

$$\mathbf{s} = \mathbf{x} + \mathbf{u}, \tag{68}$$

where $\mathbf{u}$ is given in terms of the divergence field $\mathbf{u}(\mathbf{k}) = i f_0 \hat{\mathbf{n}} \frac{\mathbf{k}\cdot\hat{\mathbf{n}}}{k^2}\theta(\mathbf{k})$.

Clearly, the map to redshift coordinates conserves the number of tracers, $\big[1 + \delta_s(\mathbf{s})\big]d^3s = \big[1 + \delta(\mathbf{x})\big]d^3x$, yielding

$$(2\pi)^3\delta_{\rm D}(\mathbf{k}) + \delta_s(\mathbf{k}) = \int d^3x \big(1 + \delta(\mathbf{x})\big) e^{-i\mathbf{k}\cdot(\mathbf{x}+\mathbf{u}(\mathbf{x}))}, \tag{69}$$

and the redshift-space PS becomes[17,18]

$$(2\pi)^3\delta_{\rm D}(\mathbf{k}) + P_s(\mathbf{k}) = \int d^3x e^{-i\mathbf{k}\cdot\mathbf{x}} \Big[1 + \mathcal{M}(\mathbf{J} = \mathbf{k}, \mathbf{x})\Big], \tag{70}$$

with the velocity moments generating function

$$1 + \mathcal{M}(\mathbf{J},\mathbf{x}) = \left\langle \big(1 + \delta(\mathbf{x}_1)\big)\big(1 + \delta(\mathbf{x}_2)\big) e^{-i\mathbf{J}\cdot\Delta\mathbf{u}} \right\rangle, \tag{71}$$

where $\Delta\mathbf{u} = \mathbf{u}(\mathbf{x}_2) - \mathbf{u}(\mathbf{x}_1)$ and $\mathbf{x} = \mathbf{x}_2 - \mathbf{x}_1$. Function $\mathcal{M}$ (or its Fourier transform) plays a central role in RSD. Different expansion procedures of eq. (71) yield different approaches to RSD modeling, grouped in Vlah et al[18] as: direct Lagrangian, moment expansion, streaming model, and smoothing kernel. We will follow here the moment expansion (ME) approach, in which the exponential in the generating function is expanded and the moments are evaluated.

The m-th density weighted velocity field moment of the generating function is an m-rank tensor defined as[17,18]

$$\Xi^{\mathrm{m}}_{i_1\cdots i_{\mathrm{m}}}(\mathbf{x}) \equiv i^{\mathrm{m}} \frac{\partial^{\mathrm{m}}}{\partial J_{i_1}\cdots\partial J_{i_{\mathrm{m}}}}\big[1+\mathcal{M}(\mathbf{J},\mathbf{x})\big]\Big|_{\mathbf{J}=0} = \langle\big(1+\delta_1\big)\big(1+\delta_2\big)\Delta u_{i_1}\cdots\Delta u_{i_{\mathrm{m}}}\rangle, \tag{72}$$

with $\delta_1=\delta(\mathbf{x}_1)$ and $\delta_2=\delta(\mathbf{x}_2)$. The PS in the moment expansion approach becomes

$$(2\pi)^3\delta_{\mathrm{D}}(\mathbf{k}) + P_s(\mathbf{k}) = \sum_{\mathrm{m}=0}^{\infty}\frac{(-i)^{\mathrm{m}}}{\mathrm{m}!}k_{i_1}\ldots k_{i_{\mathrm{m}}}\tilde{\Xi}^{\mathrm{m}}_{i_1\cdots i_{\mathrm{m}}}(\mathbf{k}), \tag{73}$$

where the $\tilde{\Xi}^{\mathrm{m}}_{i_1\cdots i_{\mathrm{m}}}(\mathbf{k})$ are the Fourier moments of the generating function —the Fourier transforms of their configuration space counterparts, $\Xi^{\mathrm{m}}_{i_1\cdots i_n}(\mathbf{x})$.

Now, to compute the moments we make the following ansatz:

$$P^{\mathrm{m}}(k,\mu) \equiv \frac{(-i)^{\mathrm{m}}}{\mathrm{m}!}k_{i_1}\cdots k_{i_{\mathrm{m}}}\tilde{\Xi}^{\mathrm{m}}_{i_1\cdots i_{\mathrm{m}}}(\mathbf{k}) = \sum_{n=0}^{\mathrm{m}}\mu^{2n}f_0^{\mathrm{m}}I_n^{\mathrm{m}}(k), \tag{74}$$

such that the total PS in redshift coordinates (s) is

$$P_s^{\mathrm{ME}}(k,\mu) = \sum_{\mathrm{m}=0}^{\infty}P^{\mathrm{m}}(k,\mu), \tag{75}$$

up to a Dirac delta function localized at $\mathbf{k}=0$. Whereas the first equality (definition) in eq. (74) depends on $\mathbf{k}$, implicitly on k and $\mu\equiv\hat{\mathbf{k}}\cdot\hat{\mathbf{n}}$, the second equality is an ansatz with explicit angular dependence as even powers of μ. This ansatz has been shown to work, at least for moments $\mathrm{m}=0,\ldots,4$, in Aviles et al,[15] where the functions $I_n^{\mathrm{m}}(k)$ are given for the momenta necessary to compute the 1-loop expansion.

8. Considering UV and IR modes

There are still two important ingredients before we have a final model: EFT counterterms and infrared (IR) resummation of modes.

• As it is known, UV modes need to be cut off in the integrals, since small scale modes are not properly captured in PT, so it will not otherwise render the correct dynamics. The EFT for large scale structure formalism, see for instance Baumann et al[19] and Hertzberg et al,[20] cuts-off the loop integrals, by directly smoothing the overdensity fields by an arbitrary scale, and introduces counterterms necessary to remove the cut-off dependence on the final expressions. In redshift space, the situation is more complex, because the counterterms not only model small scales, non-perturbative physics, but also the non-linear mathematical map between real space and redshift space densities, see various authors.[21–23] In our case, the final expression turns to:

$$P_s^{\mathrm{EFT}}(k,\mu) = P_s^{\mathrm{ME}}(k,\mu) + (\alpha_0+\alpha_1\mu^2+\cdots)k^2P_L(k) + \tilde{c}\big(\mu k f_0\big)^4P_s^K(k,\mu) + P_{\mathrm{shot}}, \tag{76}$$

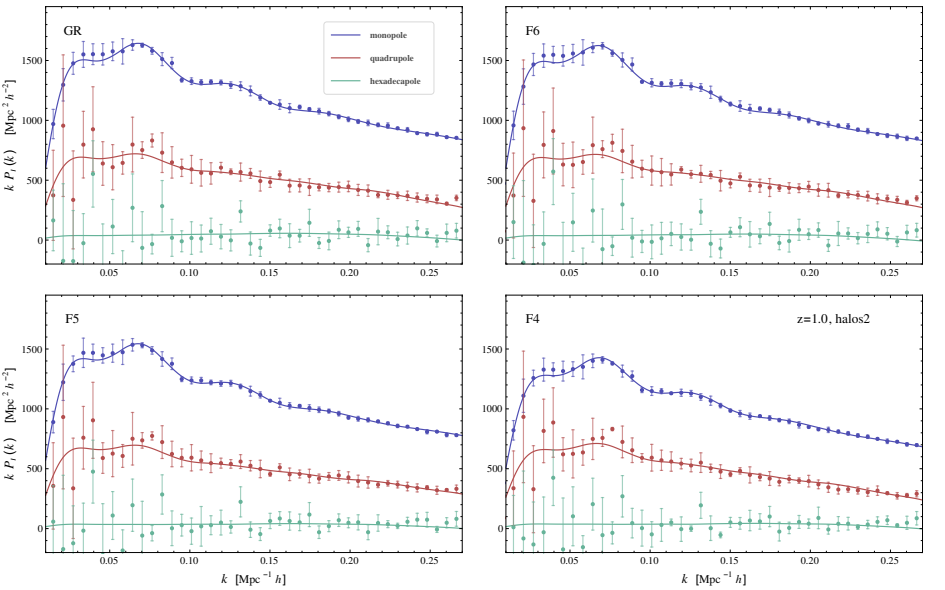

Fig. 5. Redshift-space power spectrum multipoles for halo catalogue 2 ($4.5{\times}10^{12} < M_h < 1{\times}10^{13}$ $M_\odot h^{-1}$) at redshift $z = 1$.

where the α_i stem from the nonlinear mathematical map between real space and redshift space densities and the $\tilde{c}$ from nonlinearities from the Fingers of God (FoG) that couple velocities and density fields. $P_{\rm shot}$ models the stochastic terms, uncorrelated with long wave-length fluctuations.

• Despite the success of SPT-EFT in modeling the broadband PS, the theory yet gives poor results in modeling the BAO since long-wavelength displacement fields, though being essentially linear, stream largely contributing to damp features in the PS in a manner that is non-perturbative under an SPT scheme.Then, in order to model the spread and degradation of the BAO oscillations due to large scale bulk flows, we employ IR-resummations[24] as implemented by Ivanov et al.[22,25]

The final result is a complete PS model for RSD that can be compared to dark matter halos or galaxies. In Fig. 5 we plot our analytical results against RSD multipoles for the HS n=1 model, extracted from `ELEPHANT` simulations,[1] with halo masses in the interval $4.5 \times 10^{12} < M_h < 1 \times 10^{13}$ $M_\odot h^{-1}$ evaluated at $z = 1$. These results show that theory renders precise results for wave modes as big as $k = 0.25$ h/Mpc.

9. Conclusions

In the last few years the PT for LSS has been developed to a point that most problems have been tackled, and it seems now ready to be feasibly compared against

simulations and observations, to render consistent results and to be able to extract cosmological parameter information at the level that stage-IV galaxy surveys should provide, among other probes.

The present contribution presents some PT developments for models that possess an extra degree of freedom, that is, models of MG, dynamical dark energy, or considering massive neutrinos within LCDM.[26,27] We explained mainly our results, but, because of the limited space here, we did not provide a full list of references, however, this can be found in the our cited papers in the bibliography.

In the last two decades, Modified Gravity (MG) models have been proposed to explain the accelerated expansion of the Universe. However, one of the main difficulties these theories face is that they must reduce to General Relativity (GR) at sufficiently high energy densities, such as those found in the solar system. To achieve this, MG theories typically employ so-called screening mechanisms: nonlinear effects that bring them to GR at the appropriate limits. For this reason, low-energy regions where the screenings do not operate efficiently, such as cosmic voids, are identified as ideal laboratories for testing GR. Hence, the use of *marked* statistics that up-weight low energy densities have been proposed for being implemented with data from future galaxy surveys. In this proceeding note, we show how to construct theoretical templates for such statistics and test their accuracy with the use of N-body simulations.

Keywords: Modified Gravity; Cosmic Large Scale Structure; Testing General Relativity.

1. Modified gravity in Cosmology: a very brief introduction

The standard model of Cosmology, the so-called ΛCDM, is the most successful theory to date for describing the large-scale behaviour of our Universe. The outstanding way this model fits the cosmic background radiation (CMB) anisotropies measurements from the Planck satellite[1]—and prior to that from the WMAP and COBE experiments—leaves small room for modifications of it. However, among other drawbacks in Cosmology, nowadays cosmic acceleration is still not well understood, and in models that modify the background history of the Universe at late times, the CMB differs mainly because the journey of photons from the last-scattering surface to us is affected. This is a secondary effect called the integrated Sachs-Wolfe effect and its influence over the CMB is mainly localized at small multipoles, where the error on measurements is nonetheless large because of the cosmic variance—the fact that we have only one universe and hence a small number of long wave-length modes to average over. Such a liberty has led to a lot of proposals (literally hundreds of them) as alternatives to the cosmological constant to explain the speeding up of the expansion of the Universe. Unfortunately, there is much more literature proposing new gravity models or that makes simple tests to them (the vast majority focusing only on the homogeneous and isotropic cosmology; I will come back to this in a moment), than literature that explore methods to probe the clustering due to gravity

at cosmological scales. Of course, this is a highly unbalanced situation and observational cosmologists cannot test each of the proposed models. These alternatives can be categorized into two big branches: dark energy (DE) and Modified Gravity (MG); though, one should be careful since there is not a well defined boundary between them. In this proceedings note, we will focus on the latter assuming well defined, and to the particular case of chameleon fields[2,3] although the techniques described here have been applied to other kinds of theories.

Perhaps the most difficult aspect of modifying gravity is the following. Observations indicate that the *true* model of the universe should be close to ΛCDM, at least from the epoch of the primordial ("Big-Bang") Nucleosynthesis until now. In particular the expansion history should be close to that of ΛCDM, perhaps with small differences with the aim of, for example, resolving the Hubble tension.[4] However, as a rule of thumb, MG models that slightly depart from ΛCDM at the background level, become quite different at the perturbative level.[5,6] That is, two models that have almost the same expansion history, typically predict a completely different clustering. This is because in MG the two scalar gravitational potentials of the metric, thinking of in Newtonian gauge, are different even in the absence of anisotropic stresses, which makes GR a very special theory and not easy to mimic. This would mean that the gravitational potential appearing in the geodesic potential is not the same to the gravitational potential sourced by the energy density fields in the Poisson equation; and what is particularly important to this discussion is that the homogeneous and isotropic expansion is completely insensitive to this. For example, take a look at figure 1, where we show the power spectrum of matter density fluctuations in GR and in the F5 gravitational model (we will define what is F5 in appendix A). The F5 gravitational model is indistinguishable for any practical purpose from GR at the background level, but their predicted matter power spectra differ by a lot. This is the reason why it does not make too much sense to test MG models at the background level only, for example using supernovae data only. However, for the sake of fairness we must say there are exceptions to this rule, for example the recently proposed No-Slip gravity,[7] tailored with the specific purpose that the two scalar gravitational potentials become equal.

When gravity is modified, in particular in the infrared, one should be careful to not spoil the well-tested regimes of validity of GR, as for example in the solar system or regions with much larger densities,[a] but at the same time provide the accelerated expansion of the Universe. In order to deal with this unquestionable observational constriction, MG models often invoke mechanisms that yield the theory to GR in the appropriate limits. These are generically called *screening* mechanisms: nonlinear effects that drive MG theories to GR when either the environmental energy

[a]It is perhaps surprising to consider the solar system a high energy density region, but it is very large compared to the mean background energy density $3H_0^2/8\pi G \sim 10^{-29}\,\mathrm{g/cm^3}$. The latter is the one that is important at the largest cosmological scales, and hence drives the background history of the Universe.

density is large, or there are large gravitational tidal fields, among other scenarios. The most popular is the *chameleon* mechanism,[2,3] in which a scalar field mediates a universal fifth force, but its mass depends on the environmental density where it resides: as larger is the ambient density, the lighter is the mass of the scalar field and smaller the range of the force. For example, in successful theories, and for human-like densities ($\sim$ 1 gram per cubic centimeter) the range of the fifth-force becomes so ridiculously small that it becomes effectively invisible to any experiment. On the other hand, at extremely low ambient densities the range of the fifth-force becomes quite large, with cosmological scope.

The most studied MG theory in Cosmology, one can affirm with high confidence, is the $f(R)$ gravity,[8–10] and in particular the Hu-Sawicki model.[11] Although, these theories were first understood as higher-order gravity theories, it was soon recognized that under a few assumptions they can be described as second order differential equations for the metric plus a scalar field[12,13] which propagates only an additional massive mode. In this proceeding note we will lead with the Hu-Sawicki model to exemplify our analytical results and to take advantage of the fact that we have good, *state-of-the-part* N-body simulations for them—the Extended LEnsing PHysics using ANalaytic ray Tracing `Elephant` cosmological suite of simulations.[14,15] Even though $f(R)$ is not a representative model of the vast universe of MG models (or more narrowly of Hordenski theories), the techniques reviewed here can be applied to different models and can be beneficial to study MG that rely on screening mechanisms. The material presented in this note is extracted mainly from Refs. 16–19; we refer the reader to these works for further details.

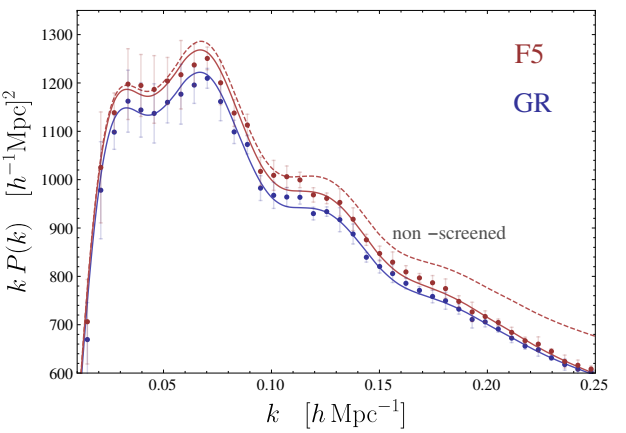

Fig. 1. Matter power spectrum in the models GR (blue line) and Hu-Sawicki F5 (red lines). The latter is further shown with and without screenings with solid and dashed lines, respectively. To generate this analytical results we use the Standard Perturbation Theory with effective field theory counterterms and infrared-resummations of Refs. 20, 21. The mock data is extracted from the `Elephant` simulations.

2. The importance of up-weight low energy density regions

In figure 1 we show the chameleon screening in action. The black line is the analytical power spectrum of the ΛCDM. The red coloured lines show the matter power spectrum in the Hu-Sawicki F5 model with screenings (solid line) and without screenings (dashed line), together with data from the `Elephant` simulations. We note the screening mechanism drives the theory to GR, more evident at small scales (high wave-numbers k), while without the screenings the differences between the two models are larger. This behaviour raises the question if the power spectrum, and its counterpart in configuration space, the correlation function, are the most clever way to test the gravitational theories from its cosmological clustering. After all, by construction these statistics give more weight to high density regions, since they sum over all tracers evenly (either particles, halos, galaxies...), and tracers tend to clump together by gravitational attraction. Meanwhile, cosmological voids are underrepresented by the power spectrum—as well as by the correlation function and their N-points generalizations—even though they are the largest regions in our universe, and as such, they contain a significant share of the total energy budget. But clumpy regions of space, being denser, behave very close to GR due to the screenings mechanism. Hence, the standard statistics used in Cosmology may not be the best option to test infrared modifications of GR.

With the above ideas in mind, M. White proposed in Ref. 16 to use *marked correlation functions*[b] to test gravity at cosmological scales. The proposal consists in weighting the tracer field density fluctuations with a function (the mark) whose value depends on the environmental density, such that objects residing in low density regions become up-weighted in 2-point statistics, while objects residing in high density become down-weighted. In this way, statistics of such marked density fields will probe low density regions where gravitational fifth-force screenings are inefficient and the effects of hypothetical MG theories would be more pronounced.

The construction of a marked density field $\delta_M(\mathbf{x}, t)$ is a three step process, depicted in figure 2. It goes as follows,

(1) One starts with the matter fluctuations field $\delta(\mathbf{x}, t)$ and convolve it with a window function $W_R(\mathbf{x})$ of width R (a Gaussian is used in this work) to obtain the smoothed density

$$\delta_R(\mathbf{x}, t) = \int d^3y \; W_R(|\mathbf{x} - \mathbf{y}|)\delta(\mathbf{y}, t). \tag{1}$$

The scale R is chosen from the beginning and it determines the size of the region which is used to define the environmental density of the tracers. In this sense,

[b]Marked statistics have a long history;[22] they have been used to assign properties to objects, such as the luminosity, color, and morphology of galaxies,[23,24] and to break degeneracies between Halo Occupation Distribution (HOD; a semi-analytical method to populate halos from N-body simulations with galaxies) and cosmologies.[25]

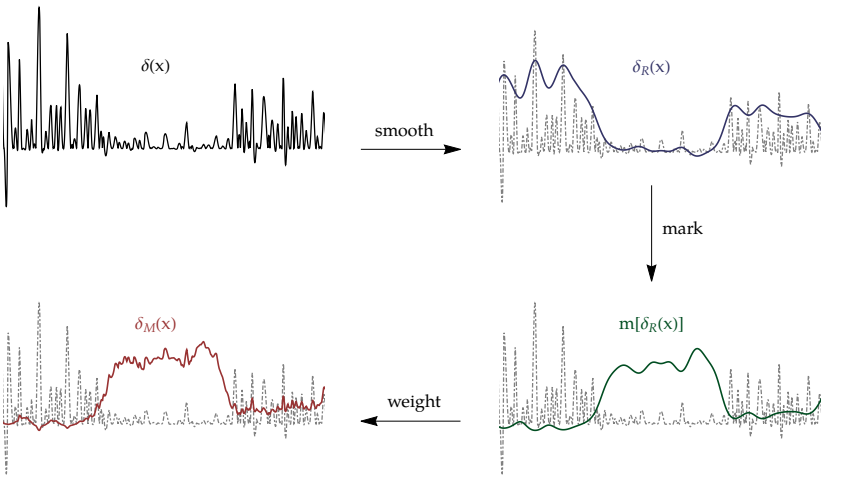

Fig. 2. 1-dimensional cartoon for the construction of the marked density field.

it is good to have sufficiently large values for R, typically comparable to, or a little bit smaller than, the size of cosmic voids. Here we use $R = 10\,h^{-1}\,\mathrm{Mpc}$.

(2) Construct the mark function $m(\delta_R(\mathbf{x}))$. We choose a function that decays with the environmental (or smoothed) density, such that low density regions are up-weighted, as required. For example, a simple exponential $m = \exp[-\alpha(1 + \delta_R(\mathbf{x}))]$ can do the job. However it is better to have more free parameters such that we have more liberty to find an optimal mark for a particular MG model. The most used weight is the White-mark[16]

$$m(\delta(\mathbf{x}), R) = \left(\frac{1+\delta_*}{1+\delta_*+\delta_R(\mathbf{x})}\right)^p, \tag{2}$$

with $p > 0$ and $\delta_* > 0$ dimensional parameters. It was find with numerical simulations that the choices $p = 10$ and $\delta_* = 4$ maximize both the Fisher information and the signal-to-noise.[26] However, these parameters are not good for perturbative analysis, so we will use the parameters $p = 7$ and $\delta_* = 10$, unless otherwise is stated. Other authors working with simulations have used different parameters and mark functions.[18,26–28]

(3) Weight the density field of tracers $1+\delta_X(\mathbf{x})$ with the mark function $m(\delta(\mathbf{x}), R)$ to obtain the marked density field

$$1 + \delta_M(\mathbf{x}, t) = \big(1 + \delta_X(\mathbf{x}, t)\big) m[\delta_R(\mathbf{x})]. \tag{3}$$

The density field can be that of any tracer of the underlying matter density, it can even be the matter density field itself. But we observe tracers, as galaxies for example, in the sky. These are related through a biasing function F to the dark matter as

$$1 + \delta_X(\mathbf{x}) = F_{\mathbf{x}}[\delta(\mathbf{x}), \nabla^2\delta(\mathbf{x}), ...; \mathbf{x}] \tag{4}$$

where the stochasticity of this relation is emphasized by writing $\mathbf{x}$ as an additional argument. The dependence on the non-local curvature operator $\nabla^2\delta(\mathbf{x})$ is expected to be small in GR, but a well defined bias expansion within chameleon theories must contain higher-order derivative operators.[29,30]

3. Marked correlation function

A marked correlation function (mCF)[16,22–25,31,32] is defined as the sum of pairs of objects (i, j) separated by a distance r, and weighted by the ratio of the mark function value to the mean mark $m_i/\bar{m}$ at each point and divided by the number of pairs $n(r)$,

$$\mathcal{M}(r) = \sum_{i,j|r_{ij}=r} \frac{m_i m_j}{n(r)\bar{m}^2}, \tag{5}$$

so it quantifies the deviation of a pair of objects to have the mean mark $\bar{m}$ subjected to be located at a separation r. By construction it can be written as

$$\mathcal{M}(r) = \frac{1 + W(r)}{1 + \xi(r)} \tag{6}$$

where $\xi(r)$ is the standard 2-point correlation function of tracers

$$1 + \xi(r) = \left\langle \big(1 + \delta_X(\mathbf{x} + \mathbf{r})\big)\big(1 + \delta_X(\mathbf{x})\big) \right\rangle, \tag{7}$$

and $W(r)$ is the 2-point correlation function of marked fields:

$$1 + W(r) = \frac{1}{\bar{m}^2} \left\langle \big(1 + \delta_M(\mathbf{x} + \mathbf{r})\big)\big(1 + \delta_M(\mathbf{x})\big) \right\rangle. \tag{8}$$

At large scales both ξ and W are small and one gets

$$\mathcal{M}(r) = 1 + W(r) - \xi(r). \tag{9}$$

Now, one may show that $\xi(r) \in W(r)$,[17] hence the mark function becomes a 2-point statistic of the clustering of marks with the clustering of objects effectively factorized out. The presence of the mean mark is not necessary to estimate the mCF, but it plays an important role in the analytical renormalization of the theory.

4. Perturbative treatment of the marked correlation function

It is well known that a good modeling of N-point statistics of density fields in configuration space requires the use of Lagrangian Perturbation Theory (LPT),[33] since the spread and degradation of the BAO oscillations is due to large scale bulk flows, long wave-length Lagrangian displacement fields that are well described in the Lagrangian framework, even at the linear order.[34] However the derivation of the marked correlation function within the Lagrangian framework is quite large and technical, so we prefer to omit it in this note; the interested reader can find it in Ref. 17, and later on we will display the main results. However, in this section we develop the Standard Perturbation Theory (SPT) approach to the marked correlation function, which is easier, but yet shows the main ingredients and insights of the theory.

We start by expanding the mark in a power series of δ_R

$$m(\delta_R; C_i) = C_0 + C_1\delta_R + \frac{1}{2}C_2\delta_R^2 + \cdots \tag{10}$$

with $C_i = m^{(i)}[0]$, the i-th derivative of $m[\delta_R]$ evaluated at $\delta_R = 0$. The fewer parameters are needed to model the mark, the better the convergence will be. We notice that $C_1 < 0$ enhances low density regions.

For the sake of simplicity we will assume a local relation between matter and tracer overdensities

$$1 + \delta_X(\mathbf{x}) = c_0 + c_1\delta(\mathbf{x}) + \frac{c_2}{2}\delta^2(\mathbf{x}) + \cdots, \tag{11}$$

with $c_i = \partial F_{\mathbf{x}}^{(i)}[\delta_R = 0]/\partial\,\delta_R$ the bare bias parameters and $F_{\mathbf{x}}$ given by eq. (4). A Taylor expansion is an unnatural and restrictive assumption for biased tracers, but being pragmatic we note that it works at the level of precision required by our simulations.

The mean mark is given by the mark weighted by the tracer density field

$$\begin{aligned}\bar{m} &= \langle m[\delta_R(\mathbf{x})](1 + \delta_X(\mathbf{x}))\rangle \\ &= \left\langle \left(C_0 + C_1\delta_R(\mathbf{x}) + \frac{C_2}{2}\delta_R^2(\mathbf{x}) + \cdots\right)\left(c_0 + c_1\delta(\mathbf{x}) + \frac{c_2}{2}\delta^2(\mathbf{x}) + \cdots\right)\right\rangle \\ &= c_0C_0 + c_1C_1\sigma_R^2 + \frac{1}{2}c_0C_2\sigma_{RR}^2 + \frac{1}{2}C_0c_2\sigma^2 + \cdots,\end{aligned} \tag{12}$$

with zero-lag correlators defined as

$$\sigma^2 \equiv \langle(\delta(0))^2\rangle, \quad \sigma_R^2 \equiv \langle\delta_R(0)\delta(0)\rangle, \quad \sigma_{RR}^2 \equiv \langle(\delta_R(0))^2\rangle. \tag{13}$$

We will use also the correlation and cross-correlation functions

$$\xi(r) \equiv \langle\delta(\mathbf{x})\delta(\mathbf{x}+\mathbf{r})\rangle, \tag{14}$$

$$\xi_R(r) \equiv \langle\delta_R(\mathbf{x})\delta(\mathbf{x}+\mathbf{r})\rangle, \tag{15}$$

$$\xi_{RR}(r) \equiv \langle\delta_R(\mathbf{x})\delta_R(\mathbf{x}+\mathbf{r})\rangle. \tag{16}$$

We have to write eq. (12) in terms of renormalized bias parameters,[35]

$$b_n^E = \int \frac{d\lambda}{2\pi} e^{-\lambda^2\sigma^2/2} \tilde{F}_{\mathbf{x}}(\lambda)(i\lambda)^n, \tag{17}$$

where $\tilde{F}_{\mathbf{x}}(\lambda)$ is the Fourier transform of $F_{\mathbf{x}}$ with spectral parameter λ (dual to δ). We are using the label "E" to distinguish Eulerian from Lagrangian biases. Equation (17) leads to the relation between bare bias c_n and renormalized bias b_n^E parameters:[36,37]

$$b_n^E = \sum_{k=0}^{\infty} \frac{\sigma^{2k}}{2^k k!} c_{n+2k}. \tag{18}$$

Analogously, we introduce the "resummed" expansion parameters B_n as

$$B_n = \frac{B_n^*}{B_0^*} \qquad \text{with} \qquad B_n^* = \int \frac{d\Lambda}{2\pi} e^{-\Lambda^2\sigma_{RR}^2/2} \tilde{m}(\Lambda)(i\Lambda)^n, \tag{19}$$

where $\tilde{m}(\Lambda)$ is the Fourier transform of $m(\delta_R)$, and Λ is a spectral parameter, dual to δ_R. One easily finds[17] the following relation between the expansion parameters B_n and the Taylor coefficients of the mark function C_n

$$B_n(C_n, \sigma_{RR}^2) = \frac{\sum_{k=0}^{\infty} C_{n+2k}\sigma_{RR}^{2k}/(2^k k!)}{\sum_{k=0}^{\infty} C_{2k}\sigma_{RR}^{2k}/(2^k k!)}. \tag{20}$$

Inserting the b_n^E and B_n parameters in eq. (12) we get

$$\bar{m} = B_0^* \big[1 + b_1^E B_1 \sigma_R^2 + \cdots\big]. \tag{21}$$

We compute now

$$\begin{aligned}
\bar{m}^2(1+W(r)) &= \langle m[\delta_R(\mathbf{x}_1)]\big(1+\delta_X(\mathbf{x}_1)\big) m[\delta_R(\mathbf{x}_2)]\big(1+\delta_X(\mathbf{x}_2)\big)\rangle \\
&= \int \frac{d\lambda_1 d\lambda_2 d\Lambda_1 d\Lambda_2}{(2\pi)^4} \langle e^{i(\lambda_1\delta_1 + \Lambda_1\delta_{R,1} + \lambda_2\delta_2 + \Lambda_2\delta_{R,2})}\rangle \tilde{F}_{\mathbf{x}}(\lambda_1)\tilde{F}_{\mathbf{x}}(\lambda_2)\tilde{m}(\Lambda_1)\tilde{m}(\Lambda_2) \\
&= \int \frac{d\lambda_1 d\lambda_2 d\Lambda_1 d\Lambda_2}{(2\pi)^4} \tilde{F}_{\mathbf{x}}(\lambda_1)\tilde{F}_{\mathbf{x}}(\lambda_2)\tilde{m}(\Lambda_1)\tilde{m}(\Lambda_2) e^{-\frac{1}{2}(\lambda_1^2+\lambda_2^2)\sigma^2 - \frac{1}{2}(\Lambda_1^2+\Lambda_2^2)\sigma_{RR}^2} \\
&\quad \times \Big[1 - (\lambda_1\Lambda_1 + \lambda_2\Lambda_2)\sigma_R^2 - \lambda_1\lambda_2\xi(r) - \Lambda_1\Lambda_2\xi_{RR}(r) - (\lambda_1\Lambda_2 + \lambda_2\Lambda_1)\xi_R(r) + \cdots\Big] \\
&= \bar{m}^2\Big[1 + (b_1^E)^2\xi(r) + B_1^2\xi_{RR}(r) + 2b_1^E B_1 \xi_R(r) + \cdots\Big],
\end{aligned} \tag{22}$$

where the ellipsis denotes second order terms in $\xi_{,R,RR}(r)$. In the second equality, we have shifted to Fourier space ($\delta \to \lambda$, $\delta_R \to \Lambda$) and in the third equality we used the cumulant expansion theorem,

$$\langle e^{iX}\rangle = \exp\left[\sum_{N=1}^{\infty} \frac{i^N}{N!}\langle X^N\rangle_c\right], \tag{23}$$

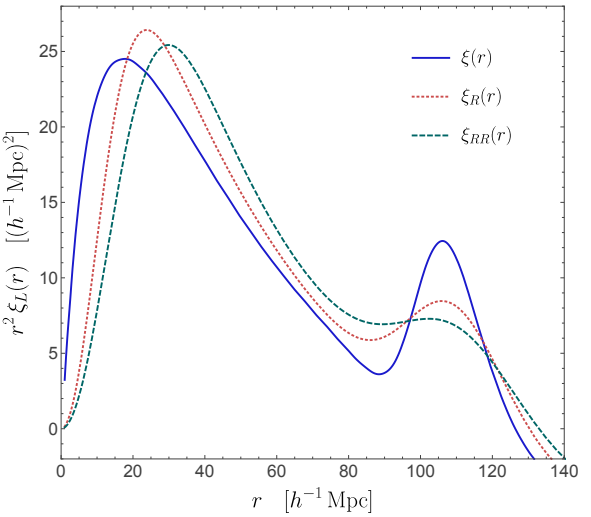

Fig. 3. Smoothed correlation functions defined in defined in eqs. (14)-(16) and appearing in the Eulerian marked correlation function [Eq. (24)]. We use a Gaussian damping kernel W_R of width $R = 10\,h^{-1}$Mpc to smooth the density fields.

and expanded out of the exponential all terms but those containing σ^2 and σ^2_{RR}, such that we can use Eqs. (17) and (19) to get biases from spectral parameters, as we did in the last equality. The mCF becomes

$$\mathcal{M}^E(r) = \frac{1+W(r)}{1+\xi_X(r)} = \frac{1+(b_1^E)^2\xi(r)+B_1^2\xi_{RR}(r)+2b_1^E B_1\xi_R(r)+\cdots}{1+(b_1^E)^2\xi(r)+\cdots}. \qquad (24)$$

In figure 3 we show the correlation functions defined in eqs. (14)-(16) and used to construct the above mCF. We use a Gaussian smoothing kernel W_R with width $R = 10\,h^{-1}$Mpc.

We notice that the zero-lag correlators σ^2 and σ^2_{RR} do not appear in the mCF as is guaranteed because we are using renormalized b and B parameters. Meanwhile, the cross-covariance σ^2_R is canceled out by the mean mark squared appearing in the definition of the mCF in eq. (5). We remark that a process of renormalization of the Taylor expansion coefficients C is not strictly necessary because the scale R is physical, and chosen from the beginning by the observer to mark the tracers, so there is no impediment for σ^2_{RR} to appear in the final expressions. However, the use of parameters B instead of the Taylor coefficients leads to simpler final equations. Furthermore, in real applications, we have to use a mark computed by the number density of galaxies. Another advantage of using the renormalized B parameters is that the effect of this reassignment can be included simply by re-scaling the B parameters. For the application to dark matter halos and galaxies, one should treat them as free parameters and fit them with simulations.

5. Lagrangian space

In Lagrangian space one considers regions of space, at an initial early time with spatial coordinates $\mathbf{q}$. We relate matter and tracers overdensities, in an analogous way to eq. (4), by

$$1 + \delta_X(\mathbf{q}) = F[\delta(\mathbf{q})], \tag{25}$$

with the difference that the overdensity fields are taken at an initial early time.[c] Assuming number conservation of tracers, $(1 + \delta_X(\mathbf{x}))d^3x = (1 + \delta_X(\mathbf{q}))d^3q$, one can relate the function $F_{\mathbf{x}}$, introduced in eq. (4), and F through

$$F_{\mathbf{x}}[\delta(\mathbf{x})] = \int \frac{d^3k}{(2\pi)^3} \int d^3q\, e^{i\mathbf{k}\cdot(\mathbf{x}-\mathbf{q})} \int \frac{d\lambda}{2\pi} \tilde{F}(\lambda) e^{i\lambda\delta(\mathbf{q}) - i\mathbf{k}\cdot\mathbf{\Psi}(\mathbf{q},\mathbf{t})}, \tag{26}$$

with $\mathbf{\Psi}(\mathbf{q})$ the Lagrangian displacement vector, that maps Lagrangian coordinates $\mathbf{q}$ to Eulerian coordinates $\mathbf{x}$ as $\mathbf{x}(\mathbf{q}, t) = \mathbf{q} + \mathbf{\Psi}(\mathbf{q}, t)$. Equivalently to eq. (17), we introduce the renormalized Lagrangian local biases[35] with

$$b_n = \int \frac{d\lambda}{2\pi} e^{-\lambda^2\sigma^2/2} \tilde{F}(\lambda)(i\lambda)^n. \tag{27}$$

The next step is to evolve initially biased tracers with overdensity $\delta_X(\mathbf{q})$ using Convolution Lagrangian perturbation theory[38,39] and thereafter assign them a mark $m[\delta_R(\mathbf{x})]$ at the moment of observation. The use of the Lagrangian approach has some advantages with respect to the Eulerian. In the first place it is well known that the two-point correlation function is poorly modeled within the Eulerian approach, particularly at the BAO peak position; second, the (renormalized) Lagrangian bias parameters are obtained through the peak background split prescription,[40–43] and hence are physically appealing. But the price to pay is that the mCF is cumbersome to compute, since it becomes a double Gaussian convolution:[17]

$$1 + W(r) = \int \frac{d^3q\, e^{-\frac{1}{2}(\mathbf{r}-\mathbf{q})^T\mathbf{A}^{-1}(\mathbf{r}-\mathbf{q})}}{(2\pi)^{3/2}|\mathbf{A}|^{1/2}} \int \frac{d^3Q\, e^{-\frac{1}{2}(\mathbf{R}-\mathbf{Q})^T\mathbf{C}^{-1}(\mathbf{R}-\mathbf{Q})}}{(2\pi)^{3/2}|\mathbf{C}|^{1/2}} \tag{28}$$

$$\times \Big(1 + \mathcal{I}^0(\mathbf{r}, \mathbf{q}, \mathbf{R}, \mathbf{Q}; b_i, B_i)\Big), \tag{29}$$

with $\mathcal{I}^0$ a function, whose expression is quite large and not very illuminating, and contains the information of the mark (through the expansion parameters B_i) and of the tracers (through the bias parameters b_i). It can be found in eq. (B.8) of Ref. 17. The matrices $\mathbf{A}$ and $\mathbf{C}$ are given by

$$A_{ij}(\mathbf{q}) = 2 \int \frac{d^3p}{(2\pi)^3} \big(1 - e^{i\mathbf{p}\cdot\mathbf{q}}\big) \frac{p_i p_j}{p^4} P_L(p), \tag{30}$$

[c]This initial time is taken early enough that all scales of interest are still in the linear regime and one can safely take $\delta(\mathbf{q}) \ll 1$, but late enough that the background universe is already in the Einstein-de Sitter phase.

and

$$C_{ij}(\mathbf{q}) = -\frac{1}{4}A_{ij}(\mathbf{q}) + \frac{1}{6\pi^2}\int_0^\infty P_L(p)dp\ \delta_{ij}, \tag{31}$$

with $P_L(p)$ the linear matter power spectrum. We notice that if $1+\mathcal{I}$ is not a function of $\mathbf{Q}$, it can be pulled out of the $\mathbf{Q}$ integral and due to that C_{ij} depends only on $\mathbf{q}$, the integration over $\mathbf{Q}$ gives 1. This is the case of the "standard" correlation function in Convolution Lagrangian Perturbation Theory (CLPT),[38] reducing the double Gaussian convolution in eq. (28), to a single three-dimensional convolution.

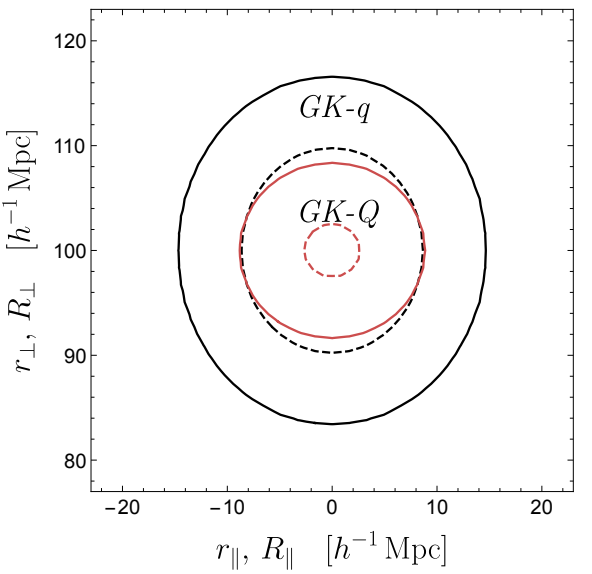

Fig. 4. Gaussian kernels in eq. (28). *GK-q* is the kernel of the q-integral (black curves) and *GK-Q* the kernel of the Q-integral (red curves). Dashed and solid curves show the regions that enclose the 68% and 95% of the volume respectively. A similar plot can be found in Ref. 44. Figure adapted from Ref. 17.

In figure 4 we show level plots for the Gaussian kernels appearing in eq. (28). *GK-q* is the kernel of the q-integral and *GK-Q* the kernel of the Q-integral. These are shown as a function of $r_\parallel$ ($R_\parallel$) and $r_\perp$ ($R_\perp$), the components of $\mathbf{r}$ ($\mathbf{R}$) parallel and perpendicular to the Lagrangian coordinate $\mathbf{q}$ ($\mathbf{Q}$) with $Q = q = 100\,h^{-1}\,\mathrm{Mpc}$ fixed. To have a sense of the meaning of this plot, consider that the kernel *GK-q* is the probability distribution of finding two dark matter particles separated by a distance $\mathbf{r}$ at the redshift of evaluation ($z = 0.5$ in the plot), given that they were separated by a distance $\mathbf{q}$ at the early initial time.[44] We notice that both kernels have their maximum value at $Q = q = 100\,h^{-1}\,\mathrm{Mpc}$, but the *GK-Q* is more sharply

peaked because $|\mathbf{C}| < |\mathbf{A}_L|$. This observation suggests to approximate

$$\frac{e^{-\frac{1}{2}(\mathbf{R}-\mathbf{Q})^T\mathbf{C}^{-1}(\mathbf{R}-\mathbf{Q})}}{(2\pi)^{3/2}|\mathbf{C}|^{1/2}} \approx \delta_{\rm D}(\mathbf{R}-\mathbf{Q}). \tag{32}$$

By doing so, one arrives at

$$1 + W^{\rm W16}(r) = \int \frac{d^3q}{(2\pi)^{3/2}|A_L|^{1/2}} e^{-\frac{1}{2}(\mathbf{r}-\mathbf{q})^T\mathbf{A}_L^{-1}(\mathbf{r}-\mathbf{q})}\Big(1 + J^0(\mathbf{q},\mathbf{r};b_i,B_i)\Big) \tag{33}$$

which is the generalization of the Zeldovich approximation (ZA) result obtained in Ref. 16. The expression for $J^0(\mathbf{q},\mathbf{r};b_i,B_i)$ is given by eq. (4.18) of Ref. 17.

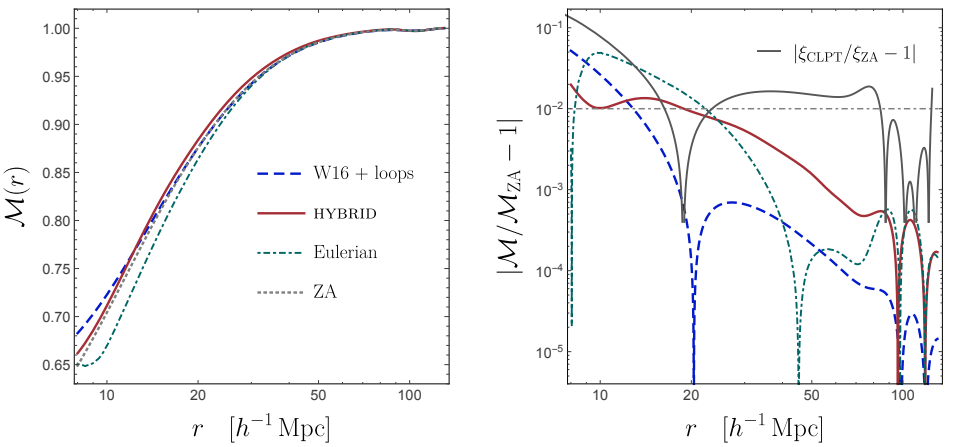

Fig. 5. Marked correlation function modeling comparison. The left panel shows the mCF with parameters $b_1 = 1.2$, $b_2 = 0.2$, $B_1 = -0.7$, $B_2 = B_1^2$, for the different methods: solid red curve is the HYBRID model presented in Ref. 17; dashed blue the method of Eq. (33), which is the method introduced in Ref. 16, plus 1-loop nonlinear contributions; in dotted gray, the ZA; and in dot-dashed green, the Eulerian linear model of eq. (24). The right panel shows the relative differences with respect to the ZA. The gray dot-dashed horizontal line denotes the 1% differences. The solid black curve in the right panel shows the relative differences between the CLPT 1-loop and ZA standard correlation functions. Figure adapted from Ref. 17.

Figure 5 shows the mCF using different analytical methods for the MG Hu-Sawicki F5 model: solid red curve is the one presented above and developed in Ref. 17—called HYBRID from now on, because it evolves the tracers using LPT but marks the tracers using the Eulerian smoothed matter overdensity fields at the moment of observation. The dashed blue is the method of eq. (33), which is that introduced in Ref. 16 with the addition of leading non-linear (loop) corrections; in dotted gray, the Zeldovich Approximation, which in this work means the linear model of Ref. 16; and, in dotdashed green, the Eulerian linear model of eq. (24).

We are using Lagrangian local biases $b_1 = 1.2$ and $b_2 = 0.2$, and mark parameters $B_1 = -0.7$, $B_2 = B_1^2$. In the right panel we show the relative difference between the models and the ZA. The agreement between them is very good, even for the linear Eulerian theory, below 1% for scales above $\sim 20\,h^{-1}\,\mathrm{Mpc}$. The relative differences between the CLPT standard correlation function with and without loop contributions (ξ_{CLPT} and ξ_{ZA}, respectively) is shown in the right panel (black curve); by comparing it with the dashed blue curve (which shows the relative differences of the W16+1-loop and ZA mCFs) we confirm that mCFs which efficiently enhance low density regions in the sky are indeed more linear than the standard correlation function.

6. Comparison to simulations

We use the `Elephant` suite of simulations run with the `ECOSMOG` code.[14] This suite contains five realisations of the initial conditions and for each realisation we have one simulation of ΛCDM (GR) together with three simulations of the Hu-Sawicki $f(R)$ model with parameters $f_{R0} = -10^{-4}$ (F4), $f_{R0} = -10^{-5}$ (F5) and $f_{R0} = -10^{-6}$ (F6). It also contains galaxy mock catalogs that were made with a Halo Occupation Distribution (HOD) method. The HOD parameters for the ΛCDM model are the best-fit parameter values from the CMASS data.[45] For the $f(R)$ models, we tune the HOD parameters so that we reproduce the correlation function in the ΛCDM model. The simulations were ran in a box of size $L = 1024\,h^{-1}\,\mathrm{Mpc}$ with $N = 1024^3$ particles and the cosmological parameters used to make the initial conditions were $\Omega_b = 0.046$, $\Omega_\Lambda = 0.719$, $\Omega_m = 0.281$, $h = 0.697$, $\sigma_8 = 0.82$ and $n_s = 0.971$, and for our analysis we choose snapshots at redshift $z = 0.5$. To compute the mark for each of our tracers (dark matter particles, halos or mock galaxies) we binned the particles/halos/mock galaxies to a grid with gridsize of $20\,h^{-1}\,\mathrm{Mpc}$ (corresponding to a $N = 52^3$ grid) using a Nearest Grid Point assignment scheme to get an estimate for the density for which the mark depends on.

Both, the standard and weighted 2-point correlation functions were computed using the Correlation Utilities and Two-point Estimates (`CUTE`)[46] code.[d] From this the marked correlation function follows simply as $\mathcal{M}(r) = (1 + W(r))/(1 + \xi(r))$.

We consider the White-mark with $\rho_* = 10$, $p = 7$, corresponding to coefficients $C_0 = 1$, $C_1 = -0.64$, $C_2 = 0.46$ in the Taylor expansion of the mark function in eq. (10). In our analytical models we smooth the matter fields that assign the mark with a top-hat filter W_R of radius $R = 10\,h^{-1}\,\mathrm{Mpc}$.

We first confront different analytical methods against matter data, since in this case the mCF does not suffer from biasing-marking degeneracies and we can observe more neatly the effects of the weights. The expansion parameters B are obtained from eq. (20): $B_1^{\mathrm{GR}} = -0.6495$, $B_1^{\mathrm{F6}} = -0.6497$, $B_1^{\mathrm{F5}} = -0.6505$, $B_1^{\mathrm{F4}} = -0.6522$,

[d] https://github.com/damonge/CUTE

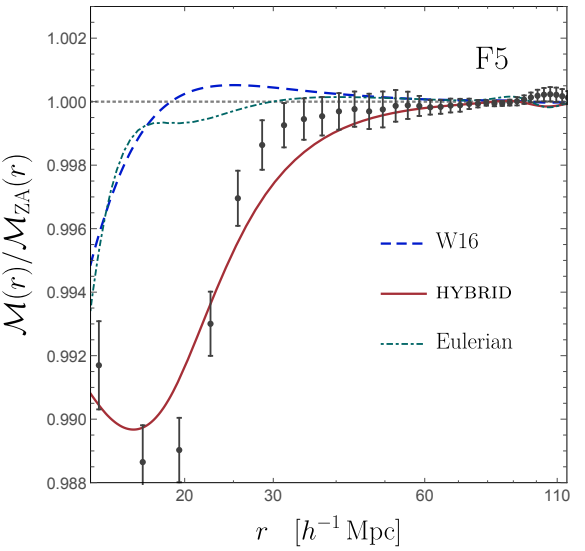

Fig. 6. Ratios of different mCFs analytical models to the ZA mCF for the F5 gravity (we obtain similar results for F4, F6 and GR). We show the W16 model plus 1-loop corrections (dashed blue); the HYBRID model (solid red); and the linear Eulerian model of eq. (24) (dot-dashed green). Figure adapted from Ref. 17.

$B_2^{\rm GR} = 0.4628$, $B_2^{\rm F6} = 0.4502$, $B_2^{\rm F5} = 0.4495$, $B_2^{\rm F4} = 0.4480$; which are numerically very close to C_1 and C_2 values because $C_0 = 1$ and the variances σ^2_{RR} are small.

In figure 6 we show the ratios of the different analytical methods to the ZA model. We do it for the Hu-Sawicki F5 gravity model, and we have checked also the gravity theories GR, F4 and F6, and obtained similar results. The dashed blue curve shows the analytical result with the W16 model plus 1-loop corrections; solid red, the HYBRID method; and dot-dashed green, the linear Eulerian model of eq. (24). The differences between the analytical methods are apparent but small, being lesser than the 1%. At scales $r > 40\,h^{-1}\,{\rm Mpc}$, all analytic models are indistinguishable and they are within the errors of the simulation data. At smaller scales, the method HYBRID outperforms the other perturbative approaches and captures reasonably the trend of the data all the way up to the smoothing scale $R = 10\,h^{-1}\,{\rm Mpc}$.

Finally, in figure 7 we use the HYBRID model to fit the data for halos and galaxies (HOD), finding very good agreement between simulations and theory for $r > 30\,h^{-1}\,{\rm Mpc}$. In the left panel we show that the MG models are differentiated by the data and the analytical curves in the interval $30 < r < 50\,h^{-1}\,{\rm Mpc}$, with the exception of the F5 and F6 models, which become indistinguishable within the error bars. However, we notice that the HOD mCFs for the different MG models do not look differently enough to be distinguished by our data. We think that the use of different parameters δ_* and p or different mark functions can help to discern between different gravitational patterns; see, for example, Ref. 18.

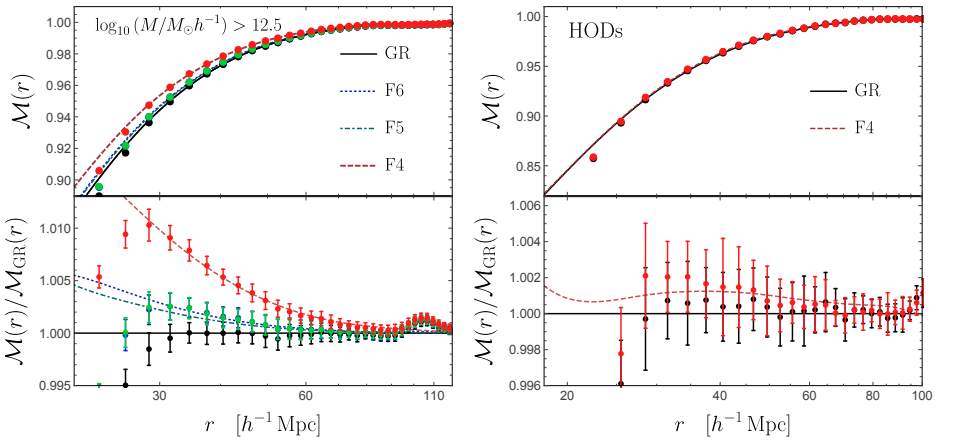

Fig. 7. Halos and galaxies mCFs. Left panel is for halo masses $12.5 < \log_{10}[M/(M_\odot h^{-1})] < 15$ and gravitational models F4, F5, F6 and GR. Right panel is for HOD and shows only the F4 and GR models. The linear local biases are fitted by using the ZA correlation function. Figure adapted from Ref. 17.

7. Marked power spectrum

Recently, it was discovered that the marked statistics can be very useful for the estimation of cosmological parameters, particularly the mass scale of the primordial neutrinos.[47] The reason is that given the large velocity dispersion of neutrinos, they do not contribute to the small scale clustering (see, e.g. Ref. 48). But instead, they free-stream over large distances, allowing them to populate the cosmic voids considerably. On the other hand, the influence of neutrinos on high density regions, for example halos, is quite marginal because their contribution to the total matter density is very small. Thus, statistics that up-weight low density regions can be very beneficial for parameter estimation. In fact, the Fisher formalism results are quite impressive: the marked power spectrum of the matter field outperforms the constraining power of the standard power spectrum by at least a factor of 2 on all cosmological parameters, and in particular of up to 80 times for the sum of the neutrino masses, when a combination of two different mark functions is used.

The analytical description of the marked power spectrum has been studied in detail in a couple of recent works. First, for matter in real space[49] and later for tracers in redshift space.[19] The main complication of such studies is that the mark parameters optimal for improving the cosmological parameter estimation are not able for a perturbative treatment, and the linear theory fails at all scales. The large-scale theory contains non-negligible contributions from all perturbative orders; in Ref. 19 a reorganization of the theory that contains all terms relevant on large-scales is proposed, with an explicit form at one-loop and the following structure at

infinite-loop:

$$\mathcal{M}(k,\mu) = \big[C_0 - C_1 W_R(k)\big]\big[(\tilde{a}_0 + \tilde{a}_2\mu^2)P_L(k) + \tilde{b}_0\big] + \text{EFT} + \text{shot noise}$$

with $\tilde{a}_0$, $\tilde{a}_2$ and $\tilde{b}_0$ free parameters of the theory. EFT refers to the standard 1-loop corrections to the linear power spectrum and the effective field theory terms, while the shot noise includes the stochastic contributions.

8. Summary

We have reviewed the analytical study of marked statistics that up-weight low density regions in the Universe.[16–19] The idea behind marked statistics is to assign a value (the mark) to each entity in a catalogue and perform statistics over the resulting weighted objects. An efficient way to suppress non-linearities is by choosing a mark that gives more weight to objects that reside in low density regions, which become less important as one consider higher density regions. This marking process can be particularly useful for testing general relativity with cosmological probes, since modified gravity models that provide cosmic acceleration, often rely on screening mechanisms to hide its range and strength on high density environments, and the screenings switch off in regions that are more depleted of matter, like cosmic voids. Therefore, the effects of an hypothetical MG are expected to be more pronounced in low density regions. It is then natural to search for such marked statistics, as proposed in Ref. 16. Further, these statistics can potentially improve the constraining power of all cosmological parameters, in particular the mass of the primordial neutrinos, as it was shown in Ref. 47.

Acknowledgments

I want to thank Alfredo Macias and Carlos Herdeiro for inviting me to give a talk in the BS1 parallel session "Scalar fields in Cosmology" of the Sixteenth Marcel Grossmann Meeting – MG16, July 5-10 2021. I also want to thank Jorge L. Cervantes-Cota, Baojiu Li, Kazuya Koyama, Hans Winther, Elisa Massara, Oliver Philcox and Martin White for their collaboration in developing the material that led to this work. I would like to thank the DiRAC Data Centric system at Durham University (`www.dirac.ac.uk`) for computational facilities.

Appendix A. Hu-Sawicki MG model

The Hu-Sawicki model[11] is a particular realisation of $f(R)$ gravity that is able to evade the strong constraints coming from local test of gravity and still give rise to interesting observable signatures on cosmological scales. $f(R)$ theories consist on replace the Einstein-Hilbert Lagrangian density $\sqrt{-g}R$ by a general function of the Ricci scalar $\sqrt{-g}\big(R + f(R)\big)$; see Ref. 50 for a review. The Hu-Sawicki model is

defined by the function

$$f(R) = -M^2 \frac{c_1 (R/M^2)^n}{c_2 (R/M^2)^n + 1} \tag{A.1}$$

where the energy scale is chosen to be $M^2 = \Omega_m H_0^2$. In this parametrized model, at high curvature ($R \ll M^2$) the function $f(R)$ approaches a constant, recovering GR with cosmological constant, while at low curvature it goes to zero, recovering GR; the manner these two behaviors are interpolated is dictated by the free parameters. Given that $d^2 f(R)/dR^2 > 0$ for $R > M^2$, the solutions are stable and the scalar tensor gravity description is possible.[12] In order to be have a similar background evolution than the ΛCDM model it is also necessary that $c_1/c_2 = 6\Omega_\Lambda/\Omega_m$, thus leaving two parameters to fix the model. One choose these parameters to be n and $f_{R0} \equiv df(R)/dR|_{R=R_0}$, with $R_0 = 3H_0^2(\Omega_m + 4\Omega_\Lambda)$ the Ricci scalar of the background cosmological metric evaluated nowadays.

In this work we have considered a fixed value $n = 1$, and hence the model has only one free parameter f_{R0}. Taking this parameter to zero we recover GR. The three choices for the parameters we are considering in this paper (F4, F5 and F6) are such that they lie in the region around where the best constraints lie today. The F4 model corresponds to $|f_{R0}| = 10^{-4}$ (is in tension with local experiments), the F5 model to $|f_{R0}| = 10^{-5}$ (agrees with most experiments and observations, but are in tension with others) and the F6 model to $|f_{R0}| = 10^{-6}$ (which is still allowed). All these models are completely compatible with observations of the expansion history of the Universe, but present large deviations from the ΛCDM in the clustering and formation of structures.

We analyze the properties of a generic bosonic cloud that we interpreted as a condensed phase of generic bosons or a Bose–Einstein condensate (BEC) type halo surrounding a Schwarzschild–type black hole. We model the halo as a condensed phase of generic bosons in terms of a massive scalar field that satisfies a self–interacting Klein–Gordon equation. To model the density of particles of the corresponding cloud, we apply the so–called Thomas–Fermi approximation that allows us to extract relevant properties of the system. By using galaxy data from a subsample of SPARC data base, we find the best fits of the BEC model by using the Thomas–Fermi approximation. We show that in the centre of galaxies we must have a supermassive compact central object, i.e., supermassive black hole, additionally the cloud or the halo behaves as a weakly interacting BEC composed of ultralight bosons.

Keywords: Dark matter; Bose–Einstein condensate.

1. Introduction

Bose–Einstein condensates (BECs) play a fascinating role in modern physics, relating many models spreading from microscopic well proved behavior of ultracold quantum gases to galactic and cosmological scales. Nevertheless, there is an issue not well understood in this scenario that deserves more in-depth study, i.e., the non–trivial conditions in which scalar fields can form BECs. However, it seems to be that scalar fields in the form of a BEC formed by generic bosons can describe the basic properties of dark matter (DM) in the universe.[1–5] According to this line of thought, DM consists of a particular type of spin–zero bosons, such as ultra–light scalar field dark matter or fuzzy dark matter, weakly interacting massive particles,

axions, etc., (depending on the specific model under consideration) which have not yet been observed. The bosonic character of these particles, by using the theory of relativistic Bose gases,[6,7] also opens the door for the existence of scalar field dark matter in the form of BECs.[8,9]

The relation between scalar fields and (relativistic) condensates (BEC's) has already a long history, which is non trivial field of study even in flat space time, see for instance[6,7,10–14] and references therein. The aforementioned relation remains a very important topic that must be still fully understood.

Let us remark that in the core of the current astrophysics and cosmology, scalar fields seem to be a relevant candidate to describe dark matter (DM).[1–4,15] Nowadays, the observations suggest that the amount of dark matter in the universe is around 26% of the total energy density. In other words, the existence of dark matter can be found in the following observations, for instance, from the kinematic of galaxies and clusters,[16,17] the physics of the cosmic microwave background radiation (CMBR) and baryon acoustic oscillations (BAO),[18,19] as well as observations from Supernovae Type Ia (SNIa) and Gravitational Lensing (GL).[20,21]

Moreover, dark matter could consist of some type of generic scalar field(–particle) of spin–zero, for instance, Weakly Interacting Massive Particles (WIMPs), axions and others. Although these particles have been not yet observed, scalar fields interpreted as dark matter open up a very interesting model to confront observations. On the other hand, the theory of relativistic bosonic gases and its transitions, under certain circumstances as BEC's open the door to the interpretation of dark matter in the form of a condensate of generic bosonic particles.[8,9,22]

At this point is important to mention that there are some models related to the above ideas in the literature, for instance, the so–called hairy wigs models.[23,24] In the above mentioned approach it is shown that these systems can form stable structures for enough time, make them plausible candidates to describe dark matter galactic halos. Even more, since it is generally accepted that almost all the galaxies host a supermassive black hole at the center, and together with the assumption that dark matter is some kind of scalar field, this leads to the analysis of the existence of bound or quasi–bound scalar field configurations surrounding these compact objects. In fact, in the case of a Schwarzschild black hole and a massive scalar field without self–interactions, it was found that such quasi–bound states exist.[25]

Furthermore, when self–interactions are present for these scalar field configurations surrounding black holes and when quasi–bound states exist, the system can be also analyzed from the Bose–Einstein condensation point of view.[5,26,27] It is quite interesting that in the aforementioned scenario a Gross–Pitaevskii like–equation can be deduced from the corresponding Klein–Gordon equation. In other words, it is possible to study the system by using the formalism behind the Bose–Einstein condensation to extract relevant information. More precisely, in the formalism developed in refs.[5,26,27] it was shown that for a spherically symmetric test–scalar field configurations surrounding different types of black holes, the system can be interpreted as a trapped BEC. In other words, the corresponding Klein–Gordon

equation can be rewritten in a form of a Gross–Pitaevskii equation, which describes the dynamics of usual laboratory BEC's, under certain circumstances. Additionally, in the three quoted references, it was analyzed the limit of validity of the so–called Thomas–Fermi approximation which is capable to give us an approximated solution (in principle, by using a simple algebraic procedure) for the system under consideration.

Here it is important to mention that in the standard theory of condensates (for instance, ref. [28]) the Thomas–Fermi approximation is an algebraic procedure that is useful for exploring relevant properties associated with the system when interactions are present. Moreover, the Thomas–Fermi approximation is valid when the kinetic energy is negligible with respect to the potential and interaction ones. Then, the kinetic energy can be neglected from the very beginning in the corresponding Gross–Pitaevskii equation. As a consequence, the non–linear differential equation becomes an algebraic equation for the order parameter, which in principle, is easy to solve. Additionally, the Thomas–Fermi approximation is valid when the corresponding scattering length, which describes the interaction among the particles within the system, is much smaller than the mean inter–particle spacing for sufficient large clouds. In other words, when the system is diluted enough and contains a large number of particles. Finally, we must add that the Thomas–Fermi approximation fails for trapped condensates near the edge of the cloud, due to the divergent behavior of the kinetic energy (i.e. the total kinetic energy per unit area diverges on the boundary of the system[28]). The last assertion can be used to define the validity of the Thomas–Fermi approximation and sets the limit in which we can extract information from the system. Therefore, in the case of the scalar field configurations viewed as BEC's surrounding black holes, the divergent behavior of the kinetic energy on the predicted boundary of the system can be used to test the region in which the Thomas–Fermi approximation is valid. In other words, we are not able to extract information beyond the region in which the approximation is valid. Deeper research is needed to support the description of these systems as dark matter. In addition, according to the results obtained in refs. ,[5,26] observable features related to the *scalar cloud* within the Thomas–Fermi approximation, for discriminating between different types of black holes are tiny.

The main goal of the present manuscript is to identify the particle density distribution obtained from the Thomas–Fermi approximation (or the BEC density distribution) as a DM density profile surrounding galaxies (i.e., we restrict our analysis to the region in which the Thomas–Fermi approximation is valid).

Galaxy rotation curves cannot be explained by luminous matter alone and we have to appeal to an extra matter component, i.e. DM or BEC–DM in our scenario, to explain the observations.[29,30] Several DM density profiles have been proposed, we can categorize the profiles by its central behavior. Profiles whose densities grow with a power law of $\rho \sim r^{-1}$ are known as cuspy profiles, i.e. Navarro–Frenk–White.[31,32] Profiles whose density tends to a constant value at the center of the galaxy are know as core profiles, i.e. isothermal, Burket profiles.[33,34] Most cuspy profiles come

from numerical simulations while the later are phenomenological proven, but must of them do not offer a clear explanation for the DM fundamental nature. Moreover, there is a tension between cores and cusp profiles because, on one hand, cuspy profiles are the one predicted from numerical simulations, on the other hand, observations seem to prefer cored profiles, the so called core–cusp problem.[35]

We are able to constrain the parameters of the BEC–DM model within the Thomas–Fermi approximation by using a total of 20 high resolution, circular galaxies, see reference.[27] The mass density of the BEC is given in terms of the mass of the bosonic particles M_Φ, a frequency ω, the coupling constant λ (which describes the interparticle interaction within the system) and, the only astronomical parameter, the mass of the black hole M. Except for the mass of the black hole, the profile is only given by the underlying particle model, the BEC indeed, which we expect to be equal for all galaxies, leaving the mass of the black hole as the only astronomical parameter that may vary from one galaxy to other.

2. Rotation Curves and Bose–Einstein Condensates

In this section, we summarize some important results obtained in refs. [5,26,27] In the aforementioned references a Gross–Pitaevskii like–equation is deduced from the corresponding Klein–Gordon equation in spherically symmetric and static black hole spacetimes. Also, a self–interacting scalar potential is assumed, allowing to link the system with the BEC's point of view. It is important to mention that both equations contain the same information related to the system. After the deduction of the Gross–Pitaevskii like–equation we apply the Thomas–Fermi approximation, which allows us to deduce with a very simple procedure, the corresponding density profile that we assume as a galactic dark matter halo.

In order to deduce the density profile we consider a test scalar field(–particle) in a spherically symmetric and static spacetime where the metric which in standard spherical coordinates is given by

$$ds^2 = -f(r)c^2dt^2 + \frac{1}{f(r)}dr^2 + r^2(d\theta^2 + \sin^2\theta d\phi^2)\,. \tag{1}$$

Thus, the Klein–Gordon equation for a complex test–scalar field Φ with a scalar potential $V(\Phi)$ in a spacetime with metric $g_{\mu\nu}$ can be written as follows:

$$\frac{1}{\sqrt{-g}}\partial_\mu\Big(\sqrt{-g}g^{\mu\nu}\partial_\nu\Phi\Big) - \frac{d\,V(\Phi\Phi^*)}{d\,\Phi^*} = 0, \tag{2}$$

where the star is complex conjugation and g is the determinant of the metric. If we want to link the system with a weakly interacting Bose–Einstein condensate of some generic bosonic particles, we assume a scalar potential of the form

$$V(\Phi\Phi^*) = \mu^2\Phi\Phi^* + \frac{\lambda}{2}(\Phi\Phi^*)^2, \tag{3}$$

where μ is the scalar mass parameter which is related to the mass of the bosonic particles M_Φ through the inverse of the Compton wavelength of the particles $\mu = \dfrac{M_\Phi c}{\hbar}$.

Additionally, λ is the self–interaction coupling constant which is interpreted as the scattering length of the particles.

We can find solutions of the Klein–Gordon equation by using the following ansatz

$$\Phi(t,r) = e^{i\,\omega\,t}\,\frac{u(r)}{r}, \tag{4}$$

where we assume that the frequency ω is *real*. Notice that in general the function $u(r)$ is a complex–valued classical function that can be interpreted as the macroscopical wave function of the system or the order parameter as in standard theory of condensates. By using the ansatz (4) the corresponding Klein–Gordon equation reduces to a Gross–Pitaevskii–like equation of the form

$$\left(-\frac{d^2}{dr_*^2} + V_{\rm eff}(r) + \lambda_{\rm eff}(r)\,\frac{|u(r)|^2}{r^2}\right) u(r) = \frac{\omega^2}{c^2}\,u(r)\,, \tag{5}$$

where we have also introducing the r_* coordinate defined as $d\,r_* = \frac{d\,r}{f(r)}$, i.e., the so–called tortoise coordinate.

Notice that in equation (5) we define the effective trapping potential as

$$V_{\rm eff}(r) = f(r)\,\left(\mu^2 + \frac{f'(r)}{r}\right) \tag{6}$$

where the prime indicates derivatives respect to the r coordinate, together with an effective self–interaction parameter with the following functional form

$$\lambda_{\rm eff}(r) = \lambda\,f(r)\,. \tag{7}$$

Here is important to mention that the effective potential in equation (6) is caused by the curvature of the spacetime itself, together with the contribution of the mass parameter μ. In other words, the effective potential V_{eff} allows the bosonic cloud to admit the existence of quasi–bound states. Additionally, λ is *modulated* by the influence of the spacetime geometry, i.e., the interactions show a position-dependent behavior as was shown in refs.[5,26] Finally, we must mention that the term ω^2/c^2 can be also identified with effective chemical potential.

As was mentioned in the introduction, the Thomas–Fermi approximation assumes that the kinetic energy is negligibly small in comparison to the potential energy and the self-interaction energy. Then, we can neglect the kinetic energy in equation (5) from the very beginning, with the result of an algebraic equation, from which we can obtain the density of particles $\rho(r) \equiv \dfrac{|u(r)|^2}{r^2}$.

The solution for the Gross–Pitaevskii–like equation (5) within the Thomas–Fermi approximation is then given by

$$\frac{|u(r)|^2}{r^2} \equiv \rho(r) = \left(\frac{\omega^2}{c^2} - V_{\rm eff}(r)\right)\,\frac{1}{\lambda_{\rm eff}(r)}\,. \tag{8}$$

Notice that the above equation is well defined as long as the right-hand side is positive. The value of $\rho(r)$ is zero outside the region delimited by the equation

$V_{\text{eff}}(r) = \omega^2/c^2$. Moreover, the equation $V_{\text{eff}}(r) = \omega^2/c^2$ sets the size of the cloud within de Thomas–Fermi approximation. The region in which the condensate lies is a spherical shell of inner radius r_{min} and outer radius r_{max}, where r_{min} and r_{max} are precisely the solutions of the equation $V_{\text{eff}}(r) = \omega^2/c^2$. Additionally, as was point it out in,[26] the Thomas–Fermi approximation becomes arbitrarily good if λN (with N the total number of particles within the condensate) becomes sufficiently big. In the present case, λN increases if the ω/c is chosen very close to the mass parameter μ. Then we expect that the Thomas–Fermi approximation becomes quite good if the corresponding parameters are chosen properly.

For simplicity, let us assume that the function $f(r)$ in the metric (1) in ordinary units is given by:

$$f(r) = \left(1 - \frac{\alpha}{r}\right), \tag{9}$$

where $\alpha \equiv 2GM/c^2$ for the Schwarzschild metric, where G is the gravitational constant and M the mass of the black hole.

Let us remark that the model under consideration comes from *first principles* in the sense that we only assume a scalar distribution in a form of some kind of Bose–Einstein condensate composed of generic bosonic particles surrounding a black hole. Then, we can obtain the density of particles or the density profile that we interpreted as a galactic dark matter halo by using the so–called Thomas–Fermi approximation.

The SPARC catalog have an observing data sample of 175 galaxies from $HI/H\alpha$ studies with large range of luminosities and Hubble types.[36] Our sample consist on galaxies with large number of observational data points, preferably with observations close to the galactic center, their rotation curve is smooth, with no relevant wiggles and extended to large radii, have none or small bulge. The total rotational velocity is computed taken the values for the gas and the stars from the mass model of the SPARC catalog. The bulge and the stellar disk model is given by the catalog.

The mass model include the four main components of a galaxy: the budge (when is present), V_b, the gas disk, V_g, the stellar disk, $V_\star$, and the BEC halo, V_{bec}. The total gravitational potential of the galaxy is the sum of each component of the galaxy, thus the observed rotation velocity is,

$$V_{\text{tot}}^2 = V_g^2 + \Upsilon_b V_b^2 + \Upsilon_\star V_\star^2 + V_{\text{bec}}^2\,, \tag{10}$$

where $\Upsilon_\star$ and Υ_b are the mass-to-light ratio of the star and bulge disk, respectively. We take the mass-to-light ratio of the star, $\Upsilon_\star$, as free parameter. We assume an heuristic relation between the bulge and the stellar disk so $\Upsilon_b = 1.4\Upsilon_\star$ is assumed.[36] Is well know that the value of $\Upsilon_\star$ is model dependent which precise value rely on extinction, star formation history, IMF, among others. We ignore a priori any knowledge of the IMF and treat $\Upsilon_\star$ as an extra free parameter.

The halo model that we are proposing have four free parameters, the mass of the black hole, M, the mass parameter of the scalar field μ, the frequency of the

field, ω and the self–interaction parameter, λ. The mass of the black hole is the only galactic parameter that can change from one galaxy to another.

We assume that galaxies with a central black hole could possibly create enough gravitational potential well in order to create a condensate cloud of almost non–interactive particles that could affect the dynamics of the galaxy. In the present work, we estimate the parameters of the scalar field(–particle) from rotation curves. It is worth pointing out that this in principle is an *universal profile* extracted from a particle model in which only the astronomical parameter is the mass of the black hole, other parameters are inherent of the particle which means should be the same for all galaxies.

The density profile is simple enough in order to compute the mass as function of the radius, the integral over the volume is given by

$$M(r) = \frac{\mu}{\lambda}\left[\alpha^2\omega^2 r + \frac{1}{2}\alpha\omega^2 r^2 - \frac{1}{3}\left(\mu^2 - \omega^2\right) r^3 \right. \\ \left. -\alpha\log(r) + \alpha^3\omega^2\log(r-\alpha)\right] \tag{11}$$

This expression should be evaluated between $r_{\min}$ and $r_{\max}$. Dimensional analysis of the expression for the mass let us conclude that the r^3 term is negligible because $\mu \sim \omega$, therefore the two most relevant terms are the ones proportional to $\log r$ and r^2, that dominates at small and large radii, respectively. And because $\alpha \gg \omega$ we can approximate the mass as,

$$M(r) \approx \frac{\mu\alpha}{\lambda}\left[\frac{1}{2}\omega^2 r^2 - \log(r)\right], \tag{12}$$

from the last expression we clear see that $r_{\min}$ can be approximately computed when $M(r) = 0$, which gives $r_{\min}^2 \approx -\mathcal{W}(-\omega^2)/\omega^2$, where $\mathcal{W}$ is the Lambert function. The value of $r_{\max}$ can also be approximated when the term proportional to r^3 gets bigger to the r^2 term in equation (11), which would lead to a negative values for the mass. Thus, $r_{\max} \sim 3\alpha/2(1-\mu^2/\omega^2)$, given the bound we fix for ω, this would lead to $r_{\max} \sim \mathcal{O}(\alpha 10^{14})$. Then, the region where the Thomas–Fermi approximation is valid is given by

$$\frac{3}{2}\frac{\alpha}{1-\mu^2/\omega^2} \gtrsim r \gtrsim \frac{[-\mathcal{W}(-\omega^2)]^{1/2}}{\omega} \tag{13}$$

Notice that if we do not have observation for $r \sim \mathcal{O}(r_{\min})$ then the parameters μ, ω and λ will be degenerate for the fitting, this is, we can find any combination of $\mu\omega^2/\lambda = \text{cte}$ to valid for one galaxy. We can break the degeneracy with α because $r_{\max}$ highly depends on its value.

We assume circular rotation velocities of test particles in the plane of the galaxy and also spherical DM halos and BEC distributions. For this distribution of matter the circular velocity at radius r is given by $V_H^2(r) = GM(r)/r$. From this last expression and equation (12) we see that in the case of the BEC at large radii the velocity grows as $v \propto r^{1/2}$. Our objective is to test the realization of the BEC model,

equation (11), through rotation curves of a sample of high-resolution galaxies. Form Fig. 1 notice that we may have no presence of BEC at the center of the galaxy (i.e. for $r < r_{\min}$), which make sense if we have a central super-massive object as a black hole. Thus, this profile is neither core or cuspy, we may call it null central profile. The extension of the condensate reaches up to $r_{\max}$, which is a finite value close to the observational limit of the galaxy.

Let us now do an analysis of the equations in order to found bounds to the parameters. The frequency ω is particularly important because the region where the Tomas–Fermi approximation is valid is given by the condition $V_{\text{eff}}(r) = \omega^2/c^2$. The region $r_{\max} > r > r_{\min}$ where the condensate could form is given by the roots of the polynomial $(\mu^2 - \omega^2)r^4 - \alpha\mu^2 r^3 - \alpha r + \alpha^2 = 0$. The extreme case where $\omega \to \mu$ gives a region where $r_{\max} \to \infty$. The closer the value of ω is to μ the larger the potential well of the condensate. For instance, assuming a black hole of $M = 10^{13}\mathrm{M}_\odot$ and $\mu = \mu_{\max}$, if ω is just 10% less than μ then $r_{\max} \sim 4$ pc, which will make the model not testable for currents observations. However, if the percentile difference is of the order $\mathcal{O}(10^{-4})$ then $r_{\max} \sim 50$ kpc, enough extension for a Milky Way galaxy size. If we assume that all galaxies are surrounded for a dark matter halo then the frequency parameter is the most constrained of all four parameters.

The maximum radius at which the approximation is valid, at least the maximum observed radius, also depends on the value of ω, the smaller the value of ω the smaller is the region. We find out that if $1 - \mu/\omega < 10^{-5}$ the maximum radius is of the order of $r_{\max} \sim \mathcal{O}(10)$ kpc. Therefore we fix the value of ω such that $1 - \mu/\omega = 10^{-7}$ in order to make sure that the maximum observed galaxy rotation curve is well inside the region where the Thomas–Fermi approximation is valid.

A special case is to compute the maximum value of the mass parameter $\mu_{\max}$, which is defined when $V_{\text{eff}}(r_\wedge) = \mu^2_{\max}$ at the radius $r_\wedge$, from this condition we obtain that $\mu^2_{\max} = f(r_\wedge)/r^2_\wedge$. Using the equation of the corresponding V_{eff} is quite to easy to compute that $f(r_\wedge) = 1/3$. Therefor $r_\wedge = 3GM/c^2$. For instance, for a black hole of $M_{\text{bh}} = 10^{13}\mathrm{M}_\odot$, the radii where the potential is maximum is $r_\wedge \sim 1.4$ pc. Is important to notice that the maximum value of $\mu_{\max}$ is given only in terms of the mass of the black hole.

We take the ansatz $V_{\text{eff}}(r_\vee) = 0.95\,\mu^2_{\min}$ in order to compute $\mu_{\min}$, which range (0.7 – 0.85) $\mu_{\max}$. Taking $V_{\text{eff}}(r_\vee) = \mu^2_{\min}$ makes no physical sense because there will be no potential well where the condensate could form.

The scattering length (or the self–interacting parameter λ) acts as a weight parameter, this should be or the order of $\mathcal{O}(10^{-70})$ 1/m to fit current observational velocities. The smaller the value of λ the higher velocities we can compute, this will also mean that the scalar field is behaving almost as an ideal condensate. Heuristically speaking, we found that the bounds should be the order of $10^{-50} > \lambda[\mathrm{m}^{-1}] > 10^{-90}$.

We use the observed rotation curve, stellar, and gas component as an input for the numerical code, in order to obtain the properties of the BEC. When fitting

Eq. (10) to the observed rotation curves, we apply a non-linear least-squares method to perform the fit, minimizing the residual sum of the χ^2-test. The χ^2-goodness-of-fit test, that tell us how close are the theoretical to the observed values. In general the χ^2-test statistics is of the form:

$$\chi^2 = \sum_{i=1}^{n} \left(\frac{V_{\mathrm{obs}_i} - V_{\mathrm{model}_i}(r, \rho_0, r_s, r_c)}{\sigma_i} \right)^2 , \tag{14}$$

where σ is the standard deviation, and n is the number of observations. Comparison of the fits derived can tell us which of the DM models is preferred. More important are the differences between the reduced $\chi^2_{\mathrm{red}} = \chi^2/(n-p-1)$ values, where n is the number of observations and p is the number of fitted parameters. The uncertainties in the rotation velocity are reflected in the uncertainties in the model parameters.

Table 1. Numerical fits for the BEC model by using the SPARC data base. For each Galaxy we reported the values of: Υ relation total mass-to-light ratio on luminosity, the reduced χ^2 in terms of the degree of freedom for the BEC model χ^2/dof, which correspond to 3 and 4 dof, respectively. The small χ^2 values are mainly due to the large data error bars. $\log_{10} M_{\mathrm{BH}}/M_\odot$ is the mass of the black hole given in solar units $M_{BH} = 10^x M_\odot$. The free parameters for the BEC model are: λ and μ. The last column is the $\ln B$ factor in comparison with the NFW model.

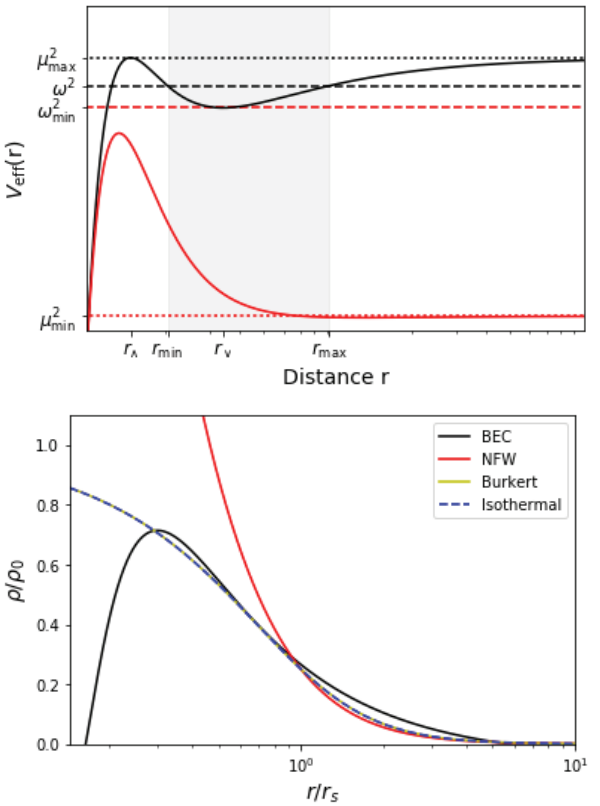

Fig. 1. *Up:* Plot of the potential $V_{\rm eff}$, Eq. (6). Solid lines are two examples for different values of mass parameter μ, the black lines is given $\mu_{\rm max} = V_{\rm eff}(r_\wedge))$ and the red line is given $\mu_{\rm min}$. The ω parameter defines the the region where the Thomas-Fermi approximation is valid, $r_{\rm max} > r > r_{\rm min}$ and could take the value $\omega_{\rm max}(=\mu_{\rm max}) > \omega > \omega_{\rm min}(= V_{\rm eff}(r_\vee))$. *Down:* Plot of the profile density of BEC (solid black), NFW (solid red), Burkert (solid yellow) and isothermal (dashed blue).

3. Discussion

According to the results summarized in the present work, it seems to be that the interpretation of dark matter as some kind of BEC is, in fact, a good model to describe the kinematics of the galaxy rotation curves. Even more, we have shown that the corresponding Thomas–Fermi approximation can give insights in a simple way that match with the observations of rotation curves in galaxies. From the simple analysis, we notice that density is proportional $\rho \propto r^{-1}$ for all radii, in contrast with most DM profiles that behave as $\rho \propto r^{-3}$ at large radii. The mass of the BEC behaves as $m_{\rm bec} \propto r^2$, and therefore $v_{\rm bec} \propto r^{1/2}$, this coincides with NFW in the limit $r \ll r_{\rm max}$ where $v_{\rm nfw} \propto r^{1/2}$, with $r_{\rm max} \sim 2.163 r_s$.

We have obtained an average $\mu = 5.43 \pm 2.24$ pc^{-1} which corresponds to an average boson mass of $M_\Phi = (3.47 \pm 1.43) \times 10^{-23}$ eV. Previous analysis has found

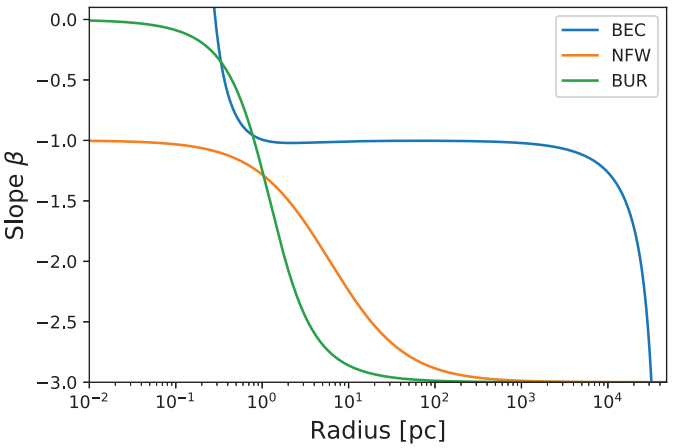

Fig. 2. The slope for different profiles. For BEC (blue line) notice that the density is bounded between some $r_{\min}$ and $r_{\max}$, in this region the slope is almost constant with value $\beta = -1$. For NFW (orange line) we notice its cuspy behavior close to the galactic centre and then dilutes as $\rho \propto r^{-3}$, while core profiles as Burkert (green line) reach constant value in the centre $\beta = 0$ and $\rho \propto r^{-3}$ at large radii.

masses for ultralight dark matter (see[42] for a compilation of results), which constrain the mass of the boson in the order of 10^{-22} eV. Notice that the latter result agrees with the one obtained in the present work. For the self–interacting parameter we get the values $\log_{10}(\lambda\ [\mathrm{pc}^{-1}]) = -91.09 \pm 0.74$. In other words, the halo viewed as a Bose–Einstein condensate can be interpreted almost as an ideal condensate of some generic bosons, which also agree with the results reported in.[26,27]

Thus, the corresponding mass of the black holes at the galaxy centre is given by $\log_{10} M/M_{\odot} = 11.08 \pm 0.43$. This kind of scenarios, e.g Abell 85 and Holm 15A, has been reported in[43,44] with a core that host supermassive black holes of mass 10^9–10^{11} $M_{\odot}$. Although recent observation of supermassive black holes in galaxies supports our fitting for the mass of the black hole, we could also think of the possibility that the black hole may not be the only option to trap the boson cloud. In future works, we could use a weak field approximation to also include the mass of stars, bulge, and gas in the center of the galaxy, even more, the self-gravitating effect of the bosonic halo or the effects caused by the rotation of the halo as a contribution to the gravitational potential and therefore reduce the contribution of the black hole as the only source of the potential. Indeed, the BEC model on average fits quite well and is not a bad fitting at all given the simplicity of the model is something that must be taken into account. The above results are sumarized in Table (1).

The BEC model in the Thomas–Fermi approximation is strong enough as the NFW model to describe galaxy rotation curves. More important, we cannot ignore that the BEC model comes from first principles and that makes use the Thomas–Fermi approximation and assume that is only a compact central object that conden-

sates the relativistic bosonic cloud. This model can be extended and generalized to include bulge and central stars contribution that may diminish the mass of the central black hole, or the–self gravitating nature of the halo and also with rotation (and maybe charged). The good fitting of the BEC model using galaxy rotation curves may be indicating that the nature of dark matter may be close to be unveiled.

The fit in this model helps us to set physical bounds to the parameters of the Bose–Einstein dark matter approach. These bounds can be used to extend the analysis in bigger samples of galaxies. Finally, more general scenarios can be taken into account in order to study the corresponding rotation curves, for instance, in charged and rotating black holes spacetimes and perhaps as discrimination criteria of the nature of supermassive black holes. Even more, we are able to extend also the analysis reported in the present manuscript in order to study the eventual relation between dark matter and the so–called boson stars from the Bose–Einstein condensation point of view, in the relativistic and non–relativistic regime.[39–41]

We constructed a new all-sky Compton parameter map (y-map) of the thermal Sunyaev-Zel'dovich (tSZ) effect by applying the MILCA component separation algorithm to the 100 to 857 GHz frequency channel maps from the Planck data release 4. The Planck team performed several improvements for the new channel maps in terms of noises and systematics, and it allowed us to produce a new y-map with reduced noises by $\sim$7% and minimal survey strips compared to the previous version released in 2015. We computed the tSZ angular power spectrum of the new y-map and performed a cosmological analysis. The results showed $S_8 = 0.764\,^{+0.015}_{-0.018}\,(stat)\,^{+0.031}_{-0.016}\,(sys)$, including systematic uncertainties from a hydrostatic mass bias and pressure profile model. The value is fully consistent with recent KiDS and DES weak-lensing observations. It is also consistent with the Planck CMB's result within 2σ, while our result is slightly lower.

Keywords: Clusters; intracluster medium; large-scale structure of Universe; cosmic background radiation

1. S_8 tension

The current standard cosmological model called the Λ cold dark matter (ΛCDM) model, mainly consisting of dark energy and dark matter, provides a wonderful fit to many cosmological data. However, a slight discrepancy was found in the latest data analyses between the CMB anisotropies ($z \sim 1100$) and other low-redshift ($z \sim 0-1$) cosmological probes for the $S_8(\equiv \sigma_8(\Omega_m/0.3)^{0.5})$ cosmological parameter representing the amplitude of the structure growth in the Universe. For example, the S_8 value was precisely measured to be $S_8 = 0.830 \pm 0.013$ with the Planck CMB observation.[1] However, a lower value of $S_8 \sim 0.77 \pm 0.03$ was measured using the population of galaxy clusters detected by Planck at low redshift ($z < 0.6$),[2,3] thus called "S_8 tension". Furthermore, other low-redshift observations with gravitational lensing by the Kilo-Degree Survey[4] (KiDS) and the Dark Energy Survey[5,6] (DES) experiments also found lower S_8 values. These results indicate that the cosmic structure growth is slower than the prediction based on the CMB measurement and may demand modifications to the standard cosmological model to explain all these measurements.

We use the thermal Sunyaev Zel'dovish (tSZ) effect to investigate the value of the S_8 parameter. The tSZ signals provide independent constraints on cosmological parameters. In particular, it is sensitive to the normalization of the matter

power spectrum, commonly parameterized by σ_8, and to the total matter density, Ω_m. It is also sensitive to other cosmological parameters, e.g., the baryon density parameter Ω_b, the Hubble constant H_0, and the primordial spectral index n_s. However, these variations are small relative to those of Ω_m and σ_8.[7] Thus, in our analysis, we varied only Ω_m and σ_8, and other cosmological parameters were fixed to the fiducial values obtained from the Planck CMB measurements.[1]

2. New all-sky tSZ map

The tSZ signal is subdominant relative to the CMB and other foreground emissions in the Planck bands. Thus a tailored component separation algorithm is required to reconstruct the tSZ map. We adopted the MILCA (Modified Internal Linear Combination Algorithm)[8] used for the Planck y-map reconstruction in 2015 and applied it to the 100 to 857 GHz frequency channel maps from the Planck data release 4 (PR4).

The Planck PR4 data implemented several improvements from the previous version: the usage of foreground polarization priors during the calibration stage to break scanning-induced degeneracies, the correction of bandpass mismatch at all frequencies, and the inclusion of 8% of data collected during repointing maneuvers, etc. These improvements allowed us to produce a new y-map with reduced noises by ∼7% and minimal survey strips than the previous version released in 2015 (Fig. 1).

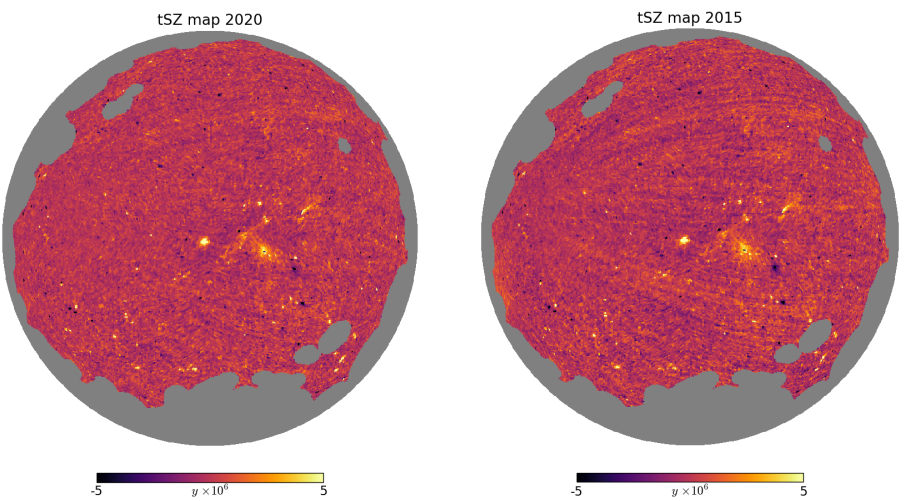

Fig. 1. MILCA all-sky Compton y parameter maps reconstructed in this work (*left*) and 2015[9] (*right*) in orthographic projections. The pixel resolution is changed from Nside = 2048 to Nside = 128 for visualization purposes.

3. Cosmological analysis and result

For our cosmological analyses, we also reconstructed two y-maps from the first and last halves of the data for a cosmological analysis. We considered a cross-angular power spectrum between these y-maps to avoid the bias induced by the noise in the auto-angular power spectrum. This tSZ cross-power spectrum is affected by residual foreground emissions from radio and IR point sources and CIB emission. Thus we fitted our measurement with the cosmology-dependent tSZ model, including the radio and IR point source models[10] and the CIB model[11] (*left* panel in Fig. 2).

The cosmological analysis of the tSZ cross-power spectrum allowed us to set constraints on cosmological parameters, mainly of the S_8 parameter. We obtained $S_8 = 0.764\,^{+0.015}_{-0.018}$. Our obtained S_8 value is fully consistent with recent weak lensing results from KiDS and DES. It is also consistent with the Planck CMB's result[1] within 2σ, while it is slightly lower by $\sim 1.7\sigma$ (*right* panel in Fig. 2).

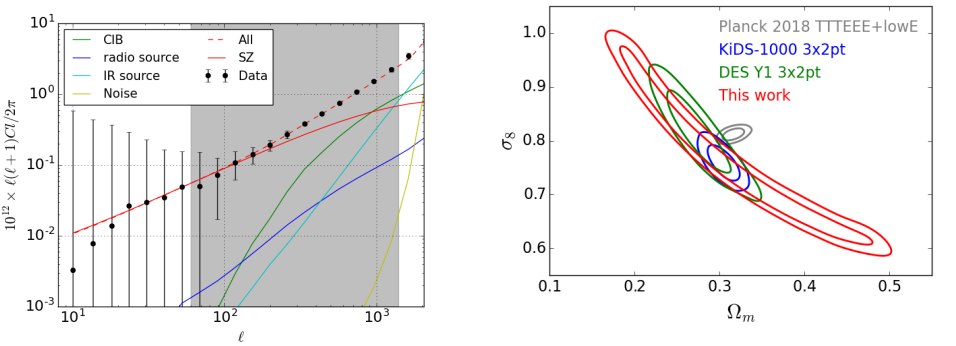

Fig. 2. *Left*: Cross-power spectrum (black) fitted with the tSZ (red), foreground models, and fiducial model of instrumental noise. The considered foregrounds are CIB (green), radio sources (blue), infrared sources (cyan) and noise (yellow). The sum of the tSZ and foreground models is shown in red dashed line. *Right*: Posterior distribution of the cosmological parameters, σ_8 and Ω_m, with 68% and 95% confidence interval contours obtained from our cosmological analysis. It is compared with the Planck CMB's (gray), KiDS-1000 3x2pt (blue), and DES Y1 3x2pt results (green).

4. Systematic effects in the cosmological analysis

Finally, we considered systematic uncertainties in our cosmological analysis introduced by the mass bias and the pressure profile model. First, we consider a systematic uncertainty from the mass bias. To investigate its impact on our cosmological analysis, we replaced our fiducial mass bias (CCCP:[12] $1-b = 0.780 \pm 0.092$) prior with two other mass bias models from WtG[13] ($1-b = 0.688 \pm 0.072$) and BIFFI[14] ($1-b = 0.877 \pm 0.015$). The left panel in Fig. 3 shows their comparison in σ_8 and Ω_m. The result shows that the S_8 value increases as the mass bias increases

(or $1-b$ decrease). This systematic uncertainty may cause a $\sim 1\sigma$ shift in the S_8 parameter from our fiducial value.

In addition, the pressure profile model may affect the cosmological analysis with the tSZ power spectrum. To investigate its impact on our cosmological analysis, we replaced the pressure profile model (P13[15]) with two other models from A10[16] and PACT21[17] . The right panel in Fig. 3 shows their comparison in σ_8 and Ω_m. The PACT21 model reduces the S_8 discrepancy between the Planck CMB and our tSZ results by $\sim 1\sigma$ relative to our fiducial model. It may imply that the discrepancy can be further reconciled or amplified by a better understanding of baryonic physics in galaxy clusters.

In conclusion, we included these systematic uncertainties and obtained $S_8 = 0.764\,^{+0.015}_{-0.018}\,(stat)\,^{+0.031}_{-0.016}\,(sys)$.

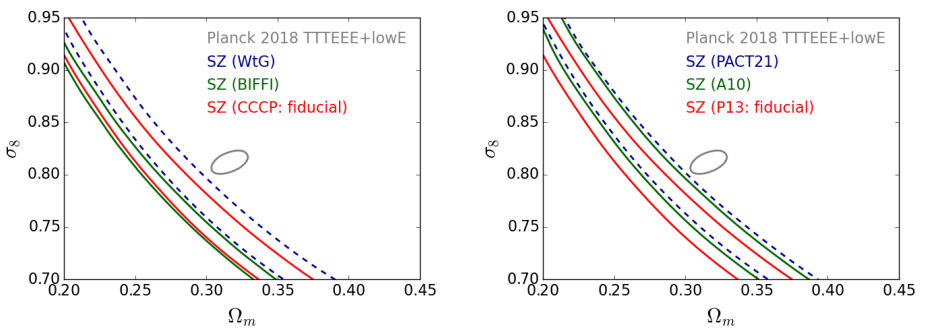

Fig. 3. *Left*: Posterior distribution of the cosmological parameters, σ_8 and Ω_m, with 68% confidence interval contours obtained from the Planck CMB analysis in gray and our tSZ analysis with three different mass bias priors. Our fiducial model of CCCP is shown in red. It is compared with the WtG model in blue and BIFFI model in green. *Right*: Posterior distribution of the cosmological parameters, σ_8 and Ω_m, with 68% confidence interval contours obtained from the Planck CMB analysis in gray and our tSZ analysis with three different pressure profile models. Our fiducial model of PA13 is shown in red. It is compared with the PACT21 model in blue and A10 model in green.

The CMB dipole: Eppur si muove

R. M. Sullivan* and D. Scott

Physics and Astronomy, University of British Columbia, Vancouver, BC, Canada

** E-mail: rsullivan@phas.ubc.ca*

www.ubc.ca

The largest temperature anisotropy in the cosmic microwave background (CMB) is the dipole. The simplest interpretation of the dipole is that it is due to our motion with respect to the rest frame of the CMB. As well as creating the ℓ=1 mode of the CMB sky, this motion affects all astrophysical observations by modulating and aberrating sources across the sky. It can be seen in galaxy clustering, and in principle its time derivative through a dipole-shaped acceleration pattern in quasar positions. Additionally, the dipole modulates the CMB temperature anisotropies with the same frequency dependence as the thermal Sunyaev-Zeldovich (tSZ) effect and so these modulated CMB anisotropies can be extracted from the tSZ maps produced by *Planck*. Unfortunately this measurement cannot determine if the dipole is due to our motion, but it does provide an independent measure of the dipole and a validation of the y maps. This measurement, and a description of the first-order terms of the CMB dipole, are outlined here.

Keywords: Cosmic Microwave Background; Cosmic Microwave Background dipole; Special relativity; Thermal Sunyaev-Zeldovich effect.

1. The CMB Sky from *Planck*

Planck[a] was a space-based telescope that measured the microwave sky in nine wavebands, allowing it to capture not only the cosmic microwave background (CMB) but also several Galactic and extragalactic foreground components. This is most clearly seen in figure 51 from Ref. 1, which shows the various wavebands of the *Planck* satellite and the frequency spectra of the foreground signals across those bands. One signal of interest to this study is the thermal Sunyaev-Zeldovich (tSZ) effect, which produces so-called y-type distortion signals. This comes from CMB photons being inverse-Compton scattered, mostly through hot galaxy clusters, which makes holes (or lowers the flux) at low frequencies and up-scatters (or makes an excess flux) at high frequencies. This signal allows us to construct a novel and independent measure of the CMB dipole because temperature anisotropies stemming from the CMB dipole contaminate the y maps. It can also be used as a valuable test of the quality of the y maps. We will start in Sec. 2 by setting out relevant notation for

[a] *Planck* (`http://www.esa.int/Planck`) is a project of the European Space Agency (ESA) with instruments provided by two scientific consortia funded by ESA member states and led by Principal Investigators from France and Italy, telescope reflectors provided through a collaboration between ESA and a scientific consortium led and funded by Denmark, and additional contributions from NASA (USA).

the unboosted CMB sky. Next, in Sec. 3 we will boost the CMB sky, and explore the relevant terms that arise from that boost in the subsections. Of particular relevance, in Sec. 3.3 we will discuss our measurement of the dipole modulation terms that mix with the tSZ effect. We will finish in Sec. 4 with a short discussion and conclusion regarding our work.

2. The Unboosted CMB Sky

To derive the connection between the y map and the dipole we will begin by defining some useful terms regarding the unboosted CMB sky:

$$x \equiv \frac{h\nu}{k_{\rm B}T}; \tag{1}$$

$$I \equiv \frac{2k_{\rm B}^3T^3}{h^2c^2}\frac{x^3}{e^x-1}; \tag{2}$$

$$f(x) \equiv \frac{xe^x}{e^x-1}; \tag{3}$$

$$Y(x) \equiv x\frac{e^x+1}{e^x-1} - 4. \tag{4}$$

These are the dimensionless frequency, the standard Planck blackbody intensity function, the frequency dependence of the CMB anisotropies and the relative frequency dependence of the tSZ effect or y type distortions, respectively. Thus, to first order the anisotropies of intensity measured by *Planck* can be written as

$$\frac{\delta I(\hat{\mathbf{n}})}{If(x)} = \frac{\delta T(\hat{\mathbf{n}})}{T_{\rm CMB}} + y(\hat{\mathbf{n}})Y(x), \tag{5}$$

where $\hat{\mathbf{n}}$ is the line of sight direction on the sky and we have only considered the temperature anisotropies and the y signals here.

3. The Boosted CMB Sky

If we apply a boost to Eq. 5, with a dimensionless velocity $\boldsymbol{\beta}$, we find

$$\begin{aligned}\frac{\delta I'(\hat{\mathbf{n}}')}{If(x)} = {} & \beta\mu + \frac{\delta T(\hat{\mathbf{n}}')}{T_{\rm CMB}}(1+3\beta\mu) \\ & + Y(x)\left(y(\hat{\mathbf{n}}')(1+3\beta\mu) + \beta\mu\frac{\delta T(\hat{\mathbf{n}}')}{T_{\rm CMB}}\right) \\ & + \beta\mu y(\hat{\mathbf{n}}')\left(Y^2(x) - x\frac{dY(x)}{dx}\right) + \mathcal{O}(\beta^2),\end{aligned} \tag{6}$$

where $\mu = \cos(\theta)$, and θ is the angle between the boost $\boldsymbol{\beta}$ and the line of sight $\hat{\mathbf{n}}'$. The first line has the same frequency dependence as thermal fluctuations and so appear in typical CMB temperature anisotropy maps. Crucially for our analysis, the middle line has the same frequency dependence as y-type distortions and thus describes the signals in the y map. The final line has more obscure frequency dependence and is

not discussed here. Additionally, the direction of the incoming photons will change from $\hat{\mathbf{n}}$ to $\hat{\mathbf{n}}'$, where $\hat{\mathbf{n}}' = \hat{\mathbf{n}} - \nabla(\hat{\mathbf{n}} \cdot \beta)$; this deflection of the photons by $\nabla(\hat{\mathbf{n}} \cdot \beta)$ is due to aberration, an effect that is not unique to the microwave sky and occurs for all astronomical observations. We will now discuss each of these terms in turn.

3.1. *The CMB dipole: $\beta\mu$*

In the first line of Eq. 6, the term $\beta\mu$ describes the pure CMB dipole, as discussed previously. This mainly (or perhaps entirely) comes from our local motion with respect to the CMB rest frame and it has been previously measured in Refs. 2, 3, and 4, and most recently in Refs. 5, 6, and 7. Taking the large dipole as being solely caused by our motion, the velocity is $v = (369.82 \pm 0.11)\,\mathrm{km\,s^{-1}}$ in the direction $(l, b) = (264.^{\circ}021 \pm 0.^{\circ}011, 48.^{\circ}253 \pm 0.^{\circ}005)$[5] and can be easily seen in the CMB frequency maps, such as in Fig. 1.

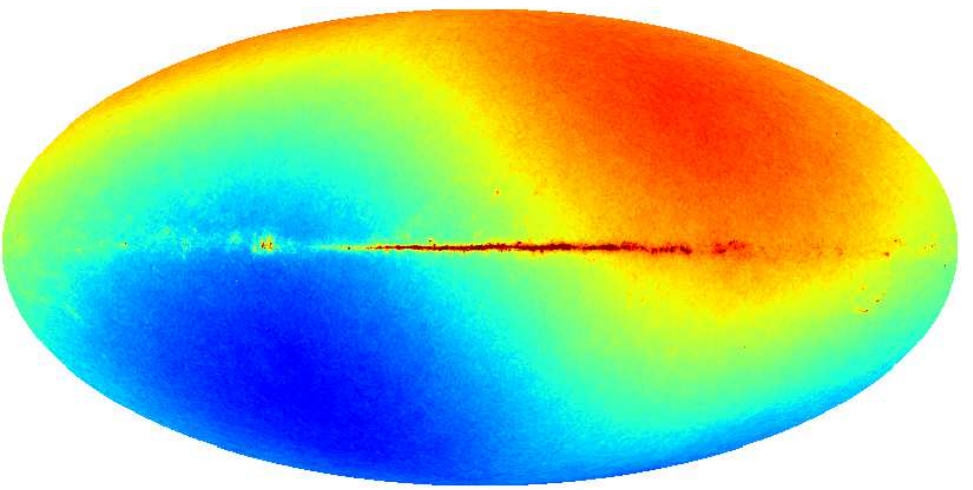

Fig. 1. *Planck* 100-GHz channel map from the NPIPE (PR4) data release,[8] showing the dominant $\ell = 1$ mode or dipole across the sky. The temperature difference across the sky here is 3.36 mK.

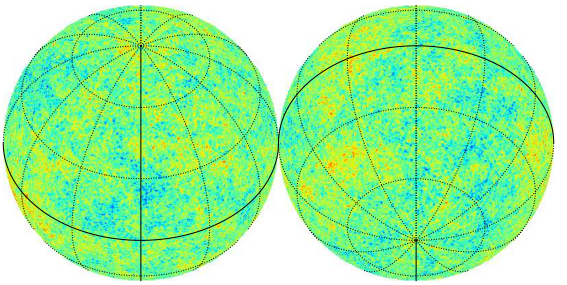
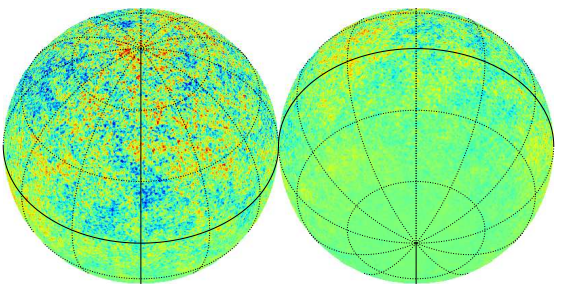
3.2. *Aberration and modulation of the CMB anisotropies: $(1 + 3\beta\mu)\delta T(\hat{\mathbf{n}}')/T_{\mathrm{CMB}}$*

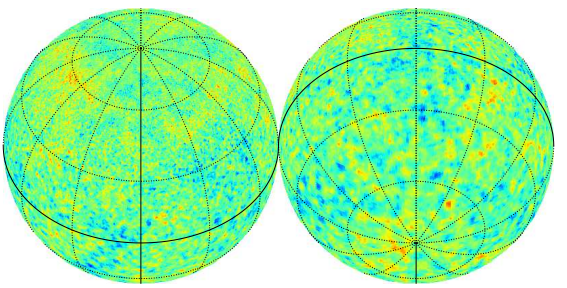
The second term in the first line of Eq. 6 is the dipole aberration and modulation of the temperature anisotropies of the CMB. The modulation causes the temperature anisotropies to be brighter in the forwards direction, and dimmer in the reverse direction. The aberration causes the anisotropies to be more condensed in the forwards direction, and more stretched out in the reverse direction (effectively the same as $\ell = 1$ lensing). These two effects can be seen in Fig. 2. This effect was first measured in Ref. 9 to about $4\,\sigma$.



(a) The unboosted CMB sky.



(b) The modulated CMB sky.



(c) The aberrated CMB sky.

Fig. 2. Here the CMB sky is shown unboosted in (a), with a modulation from a boost of 90 % the speed of light in (b), and with aberration from a boost of 90 % of the speed of light in (c). In the case of modulation, the anisotropies are more intense in the forward direction and less so in the reverse direction, whereas the aberration condenses the anisotropies in the forwards direction and causes them to be more spread out in the reverse direction.

3.3. *Temperature modulation and the tSZ effect:* $Y(x)\beta\mu\delta T(\hat{\mathbf{n}}')/T_{\rm CMB}$

The second line of Eq. 6 shows the dipole-generated signals in the y maps produced by *Planck*. The first half is the same modulation and aberration terms as were seen

in the temperature anisotropies; however, the final term is due to the second-order expansion of the intensity about $T_{\rm CMB}$ and adds a contribution to the y maps from the temperature anisotropies.

We can look for this signal by cross-correlating a template map, derived from the CMB temperature data, with a y map. To this end, we use the so-called `2D-ILC` CMB temperature map which was produced by the "Constrained ILC" component-separation method designed by Ref. 10 to explicitly null out the contribution from the y-type spectral distortions in the CMB map. We also use the `SMICA-NOSZ` temperature map, similarly produced with the express intent of removing the y-type spectral distortions, and which was generated for the *Planck* 2018 data release.[11] Likewise, we use the corresponding `2D-ILC` y map, and the *Planck* `MILCA` y map, which explicitly null out the contributions from a (differential) blackbody spectral distribution in the y map.[12,13] If we multiply our CMB map with $\beta\mu$ and cross-correlate that with our tSZ map, then we can directly probe the dipole modulation.

In Ref. 9 a quadratic estimator was used to determine the dipole aberration and modulation, in essence using the auto-correlation of the CMB fluctuation temperature maps. In this work we use the fact that we know the true CMB fluctuations with excellent precision and therefore know the signal that should be present in the y map. Thus, we fully exploit the angular dependence of the modulation signal and remove much of the cosmic variance that would be present in the auto-correlation. In order to implement this idea we define three templates, B_i (with $i = 1, 2, 3$) as

$$B_i(\hat{\mathbf{n}}) = \beta\hat{\mathbf{n}} \cdot \hat{\mathbf{m}}_i \, \frac{\delta T}{T_0}(\hat{\mathbf{n}}), \tag{7}$$

where $\beta = v/c^5$ is 1.23357×10^{-3} and $\hat{\mathbf{m}}_1, \hat{\mathbf{m}}_2, \hat{\mathbf{m}}_3$ are the CMB dipole direction, an orthogonal direction in the Galactic plane, and the third remaining orthogonal direction (see Fig. 3). Due to the presence of the CMB dipole, the signal B_1 should be present in the y map and so we can directly cross-correlate B_1 with our y map to pull out the signal. Likewise, the cross-correlation of B_2 and B_3 with our y map should give results consistent with noise.

Our y simulations are generated by first computing the power spectra of our data y maps; specifically we apply the `MASTER` method using the `NaMASTER` routine[14] to account for the applied mask.[15] Then we generate y maps using this power-spectrum with the `HEALPix`[16] routine `synfast`. We finally apply a Gaussian smoothing of $5'$ to model the telescope beam. For each analysis method we estimate the amplitude of the dipole ($\hat{\beta}_i$) in each of the three orthogonal directions. We apply the same analysis procedure on a suite of 1000 y simulations, generated with and without the dipolar modulation term.

We use two methods of cross-correlation: the first is performed directly in map-space; and the second is performed in harmonic space. For both methods we first apply our mask to the templates B_i and the y map.

In the map-space method we then locate all peaks (i.e., local maxima or minima) of the template map B_i and select a patch of radius $2\overset{\circ}{.}0$ around each peak. For every

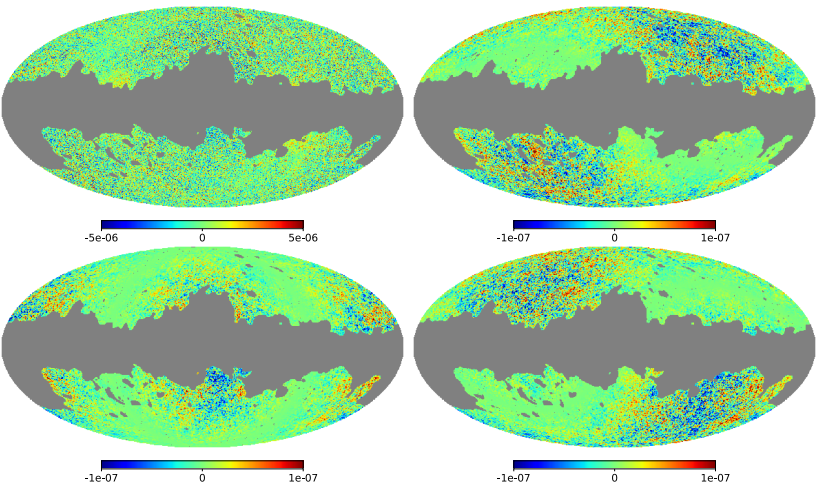


Fig. 3. Map of the tSZ effect from the `MILCA` component-separation method in y-map units (top left) and the expected modulated CMB signal (top right) generated using the `SMICA-NOSZ` CMB map in units of T_0. The bottom left and right panels are the CMB anisotropies modulated in orthogonal directions to the CMB dipole. Note that the map of the tSZ effect (top left) has a different scale bar when compared to the other three (i.e., the modulation signal is about 50 times weaker).

peak we obtain an estimate of $\hat{\beta}_i$ through the simple operation

$$\hat{\beta}_{i,p} = \beta \frac{\sum_{k\in D(p)} B_{i,k} y_k}{\sum_{k\in D(p)} B_{i,k}^2}, \tag{8}$$

where $D(p)$ is the collection of all *unmasked* pixels in a $2\overset{\circ}{.}0$ radius centred on pixel p, and p is the position of a peak. Equation 8 is simply a cross-correlation in map space and by itself offers a highly noisy (and largely unbiased) estimate. We then combine all individual peak estimates with a set of weights (w_p) to give our full estimate:

$$\hat{\beta}_i = \frac{\sum_p w_{i,p} \hat{\beta}_{i,p}}{\sum_p w_{i,p}}. \tag{9}$$

We choose w_p to be proportional to the square of the dipole, and use weights that are proportional to the square of the Laplacian at the peak;[17] this favours sharply defined peaks over shallow ones. Finally we account for the scan strategy of the *Planck* mission by weighting by the 217-GHz hits map,[18] denoted H_p^{217}. The weights are then explicitly

$$w_{i,p} = |\hat{\mathbf{n}} \cdot \hat{\mathbf{m}}_i|_p^2 \left(\nabla^2 (B_i)\big|_p \right)^2 H_p^{217}. \tag{10}$$

We apply the method for each of our simulated y maps, in exactly the same way as for the data.

Under the assumption that the y map contains the template (B_i), the y multipoles are Gaussian random numbers with mean and variance given by

$$s^i_{\ell m} = \int d\Omega\, \beta\, \hat{\mathbf{m}}_i \cdot \hat{\mathbf{n}}\, \frac{\delta T}{T_0} M(\Omega) Y^*_{\ell m}, \tag{11}$$

$$\sigma^2_\ell = C^y_\ell + N^y_\ell, \tag{12}$$

respectively, where $M(\Omega)$ is the mask over the sphere, $Y_{\ell m}$ are the spherical harmonics, and the $\hat{\mathbf{m}}_i$ are as defined in Eq. 7. We can obtain an estimate of β_i by taking the cross-correlation with inverse-variance weighting. Our estimator is therefore

$$\hat{\beta}_i = \beta \sum_{i'} \left[\sum_{\ell m}^{\ell_{\max}} s^i_{\ell m} (s^{i'}_{\ell m})^* / \sigma^2_\ell \right]^{-1} \sum_{\ell m}^{\ell_{\max}} s^{i'}_{\ell m} (y_{\ell m})^* / \sigma^2_\ell. \tag{13}$$

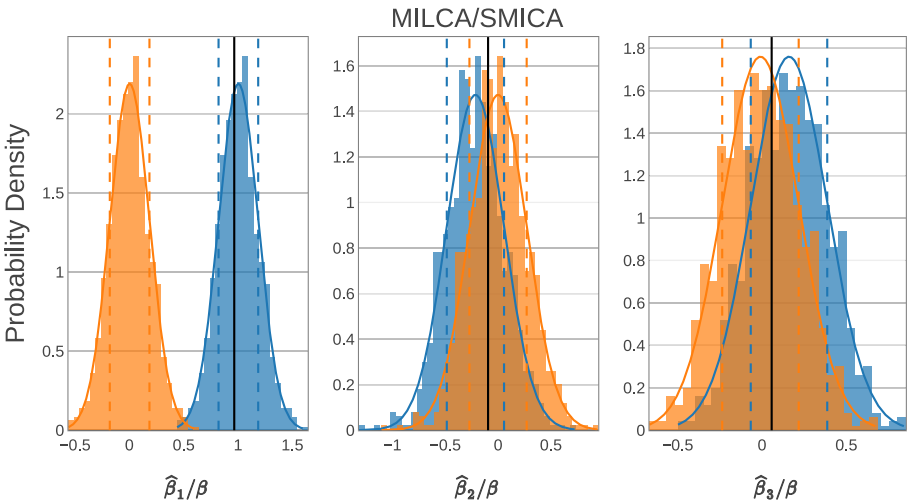

Fig. 4. Histograms of $\hat{\beta}_i/\beta$ values (with 1, 2, and 3 corresponding to the CMB dipole direction, the Galactic plane, and a third orthogonal direction) using the map-space analysis for `MILCA` y maps, and for CMB template maps `SMICA-NOSZ`. Blue histograms are simulations with the dipolar modulation term, while orange histograms are simulations without modulation. Black vertical lines denote the values of the real data, demonstrating that they are much more consistent with the existence of the dipolar modulation term than without it. Dashed lines show the 68 % regions for a Gaussian fit to the histograms. To see the full results with all data analysis combinations see Ref. 19.

First we compare the consistency of the data with our two sets of simulations (with and without the dipole term). This comparisons shown in Figs. 4 and 5 have blue histograms being the simulations *with* the dipole term and orange histograms being *without*. The data (black line) for `2D-ILC` and `MILCA` can clearly be seen to be consistent with the simulations with the dipole term. Further details and analysis may be found in Ref. 19.

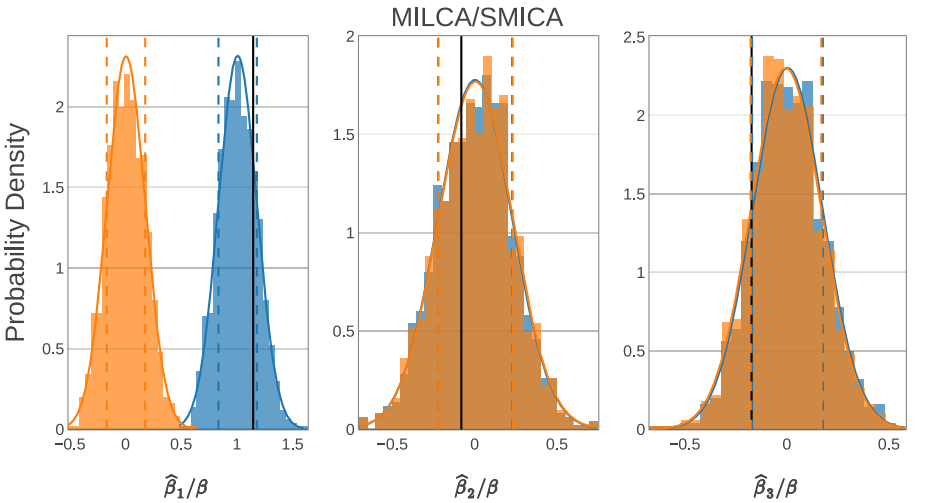

Fig. 5. As in Fig. 4, except now for the harmonic-space analysis.

4. Conclusion: Distinguishing Intrinsic and Extrinsic CMB Dipoles

The frequency-dependent part of the dipolar-modulation signal is agnostic to the source of the large CMB dipole. Therefore, its measurement is an independent determination of the CMB dipole. While it may be tempting to use this signal to distinguish an intrinsic dipole, it has been shown that an intrinsic dipole and a dipole induced by a velocity boost would in fact have the same dipolar-modulation signature on the sky.[20,21]

Due to the existence of the CMB dipole, a tSZ map necessarily contains a contaminating signal that is simply the dipole modulation of the CMB anisotropies. This occurs because CMB experiments do not directly measure temperature anisotropies, but instead measure intensity variations that are conventionally converted to temperature variations. This contamination adds power to the tSZ map in a Y_{20} pattern, with its axis parallel to the dipole direction. We have measured this effect and determined a statistically independent value of the CMB dipole, which is consistent with direct measurements of the dipole. Using a conservative multipole cut on the y map, the significance of the detection of the dipole modulation signal is around 5 or $6\,\sigma$, depending on the precise choice of data set and analysis method.

The question as to whether an intrinsic dipole could ever be observationally distinguished from an extrinsic dipole (i.e. a Doppler boost) remains an open question. The terms discussed in Eq. 6 are based on the assumption of a CMB blackbody spectrum and cannot be used to distinguish the two, as they would naturally arise whether the CMB dipole is caused by a boost, or if there is for some other reason a dipole on the sky with the same magnitude and direction.

Acknowledgements

We would like to acknowledge the support of the Natural Sciences and Engineering Research Council of Canada. Some of the results in this paper have been derived using the `HEALPix` package. Results are based on observations obtained with Planck (http://www.esa.int/Planck), an ESA science mission with instruments and contributions directly funded by ESA Member States, NASA, and Canada. The MIllimeter Sardinia radio Telescope Receiver based on Array of Lumped elements kids, MISTRAL, is a millimetric ($\simeq 90GHz$) multipixel camera being built for the Sardinia Radio Telescope. It is going to be a facility instrument and will sample the sky with 12 arcsec angular resolution, 4 arcmin field of view, through 408 Kinetic Inductance Detectors (KIDs). The construction and the beginning of commissioning is planned to be in 2022. MISTRAL will allow the scientific community to propose a wide variety of scientific cases including protoplanetary discs study, star forming regions, galaxies radial profiles, and high angular resolution measurements of the Sunyaev Zel'dovich (SZ) effect with the investigation of the morphology of galaxy cluster and the search for the Cosmic Web.

Keywords: Millimetric astronomy, large radio telescopes, Sunyaev Zel'dovich effect

1. Introduction

High angular resolution millimetric observation are key to understand a wide variety of scientific cases. Among others, the interaction of Cosmic Microwave Background (CMB) photons with the hot electron gas in galaxy clusters and surrounding medium (the Sunyaev Zel'dovich, SZ effect) promises to study galaxy clusters and their deviation from relaxed behaviour. This include high angular resolution measurements of the SZ effect with the investigation of the morphology of galaxy cluster and the search for the Cosmic Web. Also, protoplanetary discs study, star forming regions, and galaxies radial profiles are among the important scientific cases one could achieve with high angular resolution millimetric observation.

Only a handful of instruments are capable of measuring, for instance, galaxy clusters with high enough angular resolution to resolve them. Among them, we mention

MUSTANG2 at the Green Bank Telescope (GBT[a]) and NIKA2 at IRAM telescope[b]. MUSTANG2[1] is a millimetric cryogenic camera installed at the 100m GBT. It is operating in the frequency range between 75GHz and 105GHz and samples 4 arcmin f.o.v. in the sky with 223 microstrip-coupled Transition Edge Sensors (TESs). The resulted diffraction limited angular resolution is of the order of 9 arcsec. A frequency domain multiplexing technique is used to read MUSTANG2 detectors through flux-ramp modulation technique.

Another receiver which addresses similar science goals, although it takes data at higher frequencies, is NIKA2.[2–4] NIKA2 is a 2 channel millimetric camera measuring at 150GHz (one array) and 260GHz (two arrays). It observes from the 30m IRAM telescope with a field of view (f.o.v.) of 6.5 arcmin while the angular resolution is around 18 arcsec at 150GHz and around 10 arcsec at 260GHz. NIKA2 hosts 3 arrays of Kinetic Inductance Detectors (KIDs), each of around 2000 pixels, cooled down at 100mK with a dilution refrigerator. Both MUSTANG2 and NIKA2 are very active in the field of millimetric astronomy especially for the high angular resolution detection of the SZ effect.

A third instrument being prepared for such scientific cases is the MIllimeter Sardinia radio Telescope Receiver based on Array of Lumped elements kids, MISTRAL, to be fielded at the 64m Sardinia Radio Telescope (SRT[c]). MISTRAL will use an array of 408 KIDs with a f.o.v. of 4 arcmin and an angular resolution of around 12 arcsec. It is a cryogenic instrument with detectors cooled down at 270mK and with frequency domain multiplexing, ROACH2 based read-out.

2. Sardinia Radio Telescope and its upgrade

2.1. *Sardinia Radio Telescope*

The Sardinia Radio Telescope (SRT - Lat. 39.4930 N; -Long. 9.2451 E), is a Gregorian configured fully steerable 64m primary mirror radio telescope which can work from 300MHz and 116GHz[5] (see Fig. 1). It is a multipurpose instrument operated in either single dish or Very Long Baseline Interferometer mode and managed by the Italian Astrophysics National Institute (INAF). The telescope manufacturing started in 2003 and was completed in August 2012 when the technical commissioning started. The scientific exploitation of the SRT started on 2016 with an Early Science Program, while regular proposals started in 2018.

SRT has a f/0.33 primary focus and f/2.34 secondary focus allowing to host the low frequency receivers ($\nu < 2GHz$) in the primary focus, and high frequency receivers in the Gregorian room. The 64-m primary mirror (M1) is composed of 1008 electromechanically controlled aluminum elements by actuators. The secondary mirror (M2) is a 7.9m mirror composed of 49 aluminum elements adjustable for focus

[c] http://www.srt.inaf.it/

Fig. 1. The 64-m Sardinia Radio Telescope (image credits F. Guidi).

operations. Both M1 and M2 are shaped to minimize spillover and the standing waves between the receiver and the subreflector.[5]

2.2. *Observational site*

The location of the SRT is in the island of Sardinia, ≃50km north of Cagliari, at 600m a.s.l.. It is a region suited for radio-observations and the telescope was designed to be operating up to 116GHz. Estimation of sky opacity, based on recorded dedicated radiometer data, reports[d] an opacity $\tau < 0.15Np$ (50th percentile) at 93GHz during the winter nights. The average precipitable water vapour (PWV) in the same conditions is mainly 8mm. For comparison, the GBT reports $\tau < 0.125$ (50th percentile) at 86GHz, and an average $PWV < 9mm$ (50th percentile)[e]. The above estimation is confirmed by radiosondes profiles taken at Cagliari airport and scaled for the SRT site. This shown $PWV < 11mm$ (50th precentile) and opacities $< 0.2Np$ (50th percentile) at 100GHz.[6]

2.3. *PON upgrade*

In 2018, a National Operational Program (PON) grant was assigned to INAF with the aim to exploit to the full the SRT capability to reach mm wavelenghts up to 116GHz.[7] One of the Working Packages includes a metrological system to measure

[d] `http://hdl.handle.net/20.500.12386/28787`
[e] `https://www.gb.nrao.edu/mustang/wx.shtml`

with high precision deformations of the SRT due to gravitational and thermal effects; by means of the active surface it will be possible to correct the deformations of the main mirror allowing the surface roughness needed for observations up to 116 GHz. Also, the metrological system will allow high precision pointing measuring and correcting the subreflector displacement from the optical axis together with the deformation of the whole structure.

In addition an upgrade of the SRT receiver fleet is foreseen including an extension to higher frequencies up to 116GHz, thus exploiting to the full its optical surface. This grant was divided in 9 working packages which include new receivers like a 19 feeds, double polarization Q-band heterodyne receiver, a triple band (K, Q, W) coherent receiver, a 16 double polarization W-band heterodyne receiver, and a W-band, total power, 408 pixels bolometric[f] receiver: MISTRAL.

3. MISTRAL

3.1. *Introduction*

MISTRAL is a facility instrument to be installed at the SRT in 2022. It operates in an atmospheric window in the frequency range 78-103GHz, namely W-band, that is interesting for a number of scientific reasons, and most importantly it provides low optical depth and allows high efficiency observations. It will be installed in the Gregorian room of the SRT and as such, it needs to meet several requirements and limitations. These include:

- 250kg maximum weight;
- 700mm x 700mm x 2400mm (h) maximum occupation. In addition, the top part should not interfere with the Gregorian room structure;
- adeguate Radio Frequency shielding;
- ability to work from 30° elevation to 80° and the need not to be damaged in the range 0-90° elevation;
- long ($\simeq$100m) long helium lines for the Pulse Tube head-compressor connection;
- remote operations;
- MISTRAL will be installed on the Gregorian room turret (a rotating structure which hosts MISTRAL an all other receivers) and needs to be agile enough to be inserted in the SRT focus or removed through rotation of the turret itself (see Fig. 2).

[f] Actually MISTRAL will implement Kinetic Inductance Detectors which are not properly bolometers.

3.2. *Cryostat*

MISTRAL consists of a cryostat, being constructed by QMC instruments[g], with a Pulse Tube cryocooler, an He-10 sorption refrigerator, custom optics and detectors. We use a Sumitomo[h] RP-182B2S-F100H Pulse Tube (PT) cryocooler. From Sumitomo user manuals, PT heads work properly in vertical position with inclination no larger than +/-20°. In order to have the PT heads as close as possible to vertical position during observations, we have positioned the head with an inclination of 57.5° with respect to the focal plane. This allows a nominal observation elevation of 37.5-77.5°. Nevertheless, we have tested higher inclinations and there is no impact on the cryogenics with inclination of +/-25° (resulting in elevation range of 32.5-82.5°) with no degradation of the thermal performance. MISTRAL has a $40K$ shield, a $4.2K$ shield and a sub-Kelvin stage. The PT is used to cool down the $40K$ and $4.2K$ shields and provides a cooling power of $36W$ for the $40K$ shield and $1.5W$ for the $4.2K$ shield.

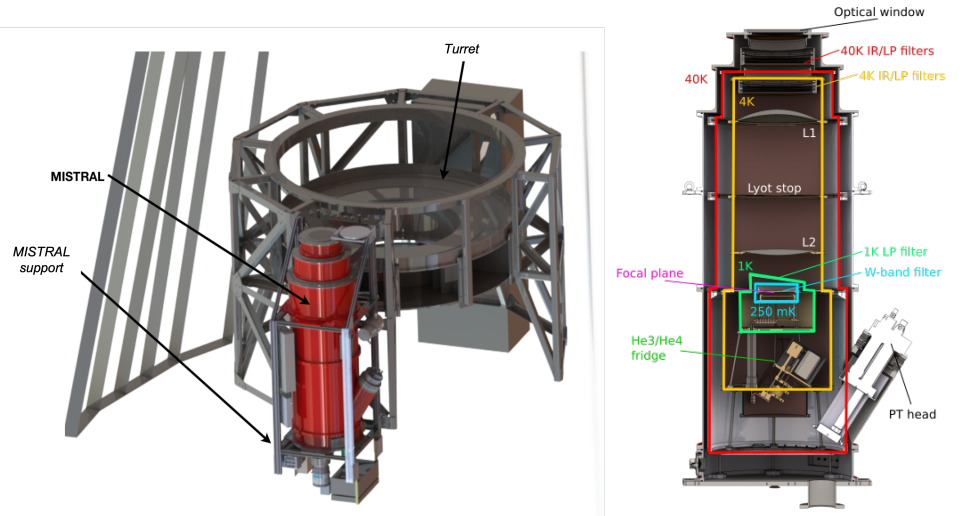

Fig. 2. Left: SRT Turret. with MISTRAL installed. Right: a cut of MISTRAL cryostat highlighting the main parts.

The PT head is controlled by a PT compressor which cannot be inclined with the telescope elevation angle. For this reason, MISTRAL compressor will not be located at the Gregorian room, but rather in a compressor room at the base of the radio telescope, that can rotate with the azimuth angle but does not change inclination with the elevation angle. This requires about 100m of flexible lines for the

[g] http://www.terahertz.co.uk/qmc-instruments-ltd
[h] https://www.shicryogenics.com/

compressor-to-PT head connection. Sumitomo (as well as other companies) report 20m maximum length for this operations so on-site tests were performed in order to verify if a PT can keep the $4.2K$ base temperature and with which dissipated power.[8] We made these tests using a Sumitomo RP-082B2S cryocooler, which is similar to the one chosen for MISTRAL but with lower cooling power (i.e. $0.9W$ at $4.2K$). It was shown that this cryocooler was able to hold a base temperature of $4.2K$ with a power load of 0.6W with $119m$ of flexible lines. Since the power dissipation requirement for MISTRAL is of the order of $0.6W$, the $1.5W$ PT will be able to satisfy the requirement with some margin. In addition, a vibration dumper, and a remote PT valve, will allow to reduce vibration into the detectors.

Attached to the $40K$ and the $4.2K$ stages, it will be applied radiation shields as well as radiation filters allowing to block thermal input of the sub-K stages of MISTRAL. The sub-K fridge is a Chase[i] He^3/He^4 sorption refrigerator (Twin GL10 sorption fridge) allowing a nominal cooling power as in the following table:

Stage	temperature no load	temperature loaded	Load applied
He^4	$0.840K$	$0.913K$	$150\mu W$
He^3	$0.299K$	$0.332K$	$30\mu W$
Ultra cold He^3	$0.195K$	$0.251K$	$20\mu W$

The total room to be cooled down is of the order of $1.5m^3$ and the total weight of MISTRAL is around $250kg$. The top part of the cryostat has been shaped in such a way it does not interfere with the Gregorian room walls while rotating in and out of the focus position (see Fig. 2).

3.3. *Optics and quasi-optics*

The optical design of MISTRAL includes a set of radiation quasi-optical filters, anchored at the different thermal stages of the cryostat, an Anti Reflection Coated (ARC) Ultra High Molecular Weight (UHMW) polyetilene window, and two ARC Silicon lenses able to image the Gregorian Focus on the array of detectors. Detectors are coupled to radiation through open space (filled array) so cryogenic cold stop, placed in between the two lenses, is needed.

Quasi-optical filters are a combination of metal mesh filters, thin IR filters, sub-mm low pass filters (LPE), and a final 78-103GHz Band pass filter produced at QMC instruments[j]. The final configuration still needs to be settled down as it depends on cryogenic tests and performance that still need to be carried on. Nevertheless, the filter chain will include:

- $300K$: ARC UHMW window of 190mm outer diameter, plus two blocking thermal filters;

[i] `https://www.chasecryogenics.com/`

[j] `http://www.terahertz.co.uk/qmc-instruments-ltd`

- $40K$: two additional thermal filters plus a Low Pass Edge filter;
- $4K$: two more thermal filters (IR5 and IR6) and another Low Pass filter;
- $1K$: Low Pass filters;
- 0.350 K: Low Pass filters;
- 0.250 K: Band Pass Filter centered at 90GHz with a bandwidth either of 30GHz or of 20GHz (to be defined).

Some characteristics of the SRT optical configuration (which were adopted to make the SRT suitable for a wide range of applications) limit the Diffraction Limited Field Of View (DLFOV) usable by the mm camera. As mentioned, we plan to implement a naked Kinetic Inductance Detectors (KIDs) array (a filled array) optically coupled to the antenna by a relay optics. This is the preferred solution for satisfying the following requirements:

- to possibly rescale the Gregorian telescope focal plane;
- to insert a cold aperture stop;
- to provide a gaussian wavelength independent beam telescope configuration;
- to provide a telecentric optics.

The first requirement allow us to tune the size of the KID array preserving the telescope DLFOV. The second condition allows us to introduce an aperture conjugated to the secondary mirror, reduces the spillover contribution due to subreflector and/or primary mirror, ensuring the highest edge taper in a cold aperture. The third condition enables a magnification of the relay optics and the output beam waist location wavelength-independent, at least inside the expected bandwidth, which is a considerable innovation point. The fourth requirement ensures a homogeneous illumination of the array, apart from a possible aberrations impact, suitable for the solution of a naked array maintaining an adequate Strehl Ratio.

Silicon is a suitable material for lens fabrication at millimetri wavelenghts due to its high dielectric constant, low loss tangent, and high thermal conductivities. The two Silicon lenses allow to report 4 arcmin of the SRT focus onto the array of 408 KIDs. They are anti-reflection coated with Rogers RO3003. Their diameter is 290mm and 240mm respectively while the aperture cold stop diameter of 125mm. All the lenses+cold stop system is kept at 4K. The in band average simulations report excellent values with a Strehl Ratio from 0.97 to 0.91 for on-axis and F. O. V. edge positions. Analogously, the FWHM is 12.2 arcsec on axis, and 12.7 arcsec at 45mm off axis.

3.4. *Detectors*

MISTRAL will take advantage of the high sensitivity and the capability of Frequency Domain Multiplexing of KIDs cryogenic detectors. KIDs are superconductive detectors where millimetric radiation with higher energy with respect to the Cooper pair binding energy, can break Cooper pairs producing a change in the pop-

ulation densities and thus in the kinetic inductance. In fact, the inductance L of a thin superconductor is dominated by the kinetic inductance L_k, which depends on the Cooper pair density.

If we integrate this inductance into a resonating RLC circuit, with a well defined resonant frequency, we will see a change in the impedance of the circuit when the inductance is illuminated. This change in impedance can be measured by exciting the circuit with an RF tone at the resonant frequency and monitoring both amplitude and phase of the outcoming tone. The amplitude, and similarly the phase, will change because of the variation in L_k. The general effect is that a decrease in the Cooper pair density increases L_k, thus it lowers the resonant frequency. Furthermore, the increase of the quasi-particle density increases the internal dissipations, thus reducing the quality factor of the resonator. KIDs are intrinsically easy to multiplex in the frequency domain because an array of resonators with different resonant frequencies can be simultaneously readout by sending a comb of Radio Frequency (RF) tones through a single feed-line.

MISTRAL KIDs are Ti-Al bilayer 10 + 30 nm with critical temperature Tc=945mK and are fabricated at CNR-IFN[k].[9,10] They are front-illuminated 3rd order Hilbert crude absorber with backshort on the opposite side of the wafer. The detector array is composed of 408 KIDs detectors. They are 3mm x 3mm each and are arranged on an equilateral triangle every 4.2mm on a 4 inches silicon wafer (see Fig. 3). They sample the focal plane with a FWHM angular spacing of 10.6 arcsec lower the each pixel angular resolution.

As mentioned, KIDs behave as high quality factor, Q, LC resonators. High values of Q allow to multiplex thousands of KIDs, with different frequencies, all coupled to the same feedline. KIDs are in fact intrinsically easy to multiplex in the frequency domain, because an array of resonators with different resonant frequencies can be simultaneously readout by sending a comb of RF tones through a single feed-line. We will use ROACH2 based Frequency Domain Multiplexing which was originally developed for the OLIMPO experiment.[11]

3.5. *Magnetic shield*

Another important part of MISTRAL is a 1-mm thick Cryoperm 10 μ-metal shield, characterized by an high magnetic permeability ($\mu > 7000$), that acts as a shielding from spurious magnetic fields such as the geomagnetic field. When a KID, usually composed of a thin wire, is exposed to an external magnetic field, a shielding current will be induced. Consequentially, its kinetic inductance changes. The external magnetic field will increase the kinetic inductance of the circuit, thus increasing the total inductance, eventually reducing the quality factor of the resonator. This effect was observed on the MISTRAL detector array[13] and required a magnetic shield to be lower than the earth magnetic shield.

[k] `https://www.roma.ifn.cnr.it/`

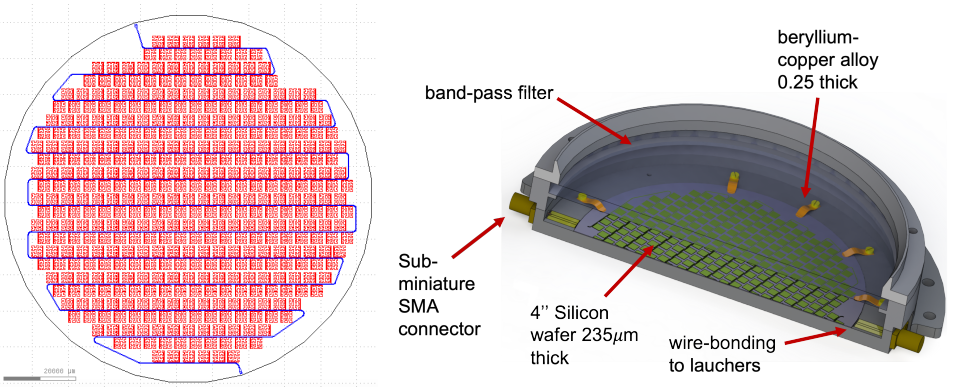

Fig. 3. Left: a design of the focal plane of MISTRAL with its feedline.[12] Right: KIDs holder with the surrounding components.

4. Sensitivity forecast and scanning strategy

4.1. *Noise estimate*

A crucial step to predict the performance on the sky is estimating the expected noise which should affect our detectors. Electrical Noise Equivalent Power (NEP) should be compared with Photon noise NEP due to warm optics and atmosphere emission. The latter, should be considered in its emission part and turbulence part which will act as correlated noise.

Electrical NEP of MISTRAL detectors was measured to be temperature dependent. If we assume a final detectors temperature of 270mK we have average values of our test-bed array of detectors of $NEP_{avg} = 3.5 \times 10^{-16} W/\sqrt{Hz}$ with a maximum and a minimum range of $NEP_{max} = 7.4 \times 10^{-16} W/\sqrt{Hz}$ and $NEP_{min} = 1.6 \times 10^{-16} W/\sqrt{Hz}$ respectively. These numbers need to be compared with estimated photon noise and turbulence noise from atmosphere. The photon noise part was estimated to be, within the 30GHz bandwidth, of $NEP_{ph} = 0.9 \times 10^{-16} W/\sqrt{Hz}$ (which converts into a Noise Equivalent Flux Density of 0.30mJy/beam). To this, in order to estimate the real sensitivity of MISTRAL, we have to add the atmospheric effects due to turbulence. An a-priori calculation of this effect is quite complicated because it also depends on the kind of filtering and on the scanning strategy: the best option would be directly measuring the atmosphere with MISTRAL. This will happen during the commissioning phase, but it is possible to give an early estimate by using experimental data taken at different frequencies. We have SRT data in the K-band (at 22GHz) and we can assume that the ratio between atmospheric fluctuations is equal to the squared ratio of the opacities. In this way, we can infer the atmospheric fluctuation noise at 90GHz using atmospheric modelling softwares such as *am*[1]. This increases the atmospheric noise estimation a factor 10 with respect to

[1] `https://www.cfa.harvard.edu/~spaine/am/`

the photon noise level even in the best 5% percentile resulting in a noise Noise Equivalent Flux Density of $3mJy/beam$. The final result is that MISTRAL detectors will be dominated by atmospheric noise rather than by electric noise, as desired.[14]

4.2. *Scanning strategy*

The final noise level of our maps will depend on the detectors sensitivity, on the atmospheric contamination but also on the scanning strategy and the filtering of the data. We can clearly clean observations very aggressively at the cost of loosing large angular scales on sky. Among the many scientific goals of MISTRAL, the possibility of retrieving large angular scales at the level of its field of view (i.e. 4 arcmin) and even more would be crucial for the study of galaxy clusters and, for instance, for the search for the Cosmic Web in close-by clusters. Scanning strategy drives also the sensitivity as we can more or less efficiently remove atmosphere emission and its fluctuations

At the SRT it is already in use an on-the-fly map scanning strategy which allows orthogonal scans in R.A./Dec or Azimuth/Elevation each composed by parallel subscans. In addition, we are working on the scanning strategy based on Lissajou daisy scanning already in use on different Telescopes such as, for instance, the GBT[m] which has the advantage to reduce to the minimum the overhead due to Telescope inversion and optimize the integration time on the center of an observed field (see Fig. 4). This kind of scanning strategy can easily be analysed with Fourier space filtering of (typically) 0.1Hz (cut-on) and 7.5Hz (cut-off frequency).

5. Science case

MISTRAL will be a facility instrument. Thus, it will be open to the scientific community to decide what kind of scientific output it can achieve and propose the observations to the Time Allocation Committee of the Sardinia Radio Telescope. Nevertheless, we will list in the following a few science cases including those that we think are the most interesting.

Protoplanetary discs millimetric measurements in star forming regions allow to break the degeneracy present in InfraRed (IR) measurements due to the optically thick nature of the hot inner disc. Measuring the SED at mm wavelengths with high angular resolution (i.e. $\simeq$ 10 arcsec) can add information to planetary formation theories.[15] Star formation in molecular clouds with high enough angular resolution allow to distinguish starless cores with respect to those hosting protostars. This is for instance what was attempted with the Large Millimeter Telescope.[n,16] Continuum resolved galaxies observations can give information about morphology and radial

profiles (gas column profiles, dust temperature profiles).[17] Spatially resolved high-z radio galaxies can provide info about cold dust re-emission.[18]

When the CMB photons scatter off a hot electron gas, for example in galaxy clusters, they undergo inverse Compton scattering which is visible in the frequency spectrum of the CMB. The resulting distorted spectrum is thus:

$$\frac{\Delta I(x)}{I_0} = y\frac{x^4 e^x}{(e^x-1)^2}\left(x\coth\frac{x}{2}-4\right) = yg(x) \tag{1}$$

where: $I_0 = \frac{2h}{c^2}\left(\frac{k_b T_{CMB}}{h}\right)^3$, T_{CMB} is the CMB temperature, $x = \frac{h\nu}{k_b T_{CMB}}$ is the adimensional frequency, and $y = \int n_e \sigma_T \frac{k_B T_e}{m_e c^2}$ is the Comptonization parameter, the integral along the line of sight dl of the electron density n_e multiplied by the electron temperature T_e (see Fig. 5). This is the Sunyaev Zel'dovich (SZ) effect[19,20] and can be used to study the physics of Galaxy clusters. In fact, galaxy clusters can experience a wide variety of situation including collisions, merging, and non-relaxed situation. In addition, not only galaxy clusters can host relativistic electrons. Hydrodynamical simulations[21,22] suggested that galaxy clusters occupy the knots of the so called Cosmic Web and Warm to Hot Intergalactic Medium (WHIM) is disposed connecting galaxy cluster forming filaments that could be seen through the SZ effect itself.

What is probably one of the most impacting expected result of MISTRAL is in fact the possibility to observe and resolve the SZ effect through galaxy clusters and surrounding medium. With respect to moderate to low angular resolution observations, high angular resolution ($\simeq$ 10 arcsec) detections can investigate non relaxed

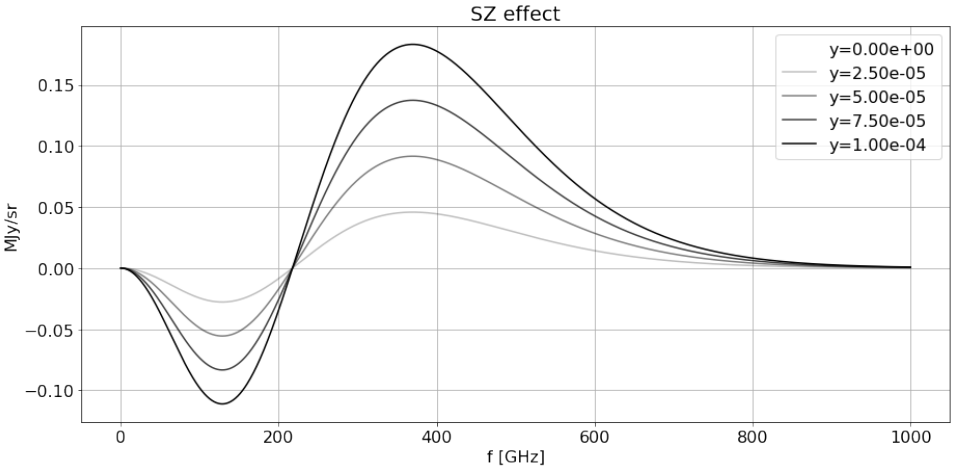

Fig. 5. The SZ effect with different Comptonization parameters.

clusters, study merging clusters, understanding the self similarities of galaxy cluster, study the pressure profiles and understand the AGN feedback expected in some environments.

Understanding the self similarities of galaxy clusters, their identical appearance or scaled properties regardless of their mass or distance is crucial. Self-similarity seems demonstrated but this is not always the case. Galaxy clusters in fact interact, collide, merge. This brings to important degeneracies and deviation from specific models. High angular resolution SZ effect measurements allow to solve the density vs temperature profile degeneracy together with X-ray information especially for high z clusters. In order to understand the physics in different environments, it is very important to study the Intra Cluster Medium (ICM) thermodynamics, including the impact of feedback, bulk and turbulent motions, substructures and cluster asphericity.

Sometimes, clusters are assumed to follow the β profile,[23] the generalized Navarro Frank and Withe (gNFW)[24] profile, or the Universal model.[25] High angular resolution SZ measurements allow to disentangle between models and to identify the most appropriate ones. Even relaxed clusters experience pressure fluctuations and compressions of the ICM. The study of pressure power spectrum allows to separate relaxed vs non-relaxed clusters where larger perturbations increase in the outer shells of the clusters (where SZ is more sensitive with respect to X-ray). Resolved SZ measurements allow to infer cluster masses from integrated Y mass (Y-M) relations. The Y-M relation is sensitive to the cluster astrophysics, radiative cooling, star formation, energy injection from stars and AGN feedback. In general, it allows to study of the pressure profiles and fluctuations of the ICM. This, again, can allow to understanding the self-similarity of galaxy clusters.

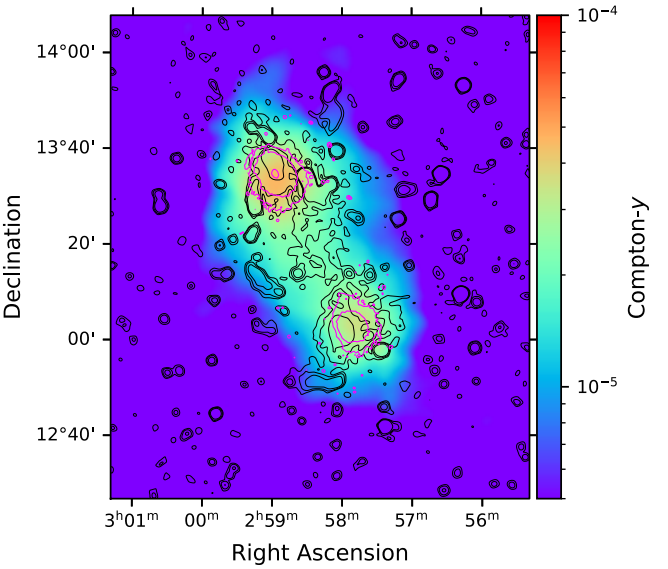

Fig. 6. Planck PR2 MILCA Compton-y map of Abell 401 (north-east) and Abell 399 (south-west). Black contour level are from the LOFAR map[26] at 0.0035, 0.008 and 0.02 Jy. Magenta contour level at 0.00008, 0.0015 and 0.001 Counts/s refer to the XMM-Newton map of the system.[27] The figure shows a good agreement between the radio and SZ signal both in the clusters and in the intracluster region, while the X-ray emission is appreciable only in correspondence with the two clusters.

In addition, point sources can be a contamination and need to be correctly subtracted not to bias the estimate of the y-parameter in a galaxy cluster. This is for instance what was achieved with MUSTANG2 at the GBT.[28]

Galaxy clusters experience hierarchical growth through mergers. Pre-mergers clusters should be connected through the Cosmic Web and simulations endorse this[21,22] (see, e.g. Figure 6). On the other hand, post mergers clusters dissipate an enormous quantity of energy with turbulence and shocks (pressure discontinuity up to mach number 3). The *Bullet* cluster or *El Gordo* are example of this unrelaxed occurrence.

The wide majority of the SZ is in fact localized towards galaxy clusters but the baryons distribution is still an open issue for modern cosmology: half of the baryons are still missing. Magneto-hydrodynamical and hydrodynamical simulations predict that they are structured in the cosmic web, filaments, and voids in the form of Warm Hot Intergalactic Medium (WHIM).[21,22] WHIM are expected to be distributed as over-desities in filamentary structures between galaxy clusters: high angular resolution SZ measurements can detect WHIM better than X-ray under low density circumstances. This is probably the most challenging and most rewarding of the achievements that an experiment like MISTRAL can achieve.

6. Conclusions

High angular resolution millimetric observation are key to understand a wide variety of scientific cases including structure formation and missing baryons issue. MISTRAL is a facility millimetric camera that will study several scientific case and that will be installed and commissioned at the Sardinia Radio Telescope during 2022. MISTRAL is going to be a unique camera: agile cryostat, 408 KIDs, optics allowing 12 arcsec resolution and a 4 arcmin f.o.v. at 90GHz. Sapienza University will do the technical commissioning, will participate to the astronomical commissioning, and will release MISTRAL to the scientific community.

Acknowledgments

The high-z submillimeter galaxies (SMGs) can be used as background sample for gravitational lensing studies thanks to their magnification bias, which can manifest itself through a non-negligible measurement of the cross-correlation function between a background and a foreground source sample with non-overlapping redshift distributions. In particular, the choice of SMGs as background sample enhances the cross-correlation signal so as to provide an alternative and independent observable for cosmological studies regarding the probing of mass distribution.

In particular the magnification bias can be exploited in order to constrain the free astrophysical parameters of a Halo Occupation Distribution model and some of the main cosmological parameters. Urged by the improvements obtained when adopting a pseudo-tomographic analysis, It has been adopted a tomographic set-up to explore not only a ΛCDM scenario, but also the possible time evolution of the dark energy density in the ω_0CDM and $\omega_0\omega_a$CDM frameworks.

Keywords: Cosmology; Gravitational lensing; Sub-millimeter galaxies.

1. Magnification bias

Magnification bias is due to the gravitational lensing effect and consists in the apparent excess in the number of high redshift sources (the lensed sources) close to the position of low redshift galaxies (the lenses). In fact, the gravitational lensing deflects the light rays of high redshift sources causing the stretching of the apparent sky area in the region affected by the lensing. This also causes a boost in the flux density of the high redshift sources, making them more likely to be detected above a given instrument flux density limit (e.g. Ref. 1). This is sketched in Fig. 1(a). The red objects in the backward plane (source plane) are the sources with flux density limit above the instrument detection limit, and thus detectable while the orange ones are those with a flux density below the instrument detection limit, and thus not detectable unless boosted by the magnification bias. The blue objects in the lens plane are the possible lenses that might cause the magnification bias effect. Finally in the observer plane, the blue objects of the lens plane will be observable together with the red objects of the source plane and some of the orange objects whose flux have been boosted. The peculiarity of such magnified orange objects is that they will be found close to some of the blue objects (their lenses).

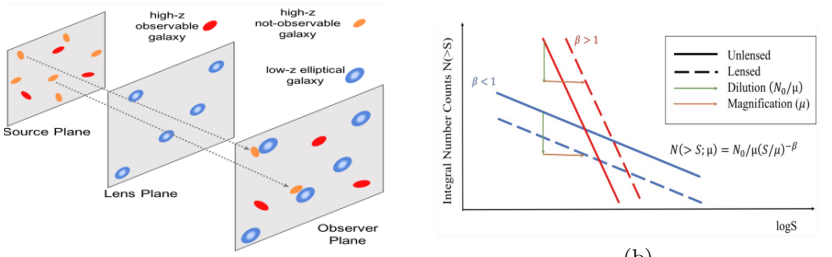

Fig. 1. Scheme of magnification bias (a) and how it affect the integral number counts of the lensed sources (b). See text for details.

On this respect, magnification bias main advantage relies on the steepness of background sources counts and on the fact that it does not require either ellipticity measurements or knowledge on the galaxies' orientation (as shear does). In particular, given that n_0 are the unlensed integrated background source number counts (number of background sources per solid angle and redshift with observed flux density larger than S in the absence of gravitational lensing):

$$n_0(>S,z) \equiv \int_S^\infty \frac{dN}{dS dz\, d\Omega} dS \tag{1}$$

the background source number counts at an angular position $\vec{\theta}$ within an image are modified by dilution and magnification following Ref. 2:

$$n(>S,z;\vec{\theta}) = \frac{1}{\mu(\vec{\theta})} n_0\left(> \frac{S}{\mu(\vec{\theta})}, z \right) \tag{2}$$

where $\mu(\vec{\theta})$ is the magnification field at angular position $\vec{\theta}$. Assuming a power-law behaviour of the unlensed integrated number counts with β the source number count steepness, i.e. $n_0(>S,z) = AS^{-\beta}$,

$$\frac{n(>S,z;\vec{\theta})}{n_0(>S,z)} = \mu^{\beta-1}(\vec{\theta}) \tag{3}$$

Depending on the value of β the source counts might increase because of lensing: Fig. 1(b) sketched the increase or decrease of the source number counts for $\beta > 1$ (in red) and $\beta < 1$ (in blue), respectively.

2. Cross-correlation

Magnification bias is usually observed by means of angular cross-correlation function (CCF) measurements between two samples of sources: how many background sources fall 'near' the position of a lens, repeated for each object in the lens sample. Since the samples are at different redshifts, the detection of a non-zero signal would be exclusively due to the gravitational lensing induced by the lenses.

2.1. *The estimator*

Thus, magnification bias can be measured through the cross-correlation between the low and high redshift objects.

The CCF of two source populations (D_f and D_b) is the fractional excess probability, relative to a random distribution (R_f and R_b), of finding a D_f source separated by an angle θ from a D_b source within an infinitesimal solid angle $d\theta$. The CCF can be computed using a modified version of the Landy & Szalay (Ref. 3) estimator (see Ref. 4):

$$\tilde{w}_{fb}(\theta) = \frac{D_f D_b(\theta) - D_f R_b(\theta) - D_b R_f(\theta) + R_f R_b(\theta)}{R_f R_b(\theta)} \tag{4}$$

In particular, $D_f D_b$, $D_f R_b$, $D_b R_f$ and $R_f R_b$ are the normalized foreground-background, foreground-Poisson, background-Poisson and Poisson-Poisson pair counts for a given angular separation θ. Given two source samples with non-overlapping redshift distributions, the excess signal when computing their cross-correlation with respect to the random case is due to the magnification bias. Being such signal related to lensing and thus to cosmological distances and the galaxy halo characteristics, it can be used to constrain cosmological and astrophysical parameters.

2.2. *The halo model*

To achieve this, the adopted theoretical description of the cross-correlation is the one by Cooray & Sheth (Ref. 5):

$$w_{fb}(\theta) = 2(\beta - 1)\int_0^\infty \frac{dz}{\chi^2(z)} n_f(z) W^{\text{lens}}(z) \int_0^\infty l \frac{dl}{2\pi} P_{\text{gal-dm}}(l/\chi^2(z), z) J_0(l\theta) \tag{5}$$

$$W^{\text{lens}}(z) = \frac{3}{2}\frac{H_0^2}{c^2}\left[\frac{E(z)}{1+z}\right]^2 \int_z^\infty dz' \frac{\chi(z)\chi(z'-z)}{\chi(z')} n_b(z') \tag{6}$$

where l is the multipole, H_0 is the Hubble constant, $E(z)$ the quantity where the contribution to the energy density are included (see section 2.3 for details), $n_b(z)$ ($n_f(z)$) is the normalized background (foreground) redshift distribution, $\chi(z)$ is the comoving distance, J_0 is the zeroth-order Bessel function of the first kind, $W^{\text{lens}}(z)$ is the lensing kernel and β is the source number count steepness, commonly fixed to 3 for submillimeter galaxies (Ref. 6 and reference therein). Therefore, the cross-correlation signal can be interpreted under the halo model parametrization (Ref. 5) considering that both galaxy samples trace the same dark matter distribution around redshift $z \sim 0.4$. This dark matter distribution is traced directly by the foreground galaxies while, in the case of the background sample, it is traced thanks to the weak lensing effect. According to this model, the galaxy distribution power spectrum is parametrized as the sum of a 2-halo term, related to the correlations between one halo traced by the foreground galaxies and another one traced by the

background sources and that therefore dominates at large scales, and a 1-halo term, that describes the correlation between sub-halos (traced by both samples) inside the same halo and therefore more important at small scales. Moreover, the halo model also suggests a simple parametrization of the cross-correlation between the galaxy and dark matter distributions (see Refs. 5,7,8). According to the halo model (Cooray & Sheth, Refs. 5):

$$P_{\text{g-dm}}(k,z) = P^{1h}_{\text{g-dm}}(k,z) + P^{2h}_{\text{g-dm}}(k,z) \tag{7}$$

$$P^{\text{1h}}_{\text{g-dm}}(k,z) = \int_0^\infty dM\, M \frac{n(M,z)}{\bar{\rho}(z)} \frac{\langle N_g \rangle_M}{\bar{n}_g(z)} |u_{\text{dm}}(k,z|M)||u_{\text{g}}(k,z|M)|^{p-1}$$

$$P^{\text{2h}}_{\text{g-dm}}(k,z) = P^{\text{lin}}(k,z)\Big[\int_0^\infty dM\, M \frac{n(M,z)}{\bar{\rho}(z)} b_1(M,z) u_{\text{dm}}(k,z|M)\Big] \cdot$$
$$\cdot \Big[\int_0^\infty dM\, n(M,z) b_1(M,z) \frac{\langle N_g \rangle_M}{\bar{n}_g(z)} u_g(k,z|M)\Big]$$

In these equations $\bar{\rho}$ is the background density, $\langle N_g \rangle_M$ the mean number of galaxies within a halo of mass M, $\bar{n}_g(z)$ the mean number density of galaxies at redshift z, p is set to 1 for central galaxies and to 2 for satellites (Ref. 5), k is the wave number, $n(M,z)$ is the Sheth & Tormen halo mass function by Ref. 9, $P^{lin}(k,z)$ is the linear matter power spectrum, $b_1(M,z)$ is the linear large-scale bias (via the peak background split), and $u_g(k,z|M)$ is the normalized Fourier transform of the galaxy density distribution within a halo, which is assumed to equal the dark matter density profile, i.e. $u_g(k,z|M) = u_{dm}(k,z|M)$. Halos are defined as overdense regions whose mean density is 200 times the mean background density of the universe according to the spherical collapse model, and the halo density profiles $\rho(r)$ adopted is the one by Ref. 10, hereafter NFW, with the concentration parameter in Ref. 11.

The halo occupation distribution (HOD) assumed is the one by Zheng et al. in Ref. 12:

$$N_{\text{cen}}(M_h) = \begin{cases} 0 & \text{if } M_h < M_{\text{min}} \\ 1 & \text{otherwise} \end{cases} \tag{8}$$

$$N_{\text{sat}}(M_h) = N_{\text{cen}}(M_h) \cdot \left(\frac{M_h}{M_1}\right)^{\alpha} \tag{9}$$

In this model, the mean number of galaxies is represented by N_{gal} where, the distinction between central and satellite galaxies is made: $N_{gal} = N_{cen} + N_{sat} = 1 + N_{sat}$. All halos above a minimum mass M_{min} host a galaxy at their centre, while any remaining galaxies are classified as satellites and are distributed in proportion to the halo mass profile (see Ref. 12). Halos host satellites when their mass exceeds the M_1 mass, and the number of satellites is a power-law function of halo mass $N_{\text{sat}}(M_h)$. These parameters define the adopted HOD.

2.3. *The barotropic index of the dark energy*

In the theoretical model, a possible redshift evolution of the dark energy (DE) can be introduced by allowing different values for the dark energy equation of state parameter, ω. For a flat cosmology, a redshift-dependent function $f(z)$ in the quantity

$$E(z) \equiv \sqrt{\Omega_r(1+z)^4 + \Omega_M(1+z)^3 + \Omega_k(1+z)^2 + \Omega_{\rm DE} f(z)} \tag{10}$$

takes into account the possible time evolution of the dark energy density, where Ω_x is the present-day density parameters for radiation r, matter (M), curvature (k) and dark energy DE. In particular, by assuming that the barotropic index of dark energy

$$\omega(z) = \omega_0 + \omega_a \frac{z}{1+z} \tag{11}$$

the dark energy density has a redshift dependence given by $\rho(z) = \rho_0 f(z)$, where

$$f(z) = (1+z)^{3(1+\omega_0+\omega_a)} e^{-3\omega_a \frac{z}{1+z}} \tag{12}$$

being ρ_0 the dark energy density at $z = 0$. As for the dark energy density parameter, it can be written as

$$\Omega_{\rm DE}(z) = \frac{\Omega_{\rm DE} f(z)}{E(z)^2} \tag{13}$$

In this framework, the ΛCDM is recovered when $\omega_0 = -1$ and $\omega_a = 0$.

3. Background and foreground samples

In order to achieve the cross-correlation measurement, a clear separation of the background and foreground sources is needed. For example, in the recent works

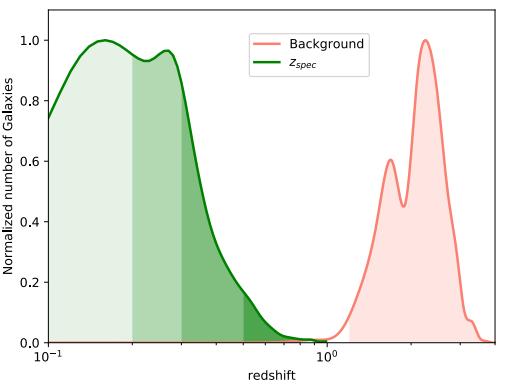

Fig. 2. Redshift distribution of background (orange) and foreground objects (green). The different shades of green indicate the bins of redshift used in Ref. 13. Credit: Bonavera et al., A&A, in press, DOI 10.1051/0004-6361/202141521, 2021, reproduced with permission © ESO.

by Bonavera et al. (Refs. 6, 13), the redshift distribution of the foreground and background galaxies sample is the one in Fig. 2 in green and orange respectively. The different shades of green indicate the bins of redshift used in Ref. 13.

As for the foreground sample, different kind of sources at relatively low redshift can be used. For example, in their recent work (Ref. 14) Bonavera et al. adopt the same sample of quasi-stellar object (QSOs) with $0.2 < z < 1.0$ as in Ref. 15. They are selected from the publicly available Sloan Digital Sky Survey (SDSS-II and SDSS-III) Baryon Oscillation Spectroscopic Survey (BOSS) catalogues. In Refs. 6, 13, 16–18 the galaxies in the Galaxy and Mass Assembly (GAMA, Ref. 19) survey with $0.2 < z < 0.8$ have been used and in Ref. 13 those with $0.1 < z < 0.8$ (see Fig. 2).

Currently the best way to measure the CCF is to choose as background samples the high-z sub-millimetre galaxies (SMGs). In fact they have steep number counts $\beta \sim 3$ (Refs. 20, 21), shown by the Herschel Space Observatory (Herschel; Ref. 22) and the South Pole Telescope (SPT; Ref. 23) observations. Such property enhances their magnification, as explained in Sect. 1. Moreover, the SMGs are faint in the optical avoiding the possibility of being confused with the foreground lens sample, which is on its turn invisible at sub-millimetre (sub-mm) wavelength (Refs. 24, 25). Finally, the redshifts of the SMGs are usually greater than $z > 1 - 1.5$, which guarantees no overlap with the foreground sample. This makes the SMGs the perfect background sample for magnification bias studies by means of CCF measurements and thus allowing the tracing of the mass density (baryonic and dark matter) and its evolution with time.

Moreover, it has been confirmed when, due to their magnification bias, Dunne et al. in Ref. 26 made a serendipitous direct observation of high-redshift SMGs. They were performing a study of gas tracers with Atacama Large Millimeter Array (ALMA) observation of galaxies by targeting a statistically complete sample of twelve galaxies selected at 250μm with z=0.35 and magnified SMGs appears around the position of half of them.

4. Recent results with SMGs magnification bias

The first attempt to measure the CCF was carried out in Ref. 27 with Herschel/SPIRE galaxies and low-z galaxies as background and foreground samples, respectively. Their results were a strong confirmation of this lensing-induced effect.

To study this possible bias, Ref. 28 relied on much better statistics and carried out a more detailed analysis by measuring the CCF with Herschel Astrophysical Terahertz Large Area Survey (H-ATLAS) high-z sources at $z > 1.5$ and two optical samples selected from SDSS (Sloan Digital Sky Survey, Ref. 27) and GAMA (Ref. 19) surveys, with redshifts $0.2 < z < 0.6$. The resulting CCF was measured with high significance, $> 10\sigma$ and using realistic simulations, they concluded that the signal was entirely explained with the magnification bias produced by the weak lensing effect caused by galaxy groups/clusters whose halo masses are in the range

of $10^{13.2} - 10^{14.5} M_{\odot}$ and that are signposted by the brightest galaxies in the optical samples. Later on, Gonazelz-Nuevo et al. in Ref. 16 and Bonavera et al. in Ref. 13 showed furthermore that the SMGs properties make them the perfect background sample for constraining the free parameters of a halo occupation distribution (HOD) model. In particular, the results by Ref. 16 suggest that the lenses are massive galaxies or clusters, with a minimum mass of $M_{min} = 10^{13} M_{\odot}$. They also carried out tomographic studies on the HOD parameters: they divided the foreground sample in four bins of redshift, $0.1 < z < 0.2$, $0.2 < z < 0.3$, $0.3 < z < 0.5$ and $0.5 < z < 0.8$. They main findings were that while M_1 is almost redshift independent, M_{min} evolves: it increases with redshift, as predicted by theoretical estimations. Bonavera et al. in Ref. 14 study with the magnification bias the mass properties of a sample of QSOs whose position signpost the lenses at $0.2 < z < 1.0$ obtaining $M_{min} = 10^{13.6^{+0.9}_{-0.4}} M_{\odot}$. This again suggests that the lensing is actually produced by halos of the size of clusters placed close to the QSOs positions.

Furthermore, magnification bias trough CCF measurements can be used to constrain the halo mass function. In particular, Cueli et al. in Ref. 18 successfully test such possibility according to two common parametrisations: the Sheth & Tormen and Tinker fits. They find general agreement with traditional values for the involved parameters, with a slight difference in the Sheth & Tormen fit for intermediate and high masses, where the results suggest a hint at a somewhat higher number of halos.

5. Cosmological studies with magnification bias

Moreover, some of the main cosmological parameters can be also estimated using the magnification bias, as in Ref. 6. They use the CCF measured between a foreground sample of GAMA galaxies with spectroscopic redshifts in the range of $0.2 < z < 0.8$ and a background sample of H-ATLAS galaxies with photometric redshifts $z > 1.2$ (as described in section 3) to constrain the astrophysical parameters (M_{min}, M_1, and α) and the Ω_M, σ_8, and H_0 cosmological ones (the matter density parameter, the present root-mean-square matter fluctuation averaged over a sphere of radius $8h^{-1}$Mpc where h is the dimensionless Hubble constant, and the Hubble density parameters). These parameters are estimated through a Markov chain Monte Carlo analysis, using the Python package `emcee` (Ref. 29). They study various cases and in particular they perform a run by setting flat priors to those in Table 1.

Table 1. Flat priors for the ΛCDM run in Ref. 6.

$\log M_{min}$	$\mathcal{U}[\ 11.6,\ 13.6]$	Ω_M	$\mathcal{U}[\ 0.1,\ 0.8]$
$\log M_1$	$\mathcal{U}[\ 13.0,\ 14.5]$	σ_8	$\mathcal{U}[\ 0.6,\ 1.2]$
α	$\mathcal{U}[\ 0.5,\ 1.37]$	h	$\mathcal{U}[\ 0.5,\ 1.0]$

Note: The HOD parameters names and flat priors are listed in the first two columns. The cosmological ones in the third and fourth columns.

They obtain a lower limit at 95% confidence level (CL) on $\Omega_M > 0.24$, a slight trend towards $H_0 > 70$ km s^{-1} Mpc^{-1} values and an upper limit at 95% CL of $\sigma_8 < 1$. Such results are summarised in the $\Omega_M - \sigma_8$ plane in Fig. 3 (a) with the dot-dashed blue line.

Given the large number of studies that can be performed with magnification bias through CCF data, a systematic analysis of possible bias that might affect the estimation have been carried out. In particular, in Ref. 17 Gonzalez-Nuevo et al. take into account different biases at cosmological scales in the source samples to carefully measure unbiased CCF. More precisely, their background sample consists of H-ATLAS galaxies with $z > 1.2$ whereas they use two independent foreground samples with $0.2 < z < 0.8$: GAMA galaxies with spectroscopic redshifts and SDSS galaxies with photometric redshifts. These independent samples allowed them to perform a pseudo-tomographic study that yields to constrain $\Omega_M = 0.50^{+0.14}_{-0.20}$ and $\sigma_8 = 0.75^{+0.07}_{-0.10}$. Such analysis also suggests that a tomographic approach might improve the results.

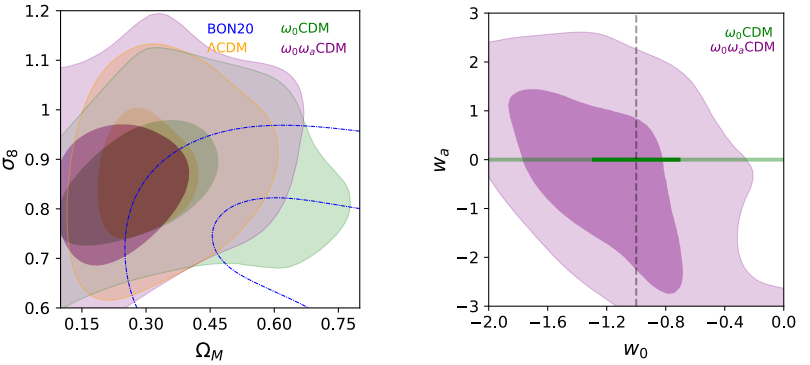
Driven by the conclusions mentioned above, Bonavera et al. in Ref. 13 adopt the unbiased sample by Gonzalez-Nuevo et al. in Ref. 17 dividing the foreground sample into four redshift bins ($0.1-0.2$, $0.2-0.3$, $0.3-0.5$ and $0.5-0.8$). The background objects are a sample of H-ATLAS galaxies with photometric redshifts $z > 1.2$. The redshift distribution are shown in Fig. 2 and the redshift bins of the foreground sample are highlighted with different shades of green. They use magnification bias in tomography to jointly constrain the astrophysical HOD parameters (M_{min}, M_1 and α) in each one of the selected redshift bins together with the Ω_M, σ_8, and H_0 cosmological ones. In particular, the analysis is carried out both in the ΛCDM scenario and with the introduction of the dark energy density related ω_0 and ω_a parameters in the ω_0CDM and $\omega_0\omega_a$CDM frameworks. The parameters priors for the three described runs are listed in Table 2.

Table 2. Flat priors for the ΛCDM, ω_0CDM and $\omega_0\omega_a$CDM models in Ref. 13.

$\log M_{min}\mathcal{U}[a_i, b_i]$	$\log M_1\mathcal{U}[c_i, d_i]$	Ω_M	$\mathcal{U}$[0.1, 0.8]
$[a_1, b_1] = \mathcal{U}[10.0, 13.0]$	$[c_1, d_1] = \mathcal{U}[12.0, 15.5]$	σ_8	$\mathcal{U}$[0.6, 1.2]
$[a_2, b_2] = \mathcal{U}[11.0, 13.0]$	$[c_2, d_2] = \mathcal{U}[12.0, 15.5]$	h	$\mathcal{U}$[0.5, 1.0]
$[a_3, b_3] = \mathcal{U}[11.5, 13.5]$	$[c_3, d_3] = \mathcal{U}[12.5, 15.5]$	ω_a	$\mathcal{U}$[-3.0, 3.0]
$[a_4, b_4] = \mathcal{U}[13.0, 15.5]$	$[c_4, d_4] = \mathcal{U}[13.0, 15.5]$	ω_0	$\mathcal{U}$[-2.0, 0.0]

Note: For the four different bins of redshift, the M_{min} flat priors are listed in the first column while the M_1 ones in the second column. The α prior is $\alpha = \mathcal{U}[\ 0.5,\ 1.37]$ in all bins. The cosmological parameters names and flat priors are in the third and fourth columns.

As for the HOD parameters, M_{min} shows a trend towards higher values at higher redshift confirming the findings in Ref. 16. For the ΛCDM model, they obtain a mean(maximum) posterior value [68% CL] of $\Omega_M = 0.33(0.26)$ [0.17,0.41]



(a) (b)

Fig. 3. Contour plot of the 2D posterior distributions with contours set to 0.393 and 0.865. (a) Ω_M and σ_8 for the non-tomographic case in Ref. 6 (dot-dashed blue line) and the tomographic runs in Ref. 13 within ΛCDM (in yellow), ω_0CDM (in green) and $\omega_0\omega_a$CDM (in purple). (b) ω_0 and ω_a for the $\omega_0\omega_a$CDM model. Credit: Bonavera et al., A&A, in press, DOI 10.1051/0004-6361/202141521, 2021, reproduced with permission © ESO.

and of σ_8= 0.87 [0.75,1], being H_0 not yet constrained. For the ω_0CDM model, they find similar results on Ω_M and σ_8 and a mean(maximum) posterior value [68% CL] of $\omega_0 = -1(-0.97)$ $[-1.56, -0.47]$. For the $\omega_0\omega_a$CDM model, $\omega_0 = -1.09(-0.92)$ $[-1.72, -0.66]$ and $\omega_a = -0.19(-0.20)$ $[-1.88, 1.48]$. These results are summarised in Tables 3 and 4, where the the mean, peak and 68%CL of the posterior distributions for the estimated cosmological parameters are given. In particular, the first column gives the parameter name, the second and third columns in Table 3 are the results for the ΛCDM model in the non-tomographic and tomographic cases, and in Table 4 are those for the ω_0CDM and $\omega_0\omega_a$CDM models in the tomographic case.

The $\Omega_M - \sigma_8$ plane is shown in Fig. 3(a) for the ΛCDM (in yellow), ω_0CDM (in green) and $\omega_0\omega_a$CDM (in purple) models. The results in the $\omega_0 - \omega_a$ plane are shown in Fig. 3(b). The ω_0 results are shown in Fig. 4 for the ω_0CDM (in green) and $\omega_0\omega_a$CDM (in purple) cases, where they are compared with other results from literature. Moreover, the tomographic analysis presented in Ref. 13 confirms that magnification bias results do not show the degeneracy found with cosmic shear measurements and that, related to dark energy, do show a trend of higher ω_0 values for lower H_0 values.

6. Conclusion

In conclusion, all these works confirm that the SMGs are a perfect background sample for magnification bias studies and serendipitous direct observation of magnified SMGs have been performed with ALMA (i.e. Ref. 26). It has been demonstrated in Ref. 28 and Ref. 16 for astrophysical studies and in Ref. 6 for cosmological ones.

Table 3. Cosmological results for the ΛCDM from Bonavera et al. in Refs. 6, 13.

	ΛCDM nontomo		ΛCDM	
	$\mu(Peak)$	$68\%CL$	$\mu(Peak)$	$68\%CL$
Ω_M	0.54(0.67)	[0.46,0.80]	0.33(0.26)	[0.17,0.41]
σ_8	0.78(0.74)	[0.63,0.85]	0.87(0.87)	[0.75,1.00]
h	0.76(-)	[0.68,1.00]	0.72(0.72)	<0.79

Note: Mean(Peak) and $68\%CL$ of the posterior distributions for the cosmological parameters (listed in the first column) estimated according to the ΛCDM model in the non-tomographic case (second and third columns) and in the tomographic one (fourth and fifth columns) models in the tomographic case. With the exception of the estimated cosmological parameters, the cosmology is fixed to the *Planck* one.

Table 4. Cosmological results for the ω_0CDM and $\omega_0\omega_a$CDM models from Bonavera et al. in Ref. 13.

	ω_0CDM		$\omega_0\omega_a$CDM	
	$\mu(Peak)$	$68\%CL$	$\mu(Peak)$	$68\%CL$
Ω_M	0.38(0.26)	[0.13,0.47]	0.34(0.21)	[0.11,0.41]
σ_8	0.87(0.85)	[0.73,0.98]	0.88(0.84)	[0.72,1.01]
h	0.70(-)	<0.75	0.70(-)	<0.76
ω_0	-1.00(-0.97)	[-1.56,-0.47]	-1.09(-0.92)	[-1.72,-0.66]
ω_a	-	-	-0.19(-0.20)	[-1.88,1.48]

Note: Mean(Peak) and $68\%CL$ of the posterior distributions for the cosmological parameters (listed in the first column) estimated according to the ω_0CDM (second and third columns) and $\omega_0\omega_a$CDM (fourth and fifth columns) models in the tomographic case. With the exception of the estimated cosmological parameters, the cosmology is fixed to the *Planck* one.

In particular magnification bias proves to be useful as an independent and additional cosmological probe for ΛCDM and beyond ΛCDM models, as done in Ref. 13.

In these works, the performance of magnification bias through CCF measurements has been compared in non-tomographic and tomographic analysis. The conclusion is that tomography improves non-tomographic studies despite the worsening in the statistics of the measured CCFs.

Moreover, the CCF can be computed adopting different foreground samples, e.g. galaxies in Ref. 6 or QSOs in Ref. 14 and the measurements are improved by taking into account observational biases correction (i.e. Ref. 17). In addition, variation of the ingredients of the models, as the HMF, might be tested with magnification bias (e.g. Ref. 18).

Up to now, the main conclusions are the fact that astrophysical results are robust for all models (ΛCDM and beyond ΛCDM) and that ΛCDM compatible

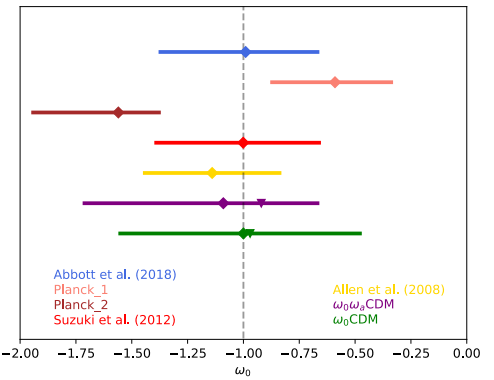


Fig. 4. Results on ω_0 within the ω_0CDM (green) and $\omega_0\omega_a$CDM (purple) models compared with those by DES (blue), Planck1 (basewwaplikHMTTlowllowEBAO, salmon), Planck2 (basewplikHMTTlowllowE, brown), Supernovae (red), x-ray measurements (yellow). Credit: Bonavera et al., A&A, in press, DOI 10.1051/0004-6361/202141521, 2021, reproduced with permission © ESO.

results have been found with tomographic and non-tomographic approaches, i.e. $\Omega_M \sim 0.33$, $\sigma_8 \sim 0.87$, $\omega_0 \sim -1$ and $\omega_a \sim -0.19$.

In the standard cosmological scenario, no circular polarization is predicted for Cosmic Microwave Background (CMB) radiation. However, in the frame of moving particle, Lorentz symmetry violation leads to circular polarization for CMB radiation. We estimate the circular polarization power spectrum $C_{Vl}^{(S)}$ in CMB radiation due to Compton scattering in the presence of the Lorentz symmetry violation. We show that the V-mode power spectrum can be obtained in terms of linear polarization power spectrum at the last scattering surface.

Keywords: Circular polarization, CMB, power spectrum

1. Introduction

Numerous valuable information could be obtained from temperature anisotropies and polarization of the CMB. In particular, tempreture anisotropy in CMB radiation could generate polarization for the CMB. The theoretical calculation predicts at the most 10% of linear polarization for the CMB known as E-mode and B-mode which is originated from Compton scattering of photons on the electron plasma at the recombination epoch. The E-mode and B-mode polarization are different polarization pattern arisen from scalar and tensor temperature anisotropy, respectively.[1–3] Besides, the standard model of cosmology peredict no circular polarization for the CMB due to Compton scattering, and circular polarization has not been measured yet. However, most recently the CLASS experiment has established tightest upper bound on angular power spectrum of the CMB at 95% confidence from $0.4\mu K^2$ to $13.5\mu K^2$ on $\ell(\ell+1)C_\ell^{VV}/(2\pi))$ at multipole moments $1 \leq \ell \leq 120$.[4] The circular polarization for the CMB is a rare process so that observation of any level of

circular polarization could be a hint for the existence of new physics. In particular, Faraday conversion could be a source of the CMB circular polarization in which linear polarized light propagates through a medium and lead to various indexes of refraction along the two transverse axes. Besides, Compton scattering of CMB from the electron in the presence of a trivial background field such as a magnetic field[5,6] or non-trivial background like Non-Commutative space-time[7,8] and Lorentz symmetry violation[6,9] will rise circular polarization for the CMB. Moreover, scattering of CMB photon from non-standard particles like vector or fermionic dark matter can lead to circular polarization of the CMB[10,11] and cosmic photons.[12]

In this study, we would like to explore the effects of Lorentz symmetry violation (LIV) as a non-trivial background on the angular power spectrum of the CMB. The energy scale for LIV is the Planck scale which is out of reach based on direct experiments. An alternative way to study such effects is the Standard Model Extension (SME) based on effective field theory approach.[13] The Lorentz violation at the SME is induced by spontaneous symmetry breaking and result in new terms including LIV parameters and can behave such as constant backgrounds. The phenomenological aspects of LIV have been widely studied in the literature which total obtained constraints are gathered at Ref.[14].

In this paper, we give a brief overview of the SME in section 2. Then the effect of LIV on the CMB polarization is given in section 3. Finally, in section 4 we give a conclusion and summary.

2. The SME

We assume the CMB photon scatter from cosmic electron while the Lorentz invariance is violated. The LIV effect is appliable by the SME. The minimal version of the SME contains all possible gauge invariant operators, made by all the SM fields and LIV is specified with new couplings.[13] The QED part of SME including charged fermion interaction with photon is defined as follows:

$$\mathcal{L}^{\rm LIV}_{\rm QED} = \frac{1}{2} i\bar{\psi}(\gamma^{\nu} + c^{\mu\nu}\gamma_{\mu}) \overleftrightarrow{D}_{\mu} \psi - \bar{\psi} m_e \psi, \tag{1}$$

where ψ is the fermion field, $\mathcal{D}_{\mu}$ shows the covariant derivative with $u \overleftrightarrow{D}_{\mu} v \equiv u D_{\mu} v - v D_{\mu} u$,[15] the mass of electron is m_e, and γ_{μ} indicates the Dirac gamma matrices and the coefficient for Lorentz symmetry violation is $c^{\mu\nu}$ in fermion sector. We assume $c^{\mu\nu}$ to be symmetric and traceless tensor. For convenience,the constraint on the SME parameters are expressed in a standard reference frame, *i.e* Sun-centered, celestial equatorial frame (SCCEF) with coordinates $\{T, X, Y, Z\}$, the coordinates of lab frame are denoted by $\{t, x, y, z\}$. Conversion to a lab frame at convenient time t is defined by[16]

$$\begin{pmatrix} \hat{x} \\ \hat{y} \\ \hat{z} \end{pmatrix} = \begin{pmatrix} \cos\chi\cos\Omega t & \cos\chi\sin\Omega t & -\sin\chi \\ -\sin\Omega t & \cos\Omega t & 0 \\ \sin\chi\cos\Omega t & \sin\chi\sin\Omega t & \cos\chi \end{pmatrix} \begin{pmatrix} \hat{X} \\ \hat{Y} \\ \hat{Z} \end{pmatrix}. \tag{2}$$

If we consider the lab frame on the earth Ω would be the earth sidereal rotation frequency equivalent to $2\pi/(23\text{h }56\text{ min})$ and $0 \leq \chi \leq \pi$. Some experimental bounds on the components of c parameter in the SCCEF frame is given in Tab 1. Therefore,

$c_{\mu\nu}$	Experimental bounds	system
c_{TT}	2×10^{-15}	Collider physics[17]
c_{YY}	3×10^{-15}	Astrophysics[18]
c_{ZZ}	5×10^{-15}	Astrophysics[18]
$c_{(XY)}$	3×10^{-15}	Astrophysics[18]
$c_{(YZ)}$	1.8×10^{-15}	Astrophysics[18]
$c_{(XZ)}$	3×10^{-15}	Astrophysics[18]
$c_{(TX)}$	-30×10^{-14}	Collider physics[17]
$c_{(TY)}$	-80×10^{-15}	Collider physics[17]
$c_{(TZ)}$	-11×10^{-13}	Collider physics[17]

we also use correlation between components of laboratory frame and SCCEF given in Ref[16] to transfer the result to SCCEF frame.

3. Effect of LIV on the CMB polarization

The theoretical aspect of polarization of the CMB photon is characterized by four Stokes parameters: $[I, Q, U, V]$[1] which can be related to component of density matrix as:

$$\rho = \frac{1}{2}\begin{pmatrix} I+Q & U-iV \\ U+iV & I-Q \end{pmatrix}, \tag{3}$$

where I indicates the total radiation intensity (temperature), Q and U indicates linear polarization and V is circular polarization of the CMB radiation which satisfy the inequality $I^2 \geq Q^2 + U^2 + V^2$. Compton scattering cannot generate circular polarization V, so in the standard model of cosmology circular polarization is not anticipated for the CMB. For an ensemble of photon which are assumed free before as well as after scattering, the time evolution for Stokes parameters will be obtained by solving the following quantum Boltzmann equation, given as[1]

$$\begin{aligned}(2\pi)^3\delta^3(0)2\,p^0\frac{d}{dt}\rho_{ij}(0,\mathbf{p}) &= i\langle[H_I^0(0),\hat{\mathcal{D}}_{ij}(\mathbf{p})]\rangle \\ &\quad -\frac{1}{2}\int_{-\infty}^{\infty}dt\langle[H_I^0(t),[H_I(0),\hat{\mathcal{D}}_{ij}(\mathbf{p})]]\rangle,\end{aligned} \tag{4}$$

where p^0 represents the energy of photon and the photon number operator is given with $\hat{\mathcal{D}}_{ij}(\mathbf{p}) = \hat{a}_i^\dagger(\mathbf{p})\hat{a}_j(\mathbf{p})$ where $\hat{a}_i^\dagger(\mathbf{p})$ and $\hat{a}_j(\mathbf{p})$ are rising and lowering operators, respectively.

In the Eq. (4), H_I^0 is an interacting Hamiltonian that includes all possible interactions at leading order. First term on the right-hand side of the above equation is known as 'forward scattering' where the incoming particles interact without exchange the momenta and this term is linearly proportional to H_I^0. The second term is called 'Damping term' and quadratically proportional to H_I^0. In the case of Compton scattering, the contribution of first term of Eq. (4) is equal to zero. Moreover, time evolution of the circular polarization is zero ($\dot{V} = 0$) for both terms of right-hand side of Eq. (4). Therefore, contribution of any new physics in polarization of photon in forward scattering would be considerable.

We obtain the Boltzmann equation for circular polarization of CMB radiation in the presence of LIV by using the Eq. (4), and reconstructing the Stokes parameters[6] as follows:

$$\begin{aligned}
&\frac{d}{d\eta}\Delta_I^{(S)} + iK\mu\Delta_I^{(S)} + 4[\dot{\psi} - iK\mu\varphi] = C_{e\gamma}^I,\\
&\frac{d}{d\eta}\Delta_P^{\pm(S)} + iK\mu\Delta_P^{\pm(S)} = C_{e\gamma}^{\pm} - i\kappa_{\rm LIV}^{\pm}\,\Delta_V^{(S)},\\
&\frac{d}{d\eta}\Delta_V^{(S)} + iK\mu\Delta_V^{(S)} = C_{e\gamma}^V + \frac{i}{2}\Big[\kappa_{\rm LIV}^{+}\,\Delta_P^{-(S)} + \kappa_{\rm LIV}^{-}\,\Delta_P^{+(S)}\Big],
\end{aligned} \tag{5}$$

where η represents conformal time. Scalar perturbation corresponding to the potential of Newton and spacial curvature perturbation are shown with ψ and ϕ. $\Delta_P^{\pm(S)} = Q^{(S)} \pm iU^{(S)}$ is a linear combination of $Q^{(S)}$ and $U^{(S)}$ polarization. The scalar product of wave vector $\mathbf{K}$ and the CMB propagating direction is given by μ. $C_{e\gamma}^I$, $C_{e\gamma}^{\pm}$ and $C_{e\gamma}^V$ represents the contribution of the SM Compton scattering in $\Delta_P^{\pm(S)}$ polarization and $\Delta_V^{(S)}$ polarization,[1] respectively. $\kappa_{\rm LIV}^{\pm}$ indicates the involvement of Compton scattering by considering fermionic part of the SME Lagrangian at Boltzmann equations (Eq. (5)) which are obtained as follows:

$$\kappa_{\rm LIV} = -a(\eta)\,\frac{3}{4}\,\frac{\sigma_T}{\alpha}\,\frac{m_e^2}{p_0}\,\frac{\bar{n}_e}{m_e},\;\; \kappa_{\rm LIV}^{\pm} = \kappa_{\rm LIV}\,c_{\{\alpha\beta\}}(\rho_Q^{\{\alpha\beta\}} \pm i\rho_U^{\{\alpha\beta\}}), \tag{6}$$

where $\rho_Q^{\{\alpha\beta\}}$ and $\rho_U^{\{\alpha\beta\}}$ are defined as:

$$\begin{aligned}
\rho_Q^{\{\alpha\beta\}} &= -\Big[\epsilon^1\cdot\hat{c}\cdot\epsilon^2 + \sum_{f=e,p}\frac{m_f v_b^2}{2k_0}(\hat{v}\cdot\epsilon^2\hat{v}\cdot\hat{c}\cdot\epsilon^1 + \hat{v}\cdot\epsilon^1\hat{v}\cdot\hat{c}\cdot\epsilon^2) - \frac{v_b}{2}(\hat{v}\cdot\epsilon^2\hat{k}\cdot\hat{c}\cdot\epsilon^1\\
&\quad + \hat{v}\cdot\epsilon^1\hat{k}\cdot\hat{c}\cdot\epsilon^2) + \sum_{f=e,p}\frac{2v_b^4 m_f^2}{k_0^2}(\hat{v}\cdot\hat{c}\cdot\hat{v}\,\hat{v}\cdot\epsilon^2\hat{v}\cdot\epsilon^1) + 2v_b^2\,\hat{k}\cdot\hat{c}\cdot\hat{k}\,\hat{v}\cdot\epsilon^1\,\hat{v}\cdot\epsilon^2\Big],\\
\rho_U^{\{\alpha\beta\}} &= \Big[\frac{1}{2}(\epsilon^1\cdot\hat{c}\cdot\epsilon^1 + \epsilon^2\cdot\hat{c}\cdot\epsilon^2) + \sum_{f=e,p}\frac{m_f v_b^2}{2k_0}(\hat{v}\cdot\epsilon^1\hat{v}\cdot\hat{c}\cdot\epsilon^1 - \hat{v}\cdot\epsilon^2\hat{v}\cdot\hat{c}\cdot\epsilon^2)\\
&\quad + \frac{v_b}{2}(\hat{v}\cdot\epsilon^2\hat{k}\cdot\hat{c}\cdot\epsilon^2 - \hat{v}\cdot\epsilon^1\hat{k}\cdot\hat{c}\cdot\epsilon^1) + \sum_{f=e,p}\frac{v_b^4 m_f^2}{2k_0^2}\hat{v}\cdot\hat{c}\cdot\hat{v}(\hat{v}\cdot\epsilon^1\hat{v}\cdot\epsilon^1\\
&\quad + \hat{v}\cdot\epsilon^2\hat{v}\cdot\epsilon^2) + \frac{v_b^2}{2}\,\hat{k}\cdot\hat{c}\cdot\hat{k}\,(\hat{v}\cdot\epsilon^1\,\hat{v}\cdot\epsilon^1 + \hat{v}\cdot\epsilon^2\,\hat{v}\cdot\epsilon^2)\Big],
\end{aligned} \tag{7}$$

here $\alpha, \beta = 0, i, j$ represent time-like and space-like LIV components of coefficient c. The direction of bulk velocity of electrons is shown by $\hat{v}$. It is convenient, to describe the statistical properties of CMB radiation via spherical harmonic. Then the Stokes parameter could be expanded over suitable multipole moment in spin weighted basis[2,3]

$$\Delta^{(S)}_{I,P,V}(\eta, \mathbf{K}, \mu) = \sum_{l=0}^{\infty}(2l+1)(-i)^l \Delta^l_{I,P,V}(\eta, \mathbf{K}) P_l(\mu), \tag{8}$$

with $P_l(\mu)$ being the Legendre polynomial of rank l. In particular, the value of $\Delta^{(S)}_{I,P,V}$ at the present time η_0 in direction $\hat{\mathbf{n}}$ are achieved by integrating the Boltzmann equations (Eq. (5)) along the line of sight and summation over all Fourier modes $\mathbf{K}$ as follows:

$$\begin{aligned}\Delta^{\pm(S)}_P(\hat{\mathbf{n}}) &= \int d^3\mathbf{K}\xi(\mathbf{K}) e^{\pm 2i\phi_{K,n}} \Delta^{\pm(S)}_P(\mathbf{K}, \mathbf{p}, \eta),\\ \Delta^{(S)}_V(\hat{\mathbf{n}}) &= \int d^3\mathbf{K}\xi(\mathbf{K}) \Delta^{(S)}_V(\mathbf{K}, \mathbf{p}, \eta),\end{aligned} \tag{9}$$

where $\phi_{K,n}$ are characterized to rotate the $\hat{\mathbf{n}}$ and $\hat{\mathbf{K}}$ dependent basis to a fixed frame in the sky. The random variable $\xi(\mathbf{K})$ is used to define the initial amplitude of the mode. Then $\Delta^{(S)}_V$ and $\Delta^{\pm(S)}_P$ are obtained as:

$$\begin{aligned}\Delta^{(S)}_V(\mathbf{K}, \mu, \eta_0) &= \frac{1}{2}\int_0^{\eta_0} d\eta\, \dot{\eta}_{e\gamma}\, e^{ix\mu - \eta_{e\gamma}} \left[3\mu\Delta^{(S)}_{V1} + i(\frac{\kappa^{+}_{LV}}{\dot{\eta}_{e\gamma}}\Delta^{+(S)}_P + \frac{\kappa^{-}_{LV}}{\dot{\eta}_{e\gamma}}\Delta^{-(S)}_P)\right],\\ &\approx \frac{1}{2}\int_0^{\eta_0} d\eta\, \dot{\eta}_{e\gamma}\, e^{ix\mu - \eta_{e\gamma}} \left[3\mu\Delta^{(S)}_{V1} + 2i\,\rho^{\{\alpha\beta\}}_Q c_{\{\alpha\beta\}}\frac{\kappa_{LV}}{\dot{\eta}_{e\gamma}}\Delta^{(S)}_P + ...\right],\end{aligned} \tag{10}$$

$$\begin{aligned}\Delta^{\pm(S)}_P(\mathbf{K}, \mu, \eta_0) = \int_0^{\eta_0} d\eta\, \dot{\tau}_{e\gamma}\, e^{ix\mu - \tau_{e\gamma}} \Big[&\frac{3}{4}(1-\mu^2)\Pi(K,\eta)\\ &- i\frac{\kappa^{\mp}_{LV}}{\dot{\eta}_{e\gamma}}\Delta^{(S)}_V\Big],\end{aligned} \tag{11}$$

where $\Pi = \Delta^{(S)}_{T2} + \Delta^{(S)}_{P2} + \Delta^{(S)}_{P0}$, the differential and total optical depth caused by Thomson scattering (σ_T) at the time of η are given by $\dot{\eta}_{e\gamma} = a(\eta)\, n_e\, \sigma_T$ and $\eta_{e\gamma} = \int_{\eta}^{\eta_0} \dot{\eta}_{e\gamma}\, d\eta$ with n_e being electron number density, and $x = \mathbf{K}\,(\eta_0 - \eta)$. The $\Delta^{(S)}_P$ is linear polarization defined as

$$\Delta^{(S)}_P(\mathbf{K}, \mu, \eta) = \int_0^{\eta} d\eta\, \dot{\eta}_{e\gamma}\, e^{ix\mu - \eta_{e\gamma}} \left[\frac{3}{4}(1-\mu^2)\Pi(K,\eta)\right]. \tag{12}$$

The $\Delta^{(S)}_V$ arised from Compton scattering in presence of LIV (Eq. (10)) can be estimated in terms of linear polarization. The term $\frac{\kappa_{LV}}{\dot{\eta}_{e\gamma}}\rho^{\{\alpha\beta\}}_Q c_{\{\alpha\beta\}}$ represents the strength of LIV contribution at circular polarization. Therefore, we consider the dominant term in $\rho^{\{\alpha\beta\}}_Q$ (Eq. (7)).

The correlation function of circular polarization in the presence of LIV in terms of primordial power spectrum is obtained as:

$$\begin{aligned} C_l^V &= \frac{1}{2l+1}\sum_m \left\langle a^*_{V,lm}\, a_{V,lm}\right\rangle \\ &\approx \frac{1}{2l+1}\int d^3K P_v(\mathbf{K}) \times \\ &\sum_m \Big| \int d\Omega Y^*_{lm} \int_0^{\eta_0} d\eta\, \dot\eta_{e\gamma}\, e^{ix\mu-\eta_{e\gamma}}\, 2i\, \rho_Q^{\{\alpha\beta\}} c_{\{\alpha\beta\}}\, \frac{\kappa_{\rm LIV}}{\dot\eta_{e\gamma}}\, \Delta_P^{(S)}|^2, \end{aligned} \tag{13}$$

and $P_\nu(K)$ is the velocity power spectrum which can be expressed as a function of primordial scalar spectrum:

$$P_\nu(\mathbf{K},\tau) \sim P_\phi^{(S)}(\mathbf{K},\tau). \tag{14}$$

Finally, we estimate the circular power spectrum C_l^V regarding to linearly polarized two point function C_l^P as follows:

$$C_l^V \approx (\tilde\kappa_{\rm LIV}^{\rm avg})^2 C_l^P, \tag{15}$$

where

$$\tilde\kappa_{\rm LIV} = c_{\{\alpha\beta\}}\, \rho_Q^{\{\alpha\beta\}} \frac{\kappa_{\rm LIV}}{\dot\tau_{e\gamma}}, \qquad \tilde\kappa_{\rm LIV}^{\rm avg} = \frac{1}{z_{lss}}\int_0^{z_{lss}} dz\ \tilde\kappa_{\rm LIV}(z) \simeq 10^{-3}. \tag{16}$$

here $\tilde\kappa_{\rm LIV}^{\rm avg}$ is the mean of $\tilde\kappa_{\rm LIV}(z)$ over redshift from last scattering surface $z_{lss} \simeq 1100$ up to today $z = 1$. Similar to Ref,[19] we assume $c^{\alpha\beta}$ tensor with symmetric component $\alpha = \beta = T, X, Y, Z$ at the order of 10^{-15} and $\chi = \pi/4$.[14] Current experimental value for linearly polarized power spectrum for the CMB is at the order of $C_l^P \equiv 0.1\mu K^2$ for $l < 250$.[20] Applying the value of linearly polarized power spectrum, we estimate the V-mode power spectrum generated from Compton scattering in the presence of LIV as follows

$$C_l^V \approx 0.8\ (nK)^2 \big(\frac{c^{\alpha\beta}}{10^{-15}}\big)^2. \tag{17}$$

As we mentioned before, the tightest experimental bound on the circular polarization is obtained by CLASS experiment which is $0.4\mu K^2$ to $13.5\mu K^2$ for $1 \le l \le 120$. By improving the sensitivity of experiments in the future, we expect the obtained constraint in Eq. (17) would be comparable to experimental bounds.

4. Summary

In this work we studied the circular polarization of CMB due to forward scattering with cosmic electron in the presence of LIV and scalar perturbations. We derived the Boltzmann equations describing the time evolution of CMB polarization. We also showed that the circular power spectrum of CMB in the presence of LIV can be expressed as linear power spectrum. Circular polarization of CMB might be originated from different sources so that the possibility to separate the contribution of

different sources would be valuable. The dominant term of circular polarization for the CMB due to LIV is linearly proportional to wavelength $\lambda = (1/k_0)$ (Eq. (7)) while the wavelength dependence for other effects could be different. This various dependency to wavelength leads to a different distribution of V-mode power spectrum arising from different models and can help us to compare our result with other bounds on circular polarization.

problem, and the perspectives from the analysis of the 21 cm redshifted line from neutral hydrogen. We then describe the *Planck* Legacy Archive, its wealth of scientific information and next developments, and the promising perspectives expected from higher resolution observations, in particular for the analysis of the thermal Sunyaev-Zel'dovich effect. Three cosmological results of the *Planck* mission are presented next: the implications of the map of Comptonization fluctuations, the dipole analysis from cross-correlating cosmic microwave background anisotropy and Comptonization fluctuation maps, and the constraints on the primordial tensor-to-scalar perturbation ratio. Finally, we discuss some future perspectives and alternative scenarios in cosmology, such as the study of the Lorentz invariance violation with the cosmic microwave background polarization, the introduction of new gravitational degrees of freedom to solve the dark matter problem, and the exploitation of the magnification bias with high-redshift sub-millimeter galaxies to constrain cosmological parameters.

Keywords: Cosmology; background radiations; observational cosmology; radio, microwave; submillimeter; infrared emission; large-scale structure of the universe; galaxy clusters; radio sources; IR sources; gravitational lenses and luminous arcs; relativity and gravitation; modified theories of gravity; dark matter; special relativity; radiation mechanisms, polarization.

1. Introduction

Over the last century or so, cosmology has progressed from a field that was essentially philosophy to a precision science. The current standard cosmological model is the Λ cold dark matter (ΛCDM) model, which mainly consists of a cosmological constant (Λ) or dark energy (DE) component and cold dark matter (CDM) component, with general relativity (GR) as the assumed theory of gravity. It makes predictions on the smallest and largest scales, that, despite some open questions, are largely verified by a host of observational cosmology experiments.

Cosmological and astrophysical surveys in various wavebands, in particular from the radio to the far-infrared, are crucial to solve many problems in cosmology and to understand the origin and evolution of the cosmic structures at various scales through cosmic time. The accurate observations of the properties of the cosmic microwave background (CMB) began the era of precision cosmology, furthering our understanding of the early universe and its evolution up to the present time and beyond. Similarly, the information contained in the radio sky is of increasing relevance to unravel the complexity of cosmic evolution and to answer a wide range of open questions, thanks to the spectacular experimental improvement achieved in the past years and expected in the future.

The structure of this paper is as follows. In Sect. 2, we begin with a preamble to the so-called tension problem, which occurs when different data are used to determine cosmological parameters. We then discuss the role of fast radio bursts (FRBs) in cosmology to solve the missing baryons problem, followed by the perspectives represented by the analysis of the 21 cm redshifted line from neutral hydrogen (HI). Sect. 3 describes the wealth of scientific information and tools publicly available at the *Planck* Legacy Archive (PLA), with its current and future developments, and the perspectives expected from higher resolution observations at millimeter (mm)

and sub-mm wavelengths, in particular for the analysis of the thermal Sunyaev-Zel'dovich (SZ) effect towards galaxy clusters (GCs), focusing on a forthcoming well-defined facility instrument. In Sect. 4 we discuss three important cosmological results based on the data from the *Planck* mission: the implications of the analysis of the thermal SZ (tSZ) map, the dipole analysis based on the cross-correlation of CMB anisotropy and tSZ maps, and the constraints on the ratio between the primordial tensor and scalar perturbations. Finally, Sect. 5 is dedicated to future perspectives and alternative scenarios in cosmology. We consider three specific examples: the study of Lorentz invariance violation with the analysis of CMB polarization, the solution to the dark matter (DM) problem introducing new gravitational degrees of freedom, and the exploitation of the magnification bias with high-z sub-mm galaxies to constrain a set of cosmological parameters.

2. Cosmology in the radio

2.1. *Cosmology with radio astrophysics and tensions in cosmology*

Amongst the successes of modern cosmology, is the remarkable precision in the estimation of the cosmological parameters that describe the contents, geometry and history of our universe. Herein also lies the current greatest tension in the data. Indeed, in spite of the increasing precision in observational cosmology, it is possible we have lost some accuracy: a number of tensions now appear within our data, tensions that more cosmology experiments do not appear to solve. These tensions may require a change in the underlying theory or they may be resolved with novel observational probes of the large scale picture of the universe. Here we will describe an example of the latter, namely, the FRBs, the novel discovery of our century, as potential instruments for cosmology. Indeed we will highlight more broadly the use of radio astrophysics - encompassing both the use of radio transients and intensity mapping tools, and the potential they hold for groundbreaking cosmology discovery.

The Hubble constant, H_0, is anything but constant across observations at different scales (see Ref. 1 for a recent review of most of the data). A brief summary however, is that historically there were two independent measures for H_0, very far apart in value with measurements of roughly $50\,\mathrm{km\,s^{-1}\,Mpc^{-1}}$ or $100\,\mathrm{km\,s^{-1}\,Mpc^{-1}}$ from the early and late universe respectively. However, the error bars on each measurement was large enough, that each was within errors of the other and it was assumed that with improved observations, the error bars would get smaller and the values would get closer and converge. Indeed, this appeared to be the case early this century, but every new data set over the last several years has the values diverging with ever smaller error bars, that critically no longer allow for a simple convergence in the value of H_0. Measurements from the early universe, such as *Planck*, Dark Energy Survey[2,3] (DES), and baryonic acoustic oscillations (BAO) and Big Bang nucleosynthesis (BBN) observations, all point to a smaller value of around $H_0 \simeq 67\,\mathrm{km\,s^{-1}\,Mpc^{-1}}$ and measurements from the late universe, using Cepheids as distance ladders, or lensing for example, find $H_0 \simeq 73\,\mathrm{km\,s^{-1}\,Mpc^{-1}}$ with each

measurement having error bars in the range $\simeq 1 \div 4\,\mathrm{km\,s^{-1}\,Mpc^{-1}}$. Thus this tension is growing with data rather than resolving.

There are longer standing issues with the standard cosmological model, of course, the lack of direct observational evidence for DM which makes up roughly 25% of the total energy budget of the universe is of particular concern. No less resolved is the issue of DE, here making up $\sim 70\%$ of the energy budget of the universe and yet only observed in indirect cosmological experiments with no direct detection and also no compelling theoretical explanation for why it even exists or why it appears to be dominating the total energy budget of the universe at a cosmological time when we are both possible and here to observe it. Early universe inflation is a key component in the model, solving several open problems such as the flatness and horizon problems and yet we still have no theory of inflation that fits within an ultraviolet complete theory with a natural candidate for the inflaton lacking. One hopes that these three problems are resolved together with a leap in the theory space - yet the obligation remains to continue to search for observational data that may yet play a role.

Other problems have lingered for very long, such as the missing baryon problem, where even the $\sim 5\%$ of the universe that we know exists is not entirely accounted for. Indeed adding up all of the observed contributions to the baryons accounts for only $\sim 70\%$ of the total expected. Roughly 30% are considered missing, and expected to be somewhere in the warm hot intergalactic medium (WHIM). Indeed, we should say were considered missing, as we discuss below how to find these missing baryons using the FRBs.

2.1.1. *Fast radio bursts and their role in cosmology*

As the name suggests, FRBs are very bright ($\sim$ Jy), brief ($\sim\mu$s to $\sim$ ms scale) transients, observed in the broad spectrum of the radio. The first was discovered[4] in 2007 and ever since the search has been on to discover more and their properties, first through searches in archival data and more recently through purpose built radio telescopes and arrays to find thousands if not tens of thousands of bursts every year. Our understanding of the properties of FRBs is still evolving; it appears that many but not all repeat, it is not yet known if any of the repeaters repeat in a periodic fashion, and indeed it is likely that ultimately FRBs will fall in several classes as has happened with transients historically. Their other properties such as polarisation, rotation measures etc are all still unknown as the observations do not all point to a single pattern and it is not always possible to disentangle host galaxy effects from propagation effects from intrinsic properties of the bursts. It does appear certain that they are found in host galaxies, and that they lie at cosmological distances,[5] thus making them excellent candidates for cosmology as their propagation will probe the intergalactic medium (IGM) and thus give us a number of novel ways to constrain cosmological parameters (see, e.g., Refs. 6–8 and references therein). From a theoretical standpoint, the progenitor mechanism

driving FRBs is not yet known though there are strong hints that at least some are driven by magnetars through one of many physical possible mechanisms. A full database of theories,[9] once outnumbered the observations, but as the amount of data grows, the possibilities for theoretical explanations shrinks and so it is likely that in a few years we will have only a handful of possible contenders remaining, perhaps matching future classes of FRBs.

There are a number of ways FRBs can be used as cosmological probes. Here we focus on a single application. After emission from the source, the photons from the burst travel to the observer through the IGM, and are slowed down differentially as a function of their wavelength, λ, or frequency, $\nu = c/\lambda$, c being the speed of light. The dispersion measure, $M_D \simeq \int n_e dl$, where n_e is the electron number density and the integral along the line of sight runs from the source to the observer, thus contains cosmological information about the distribution of electrons. Indeed, this simple equation combined with precision cosmology constraints from the early universe allows us to make a prediction for the fraction of baryons in the IGM,[7] which can then be experimentally verified. Indeed, the so-called missing baryon problem is not longer an outstanding problem as the results of Ref. 10 used a handful of well located FRBs with the observed dispersion measures to show that indeed the missing baryons are in the IGM as expected, and are playing the predicted role of dispersing the FRB signal. This longstanding open problem is thus resolved not due to any great technological or theoretical breakthrough, but simply through the use of a few transient observations and an understanding of the contributions to M_D from our own galaxy. This suggests that there is immense and untapped potential for great discovery with FRBs and that the future is very bright for this young field.

2.2. *High-redshift universe with redshifted 21 cm line*

The redshifted 21 cm line of HI is one of the most useful probes of the early universe. Several experiments are ongoing and are being planned to detect the signal at high redshift, z. Detection of the signal will help in understanding the first stars in the universe, the formation and evolution of galaxies and also constraining cosmological parameters. This section summarizes the status of observational efforts and theoretical understanding.

The HI evolution can be used to study the thermal and ionization history of the universe and also the evolution of the galaxies.[11,12] The very first HI atoms formed during the so-called 'recombination' epoch. The hydrogen remains in the neutral form until the first stars form which can then start ionizing the HI in the IGM, a process known as *reionization*. This epoch is believed to end around redshifts $z \sim 5.5$ by when almost all the HI in the IGM gets ionized. In the *post-reionization* era, the only regions where HI can survive are the high-density regions, e.g., the interstellar medium (ISM) of the galaxies.

The evolution of HI can be efficiently tracked by the redshifted 21 cm signal arising from hyperfine transition of the ground state of the atom. The signal is

observed, either in emission or absorption, in contrast to the CMB signal using low-frequency radio telescopes. Since the hyperfine transition is forbidden, the signal amplitude turns out to be extremely weak and hence is appreciable only when the HI density is significant. There are broadly three regimes where the detection of the 21 cm radiation is being planned: (i) the *cosmic dawn* when the ultraviolet (UV) and X-ray radiation from the very early galaxies lead to a strong absorption signal around $z \sim 20$; (ii) the *epoch of reionization* when the heated and ionized IGM leads to an emission signal around $z \sim 15 - 6$; and (iii) the *post-reionization* signal when HI in galaxies can be detected either directly or through intensity mapping.

Among the different ways to detect the 21 cm signal, perhaps the one that requires simplest of the instruments is the signal averaged over large regions of the sky, i.e., the *global signal*. This signal is believed to be most prominent during the cosmic dawn corresponding to $\nu \simeq 50 - 100$ MHz. The amplitude of the cosmological signal is weak and is buried under other astrophysical signals few orders of magnitude stronger, which makes it extremely challenging to separate it out.

Recently, there has been a claim of a detection of the 21 cm signal from cosmic dawn at $z \sim 18$ by the Experiment to Detect the Global EoR Signature[26] (EDGES), although the recovered signal seems to be 3–4 times larger than that predicted by standard galaxy formation models. This lead to several theoretical interpretation beyond the standard calculations, e.g., exotic physics in the DM sector[27] or strong

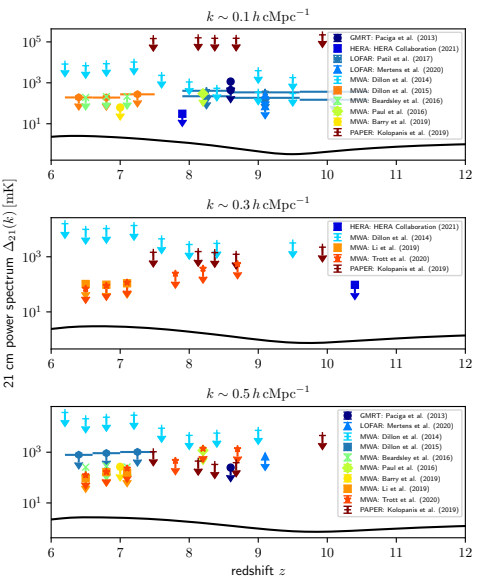

Fig. 1. Observational upper limits to the 21 cm PS, $\sqrt{k^3 P_{21}(k)/2\pi^2}$, for three different comoving wavenumbers k; here $h = H_0/(100\,\mathrm{km\,s^{-1}\,Mpc^{-1}})$ and cMpc denotes comoving Mpc. Data from different telescopes, namely, the Giant Metrewave Radio Telescope[13] (GMRT), the Low Frequency Array[14,15] (LOFAR), the Murchison Widefield Array[16–22] (MWA), the Precision Array for Probing the Epoch of Reionization[23] (PAPER), the Hydrogen Epoch of Reionization[24] Array (HERA), are shown in comparison with the signal predictions from the Semi-numerical Code for ReIonization with PhoTon-conservation[25] (`SCRIPT`).

radio background from the first galaxies.[28–30] There have also been concerns regarding the foreground subtraction and other systematics in the data,[31] hence it is important to validate the signal through other low-frequency telescopes.

An alternate way of detecting the 21 cm signal is through the spatial fluctuations. These can, in principle, be useful throughout the cosmic history starting from the cosmic dawn to the post-reionization universe. During the cosmic dawn, the fluctuations arise from those in the galactic radiation, while in the epoch reionization it is the patchiness in the ionization field that drives the 21 cm fluctuation signal. In the post-reionization era, the fluctuations in the 21 cm signal essentially trace the distribution of galaxies and hence the underlying matter fluctuations.

At present, a number of low-frequency interferometers are attempting to detect the 21 cm power spectrum (PS) from the epoch of reionization at scales $\sim 10h^{-1}$ cMpc. Fig. 1 shows the current upper limits (see Ref. 32 for a complete compilation of available data). These observational attempts are ably complemented by numerical and semi-numerical theoretical models to help interpret the data. The result from the one such semi-numerical simulation `SCRIPT`[a] is shown in Fig. 1 for a model of reionization consistent with all other available observations.[25] Upcoming facilities like the Square Kilometre Array[b] (SKA) will be able to reach a noise level of ~ 1 mK (~ 0.3 mK) within ~ 100 (1000) hours of observations and hence should constrain reionization models with high statistical significance.

3. Observational results and perspectives in the microwaves

3.1. *The Planck Legacy Archive, present and future*

Planck was an ESA space satellite that measured the microwave sky in nine wavebands, allowing it to not only capture the CMB to incredible precision, but also to accurately study a number of astrophysical diffuse emissions and discrete sources (see fig. 51 in Ref. 33, which shows the various wavebands of the *Planck* satellite, as well as the foregrounds signals and their frequency spectra across those bands).

The PLA hosts and serves over 150 TB of products from *Planck* that are publicly available via the PLA web interface[c] (Fig. 2). This interface provides direct access to the users to a wide variety of products of the *Planck* Collaboration[d] through the Low Frequency Instrument (LFI) Data Processing Centre (DPC) in Trieste, Italy, by the High Frequency Instrument (HFI) DPC in Paris, France, and, more recently, by the US *Planck* Data Center in Pasadena and Berkeley, California, USA. The

[d] The *Planck* Collaboration acknowledges the support of: ESA; CNES, and CNRS/INSU-IN2P3-INP (France); ASI, CNR, and INAF (Italy); NASA and DoE (USA); STFC and UKSA (UK); CSIC, MINECO, JA, and RES (Spain); Tekes, AoF, and CSC (Finland); DLR and MPG (Germany); CSA (Canada); DTU Space (Denmark); SER/SSO (Switzerland); RCN (Norway); SFI (Ireland); FCT/MCTES (Portugal); ERC and PRACE (EU). A description of the *Planck* Collaboration and a list of its members, indicating which technical or scientific activities they have been involved in, can be found at `http://www.cosmos.esa.int/web/planck/planck-collaboration`.

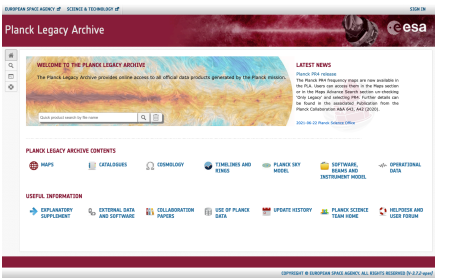

Fig. 2. *Left*: the *Planck* Legacy Archive home page.

PLA is located at the European Space Astronomy Centre (ESAC) near Madrid, Spain, and is maintained by the Data Science and Archives Division personnel.

In the last years, four major releases of *Planck* products have taken place, providing users with the most complete cosmology data set to date.

The *Planck* products can be divided into various categories. *First*, the time-ordered data, that comes in multiple flavors: raw, semi-calibrated and calibrated science ready timelines and compressed timelines (called HPRs). *Second*, the frequency maps produced by the DPCs, in most cases for each detector, detector pair and frequency, and for different combinations of the mission coverage (e.g., yearly maps, nominal mission, half-mission, half-ring, full mission, etc); *third*, the maps of the CMB; and, *fourth*, the so-called astrophysical component maps that contain the diffuse emission from our Galaxy as produced by the dust grains, synchrotron emission from spiraling electrons moving along the magnetic field lines, cosmic infrared background (CIB), etc. See Fig. 3, *left* panel. These CMB and astrophysical maps are derived in the scheme offered by the Hierarchical Equal Area isoLatitude Pixelization of a sphere[34] (`HEALPix`) using different component separation methods, e.g., `Commander`, Spectral Matching Independent Component Analysis (`SMICA`), Spectral Estimation Via Expectation Maximisation (`SEVEM`) and Generalized Needlet Internal Linear Combination (`GNILC`), the four official component separation methods used to extract the CMB maps in the third *Planck* Release (PR3). *Fifth*, source catalogues in various forms, from Galactic and extragalactic compact source catalogues, available in the *Planck* Catalogue of Compact Sources (PCCS), to galactic cold cores, SZ GCs, high-z lensing candidates, etc (Fig. 3, *right* panel). *Sixth*, cosmology products, e.g., the *Planck* likelihood code and associated files, the different flavors of the *Planck* CMB angular PS as a function of the multipole ℓ (e.g., low-ℓ, high-ℓ, temperature-only, temperature and polarization, etc), lensing products and more (Fig. 4, *left* panel).

Advance Search panels are available to extensively query the PLA database, in addition to embedded links to the *Planck* Explanatory Supplement documentation,[e] multiple data download options, and Helpdesk support.

[e] `https://wiki.cosmos.esa.int/planck-legacy-archive`

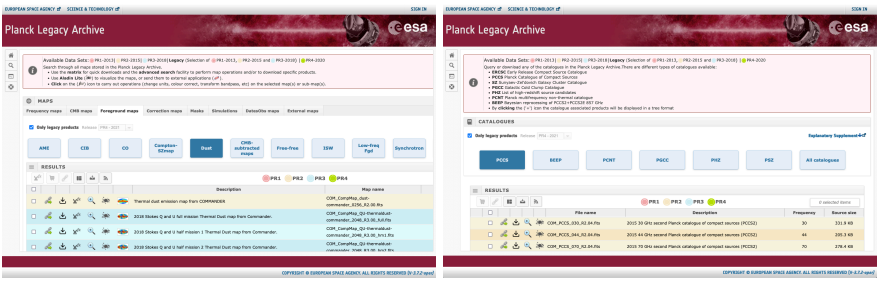

Fig. 3. *Left*: the *Planck* maps area in the PLA, with emphasis to the astrophysical components, and in particular to the Galaxy dust emission. *Right*: the *Planck* source catalogues area in the PLA, with emphasis to the PCCS.

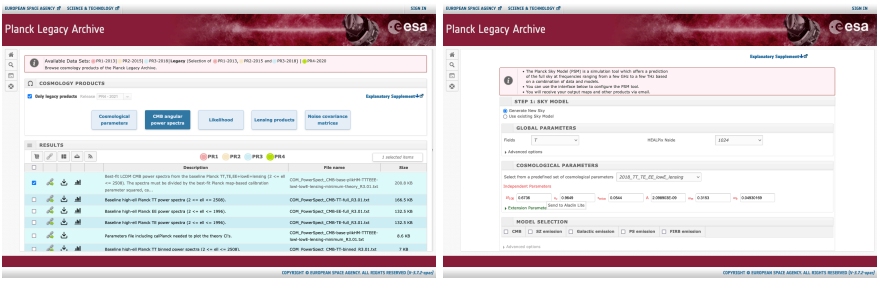

Fig. 4. *Left*: the *Planck* cosmology products area in the PLA, with emphasis to the CMB angular PS. *Right*: the `Planck Sky Model` simulation tool area in the PLA.

Three major releases of *Planck* products took place in 2013, 2015, and 2018 and a selection of products have been tagged as "Legacy" to identify the version of each product most appropriate for general scientific use. In 2021 a new release of products will take place with a joint reprocessing of LFI+HFI time-ordered data that includes additional information not used in previous releases. In addition, EU funded projects reprocessing *Planck* data, or combining it with other experiments, are expected to the deliver to the PLA higher level data products of interest. The PLA also offers specialized tools that facilitate the processing of *Planck* products. These tools are mainly designed to help users who are not familiar with some of the particularities of the *Planck* products, and can be categorized into distinct groups: map operations including component subtraction, unit conversion, colour correction, bandpass transformation, and masking of map-cutouts/full-sky maps; component separation codes, map-making codes and effective beam-averaging. In addition, the PLA includes an interface to the latest version of the `Planck Sky Model` simulation tool (Fig. 4, *right* panel), with a simple user interface that allows users to simulate the microwave/sub-mm sky with *Planck*, as well as future CMB experiments and custom-defined instruments.

In the coming years it is planned to continue releasing data products from improved reprocessing of *Planck* data and combining *Planck* with other experiments.

3.2. *High angular resolution SZ observations with MISTRAL*

High angular resolution mm observations are key to understand a wide variety of scientific cases. Among the others, the interaction of CMB photons with the hot electron gas in GCs and surrounding medium promises to study GCs and their deviation from relaxed behaviour. When the CMB photons scatter off a hot electron gas, for example in GCs, in fact, they undergo inverse Compton scattering which is visible in the frequency spectrum of the CMB. The resulting distorted spectrum is

$$\frac{\Delta I(x)}{I_0} = y \frac{x^4 e^x}{(e^x - 1)^2} \left(x \coth \frac{x}{2} - 4 \right) = y g(x) \,, \tag{1}$$

where $I_0 = (2h_P/c^2)(k_B T_{CMB}/h_P)^3$, T_{CMB} is the CMB temperature, $x = h_P \nu/(k_B T_{CMB})$ is the dimensionless frequency, and $y = \int n_e \sigma_T k_B T_e/(m_e c^2) dl$ is the Comptonization parameter, the integral along the line of sight of the electron density n_e multiplied by the electron temperature T_e; σ_T is cross-section of Thomson scattering, k_B and h_P are the Boltzmann and Planck constants. This is the tSZ effect[35,36] and it can be used to study both relaxed and non-relaxed GCs. In fact, GCs can experience a wide variety of situation including collisions, merging, and non-relaxed situation. In addition, not only GCs can host relativistic electrons. Hydrodynamical simulations[37,38] suggested that GCs occupy the knots of the so called cosmic web (CW) and WHIM is disposed connecting GCs forming filaments that could be seen through the SZ effect itself.

An instrument being prepared for such scientific cases is the MIllimeter Sardinia radio Telescope Receiver based on Array of Lumped elements kids[39] (MISTRAL), to be fielded at the 64m Sardinia Radio Telescope[f] (SRT). MISTRAL will use an array of 408 kinetic inductance detectors (KIDs) with a field of view of $4'$ and an angular resolution of $\sim 12''$. It is a cryogenic instrument with detectors cooled down at 270 mK and with frequency domain multiplexing (FDM), Reconfigurable Open Architecture Computing Hardware 2 (ROACH2) based read-out.

MISTRAL is a facility instrument to be installed at the SRT in 2022. It operates in an atmospheric window in the frequency range $78 \div 103$ GHz, namely W-band, that is interesting for a number of scientific reasons, and most importantly it provides low optical depth and allows high efficiency observations. It will be installed in the Gregorian room of the SRT (Fig. 5).

MISTRAL consists of a cryostat, being constructed by Queen Mary College (QMC) Instruments,[g] with a Pulse Tube (PT) cryocooler, an He-10 sorption refrigerator, custom optics and detectors. In order to have the PT heads as close as possible to vertical position during observations, we have positioned the head with an inclination of $57.5°$ with respect to the focal plane. This allows observation elevations in the range of $32.5° \div 82.5°$ with no degradation of the thermal performance.

[f] `http://www.srt.inaf.it`
[g] `http://www.terahertz.co.uk/qmc-instruments-ltd`

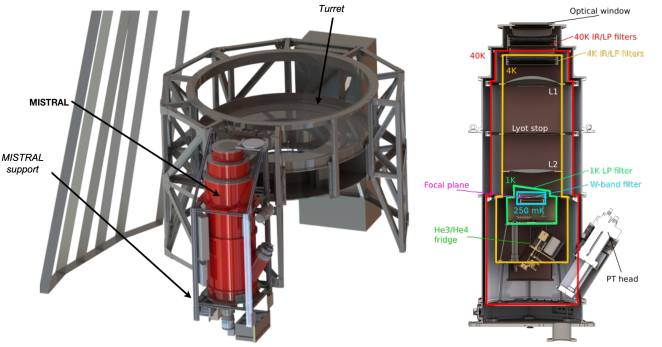

Fig. 5. *Left*: SRT Turret with MISTRAL installed. *Right*: a cut of MISTRAL cryostat highlighting the main parts. Acknowledgement: MISTRAL Collaboration.

The optical design of MISTRAL includes a set of radiation quasi-optical filters, anchored at the different thermal stages of the cryostat, an Anti Reflection Coated (ARC) Ultra High Molecular Weight (UHMW) polyetilene window, and two Silicon lenses able to image the Gregorian Focus on the array of detectors. Detectors are coupled to radiation through open space (filled array) so cryogenic cold stop, placed in between the two lenses, is needed.

MISTRAL will take advantage of the high sensitivity and capability of FDM of KIDs cryogenic detectors. KIDs are superconductive detectors where mm radiation with higher energy with respect to the Cooper pair binding energy, can break Cooper pairs producing a change in the population densities and thus in the kinetic inductance. In fact, the inductance L of a thin superconductor is dominated by the kinetic inductance L_k, which depends on the Cooper pair density. The detector array is composed of 408 KIDs detectors. They are $3\,\text{mm} \times 3\,\text{mm}$ each and are arranged on an equilateral triangle every 4.2 mm on a 4 inches silicon wafer. They sample the focal plane with a full width half maximum (FWHM) angular spacing of $10.6''$ lower the each pixel angular resolution. The ROACH2 based FDM, originally developed for the Osservatorio nel Lontano Infrarosso Montato su Pallone Orientabile[h] (OLIMPO) experiment,[40,41] will be used.

MISTRAL will be a facility instrument: it will be open to the scientific community to decide what kind of scientific output it can achieve and propose the observations to the Time Allocation Committee of the SRT. Nevertheless, we will list some scientific cases below, including those we find most interesting.

Protoplanetary discs mm measurements in star forming regions allow to break the degeneracy present in infrared (IR) measurements due to the optically thick nature of the hot inner disc.[42] Observations of star formation in molecular clouds with high enough angular resolution allow to distinguish starless cores with respect to those hosting protostars.[43] Continuum resolved galaxies observations can give

[h]Far Infrared Observatory Mounted on Orientable Balloon. See `http://olimpo.roma1.infn.it.`

information about morphology and radial profiles, e.g., gas column profiles, dust temperature profiles.[44] Spatially resolved high-z radio galaxies can provide information about cold dust re-emission.[45]

What is probably the most impacting expected result of MISTRAL is the possibility to observe and resolve the SZ effect through GCs and surrounding medium. With respect to moderate to low angular resolution observations, high ($\simeq 10''$) etections can investigate non relaxed GCs, study merging GCs, understanding the self similarities of GCs, their identical appearance regardless of their mass or distance. Study the pressure profiles and understand the active galactic nuclei (AGN) feedback expected in some environments. Often GCs are assumed to be spherical and isothermal. Nevertheless, they interact, collide and merge, bringing to important degeneracies and deviation from specific models. High angular resolution SZ measurements allow to disentangle between models and to identify the most appropriate ones. Even relaxed GCs experience pressure fluctuations and compressions of the intra cluster medium which would be interesting to study.

GCs experience hierarchical growth through mergers. Pre-mergers GCs should be connected through the CW and simulations endorse this.[37,38] WHIM are expected to be distributed as over-densities in filamentary structures between GCs: high angular resolution SZ measurements can detect WHIM better than X-ray under low density circumstances. This is probably the most challenging and most rewarding of the achievements that an experiment like MISTRAL can achieve.

4. *Planck* cosmological implications

4.1. *New Planck thermal SZ map and its cosmological analysis*

The ΛCDM model provides a wonderful fit to many cosmological data. However, a slight discrepancy was found in the latest data analyses between the CMB anisotropies ($z \sim 1100$) and other cosmological probes at low ($z \sim 0 \div 1$) redshift, z, for the $S_8(\equiv \sigma_8(\Omega_M/0.3)^{0.5})$ cosmological parameter representing the amplitude of the structure growth in the universe; here Ω_M and σ_8 are the usual non-relativistic matter density parameter and the density contrast on a scale of 8 $[H_0/(100\,\mathrm{km\,s^{-1}\,Mpc^{-1}})]^{-1}$ Mpc.

For example, the S_8 value was precisely measured to be $S_8 = 0.830 \pm 0.013$ with the *Planck* CMB observation.[46] However, a lower value of $S_8 \sim 0.77 \pm 0.03$ was measured using the population of GCs detected by *Planck* at low-z[47,48] ($z < 0.6$), thus called "S_8 tension". Furthermore, other low-z observations with gravitational lensing by the Kilo-Degree Survey[49] (KiDS) and DES experiments also found lower S_8 values. These results indicate that the cosmic structure growth is slower than the prediction based on the CMB measurement and may demand modifications to the standard cosmological model to explain all these measurements.

One of the most interesting signals extensively studied with *Planck* is the tSZ effect, which produces what are known as y distortions, or y type signals. These primarily come from CMB photons being inverse-Compton scattered through hot

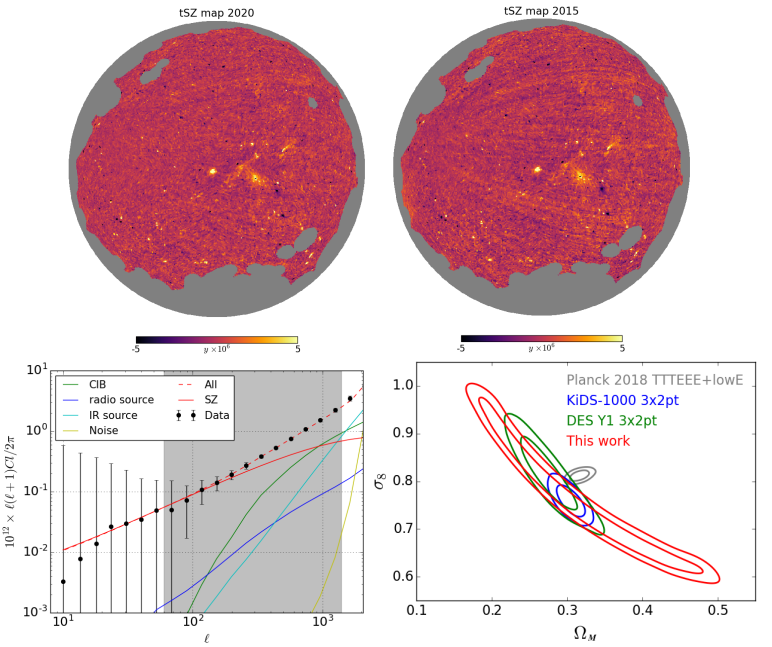

Fig. 6. *Top*: Orthographic projections of the all-sky Compton y parameter maps reconstructed with `MILCA` (*left*) and in 2015[50] (*right*), with appreciable differences in the striping features. Pixel resolution changed for visualization purposes from $N_{\rm side} = 2048$ to $N_{\rm side} = 128$ (i.e. from $\simeq 1.72'$ to $\simeq 27.48'$ pixel size), according to the sky pixelization in Ref. 34. *Bottom*: Cross-PS (black) fitted with the tSZ (red) and foreground models, namely the CIB (green), radio (blue) and IR (cyan) sources, plus noise (yellow), the sum of the tSZ, foreground models and noise being shown in red dashed line (*left*); posterior distribution of the cosmological parameters σ_8 and Ω_M, with 68% and 95% confidence level (CL) interval contours obtained from our cosmological analysis (*right*), compared with the *Planck* CMB's (gray), KiDS-1000 3x2pt (blue), and DES Y1 3x2pt results (green). Acknowledgements: H. Tanimura, M. Douspis, N. Aghanim (CNRS/Univ. Paris-Saclay).

GCs (see Sect. 3.2), which makes holes, or lowers the flux of low frequency photons and up scatters, or makes an excess flux of high frequency photons.

The tSZ signal is subdominant relative to the CMB and other foreground emissions in the *Planck* bands. Thus a tailored component separation algorithm is required to reconstruct the tSZ map. We adopted the Modified Internal Linear Combination Algorithm[51] (`MILCA`) used for the *Planck* y-map reconstruction in 2015 and applied it to the 100 to 857 GHz frequency channel maps (see Sect. 3.1) from the fourth *Planck* Release (PR4).

The *Planck* PR4 data implemented several improvements from the previous version: the usage of foreground polarization priors during the calibration stage to break scanning-induced degeneracies, the correction of bandpass mismatch at all frequencies, the inclusion of 8% of data collected during repointing maneuvers, etc. With these improvements we produced a new y-map with smaller noises (by $\sim$7%) and reduced strips than the previous version released in 2015 (Fig. 6, *top* panels).

We also reconstructed two y-maps from the first and last halves of the data for a cosmological analysis and considered a cross-angular PS between these y-maps to avoid the bias induced by the noise in the auto-angular PS (see Ref. 52 for more details). This tSZ cross-PS is affected by residual foreground emissions from radio and IR point sources and CIB emission. Thus we fitted our measurement with the cosmology-dependent tSZ model, including the radio and IR point source models,[53] the CIB model[54] and the noise (Fig. 6, *left bottom* panel).

The cosmological analysis of the tSZ cross-PS allowed us to set constraints on cosmological parameters, mainly of the S_8 parameter. We obtained $S_8 = 0.764\,^{+0.015}_{-0.018}\,(\mathit{statistical})\,^{+0.031}_{-0.016}\,(\mathit{systematic})$, in which the systematic uncertainty includes the contributions from the mass bias and pressure profile model. Our obtained S_8 value is fully consistent with recent weak lensing results from KiDS and DES. It is also consistent with the *Planck* CMB's result[46] within 2σ, while it is slightly lower by $\sim 1.7\sigma$ (Fig. 6, *right bottom* panel).

4.2. *The CMB dipole and the thermal SZ effect: Eppur Si Muove*

The largest temperature anisotropy in the CMB is the dipole pattern at $\ell = 1$. The simplest interpretation of the dipole is that it is due to our motion with respect to the rest frame of the CMB (with debate over the possibility of alternative explanations), and is measured to be $\beta = v/c = (1.23357 \pm 0.00036) \times 10^{-3}$ in the direction of the constellation Crater, $(l, b) = (264.021^\circ \pm 0.011^\circ, 48.253^\circ \pm 0.005^\circ)$, see Ref. 55. As well as creating the ℓ=1 mode of the CMB sky, this motion affects all astrophysical observations by modulating and aberrating sources across the sky, such as the CMB temperature anisotropies. These and other effects will be discussed.

As discussed above, an accurate mapping of the tSZ signal on the sky has been achieved with the *Planck* satellite. This allows us to construct a novel and independent measure of the CMB dipole because the y maps are contaminated by temperature anisotropies stemming from the CMB dipole. This is also valuable as a test of the quality of the y maps.

To derive the connection between the y map and the dipole we will begin by defining some useful terms regarding the unboosted CMB sky,

$$I(x) \equiv \frac{2k_{\rm B}^3 T_{CMB}^3}{h_P^2 c^2} \frac{x^3}{e^x - 1} \tag{2}$$

$$f(x) \equiv \frac{x e^x}{e^x - 1} \tag{3}$$

$$Y(x) \equiv x \frac{e^x + 1}{e^x - 1} - 4\,, \tag{4}$$

which are the standard Planck blackbody intensity function, the frequency dependence of CMB anisotropies, and the relative frequency dependence of the tSZ effect

or y type distortions, x being the dimensionless frequency (see Sect. 3.2). Thus, to first-order the anisotropies of intensity measured by *Planck* can be written as

$$\frac{\delta I(\hat{\mathbf{n}})}{If(x)} = \frac{\delta T(\hat{\mathbf{n}})}{T_{CMB}} + y(\hat{\mathbf{n}})Y(x)\,, \tag{5}$$

where we have included just the temperature anisotropies and the y signals here.

If we apply a boost to Eq. (5) with a dimensionless velocity $\boldsymbol{\beta}$, it becomes

$$\begin{aligned}\frac{\delta I'(\hat{\mathbf{n}}')}{If(x)} = {} & \beta\mu + \frac{\delta T(\hat{\mathbf{n}}')}{T_{CMB}}(1+3\beta\mu) \\ & + Y(x)\left(y(\hat{\mathbf{n}}')(1+3\beta\mu) + \beta\mu\frac{\delta T(\hat{\mathbf{n}}')}{T_{CMB}}\right) \\ & + \beta\mu y(\hat{\mathbf{n}}')\left(Y^2(x) - x\frac{dY(x)}{dx}\right) + \mathcal{O}(\beta^2)\,;\end{aligned} \tag{6}$$

here $\mu = \cos(\theta)$, and θ is the angle from the direction of the boost $\boldsymbol{\beta}$ and the line of sight. Additionally, the aberration effect deflects the direction of the incoming photons from $\hat{\mathbf{n}} \to \hat{\mathbf{n}}'$ where $\hat{\mathbf{n}}' = \hat{\mathbf{n}} - \nabla(\hat{\mathbf{n}}\cdot\boldsymbol{\beta})$. The first line has the same frequency dependence as thermal fluctuations. The term $\beta\mu$ simply describes the pure CMB dipole, as discussed previously. The second term represents the dipole aberration and modulation of the temperature anisotropies of the CMB. This was first measured in Ref. 56 to 5σ. Crucially for our analysis, the middle line has the same frequency dependence as y type distortions, and so encompasses the signals in the y-map. The final line has more obscure frequency dependencies and so will not be discussed here. See Refs. 57, 58 for further details.

The second line of Eq. (6) shows the signals in the y maps produced by *Planck*. The first half is the same boost as was seen in the temperature anisotropies, however, the final term is due to the second-order expansion of the intensity about T_{CMB} and adds a contribution to the y maps from the temperature anisotropies. We measured this signal in Ref. 57 to 6σ by cross-correlating the expected modulated temperature map with the y maps. We confirmed the dipole direction by cross-correlating the temperature maps modulated in two additional perpendicular directions. To test consistency and rule out different systematics, we used the Internal Linear Combination (`ILC`) in two dimensions, `2D-ILC`, and `MILCA` y-maps, the temperature anisotropies from both `2D-ILC` and `SMICA`, and finally both a harmonic space analysis and a map space analysis.

The question as to whether an intrinsic dipole could be observationally distinguished from an extrinsic dipole remains an open question. The terms discussed in Eq. (6) are based on the assumption of a CMB blackbody spectrum[i] and cannot be used to distinguish the two, as they would naturally arise whether the CMB dipole

[i]See instead Ref. 59 for a study exploiting the relaxation of the blackbody assumption and references to other methods.

were caused by a boost, or if there were simply a dipole in the sky with the same magnitude and direction.

4.3. *Planck constraints on the primordial tensor-to-scalar ratio*

Discovering the stochastic field of gravitational waves generated during the early phases of the universe is one of the most ambitious goals of modern cosmology. Various models of inflation predict cosmological perturbations from quantum fluctuations[60–66] in terms of tensor component (gravitational waves) and scalar component (density variations). Inflationary gravitational waves entering the horizon since recombination epoch generate a tensor component contributing to temperature (T), polarization (E and B modes) and cross-correlation TE angular PS, C_ℓ^X where X stands for a given mode[j], of CMB anisotropy,[67–69] in particular at large angular scale (or at low multipoles, $\ell \lesssim 150$, where $\ell \sim 180°/\theta$ approximately relates ℓ to the angular scale θ). C_ℓ^X is typically represented in terms of $D_\ell^X = \ell(\ell+1)C_\ell^X/(2\pi)$, which is nearly flat at low multipoles for $X = T$, although a power suppression at very large scales, first observed by the Cosmic Background Explorer (COBE) an then confirmed by the Wilkinson Microwave Anisotropy Probe (WMAP) and by the *Planck* satellite, is predicted in several inflationary models possibly in connection with universe geometry and topology.

While the E and TE modes contain both scalar and tensor signals mainly coming from the epochs of recombination and reionization, the model does not predict primordial scalar fluctuations in the B-mode. The detection of the primordial B-mode then constitutes a direct way to unravel tensor perturbations from the early universe, and the efforts to measure of the ratio, r, between the amplitudes of primordial tensor and scalar perturbations is the main scientific aim of many ongoing and future CMB projects. When CMB photons pass through gravitational potentials produced by cosmic structures, part of the E-mode power is transformed to B-mode power, the so-called lensing B-mode. This signal, already detected by a number of ground-based observatories and by *Planck*, is particularly important at small angular scale[70] ($\ell \gtrsim 150$), but it may mask the primordial B-mode also at intermediate angular scale and, for low r, even at large angular scale.

Assuming the spectra of scalar and tensor perturbations are described by pure power-laws, $\mathcal{P}_\mathrm{s}(k) = A_\mathrm{s}(k/k_0)^{n_\mathrm{s}-1}$, $\mathcal{P}_\mathrm{t}(k) = A_\mathrm{t}(k/k_0)^{n_\mathrm{t}}$, they are fully defined by the two amplitude parameters $A_\mathrm{s}, A_\mathrm{t}$ and by the so-called (comoving wavenumber) pivot scale k_0, the definition of $r = A_\mathrm{t}/A_\mathrm{s}$ being then related to the choice of k_0. Among the various choices adopted in the literature, $k_0 = 0.05\,\mathrm{Mpc}^{-1}$ approximately corresponds to the middle of the logarithmic range of k probed by *Planck*. For historical reasons, a scale-invariant spectrum corresponds to $n_\mathrm{s} = 1$ or to $n_\mathrm{t} = 0$ for scalar or tensor perturbations, respectively.

[j]For simplicity, we use here two letters only for cross modes.

The multipole range $2 \lesssim \ell \lesssim 150$ is the most advantageous to directly extract r from B-mode analyses. According to theoretical predictions, the primordial D_ℓ^B is close to the maximum at $50 \lesssim \ell \lesssim 150$, the region of the so-called recombination bump (i); at large scale, $\ell \lesssim 10$, D_ℓ^B exhibits a pronounced bump generated at late epochs by the reionization process (ii); at $10 \lesssim \ell \lesssim 50$, $\log(D_\ell^B)$ increases almost linearly with $\log(\ell)$ (iii). Exploiting higher ℓ's is of particular relevance for a very accurate treatment (delensing) of lensing B-mode. C_ℓ^B increases almost linearly with r, the reionization bump features depending on r and on the details of the reionization process, which is parametrized to first approximation by the corresponding Thomson optical depth, τ. In general, the detection of primordial B-modes requires exquisite experimental sensitivity and accuracy as well as very precise treatment of the polarized foreground emissions (see, e.g., Ref. 71), particularly for low values of r, which is why a primordial B-mode tensor signal has not yet been detected. On the other hand, recent CMB projects set significant upper limits to r. The great sensitivity achievable by ground-based experiments on selected sky areas has been used to strongly constrain (i), the current tightest B-mode limits on r from these scales coming from the Background Imaging of Cosmic Extragalactic Polarization (BICEP)/Keck measurements[72] (BK15), while the *Planck* all-sky survey allows to constrain (i), (ii) and (iii). In particular, Ref. 73 presents B-mode limits on r from *Planck* data at $\ell \lesssim 30$.

A recent reanalysis of *Planck* data alone and in combination with BK15 (see Ref. 74 for a previous joint analysis) has been performed in Ref. 75 exploiting the whole multipole range $2 \leq \ell \leq 150$. In this study, the *Planck* PR4 data (see Sect. 3.1) were adopted, where the `NPIPE`[76] processing pipeline was used to create calibrated frequency maps in temperature and polarization from LFI and HFI data, providing several improvements in noise and systematics levels in both frequency and component-separated maps. Various sky masks were considered in order to retain different sky fractions (from 30% to 70%) and to test the impact of data treatment. In polarization, the CMB sky was separated from foregrounds applying the `Commander`[77] code to a model with three components, namely the CMB, synchrotron, and thermal dust emission, starting from the PLA PR4 maps but downgraded from $N_{\rm side} = 2048$ to $N_{\rm side} = 16$ and to $N_{\rm side} = 1024$ respectively for the analysis at $2 \leq \ell \leq 35$ and at $35 \leq \ell \leq 150$. An updated version of the LOw-ℓ LIkelihood on POlarised Power-spectra (`LoLLiPoP`) code previously employed by the *Planck* Collaboration in the reionization analysis[78] was used to derive the likelihood from *cross*-power spectra for the CMB maps reprocessed as outlined above. Here, *cross* denotes that the angular PS is extracted analyzing different sets of detectors: indeed, for these *cross*-power spectra the bias is zero when the noise is uncorrelated between maps. Unbiased estimates of the angular PS were derived using an extension of the quadratic maximum likelihood estimator and a classical pseudo-C_ℓ estimator at $2 \leq \ell \leq 35$ and at $35 \leq \ell \leq 150$, respectively. The C_ℓ covariance is deduced from end-to-end simulations and thus includes CMB sample variance,

statistical noise, residuals from systematics, uncertainties from foreground subtraction, and correlations generated by masking. These uncertainties are propagated through the likelihood up to the level of cosmological parameters.

Applying this analysis to the B-mode alone, fixing the other cosmological parameters to the fiducial ΛCDM spectrum of *Planck* 2018 results, and considering the cleanest 50% fraction of the sky, the values of r (for $k_0 = 0.05\,\mathrm{Mpc}^{-1}$) retrieved from the posterior distribution analysis at $2 \leq \ell \leq 35$ (that includes the reionization bump) or at $35 \leq \ell \leq 150$ (that includes the recombination bump) are $r_{0.05} = -0.014^{+0.108}_{-0.111}$ or $r_{0.05} = +0.069^{+0.114}_{-0.113}$, respectively. The two multipole windows contribute almost equally to the overall *Planck* sensitivity to r. Combining them gives $r_{0.05} = 0.033 \pm 0.069$, while setting also a positive value of r as a physical prior implies $r_{0.05} < 0.158$ at 95% CL.

A tighter result, $r_{0.05} = -0.031 \pm 0.046$, and a stronger constraint, $r_{0.05} < 0.069$ at 95% CL, slightly improving the BK15 95% CL limit $r_{0.05} < 0.072$, is derived applying the same method but jointly considering the three polarization modes B, E and EB.[k]

These results on r do not depend significantly on the choice of other ΛCDM cosmological parameters. In particular, the constraints on r are unchanged when r is retrieved together with τ: considering all polarization modes $r_{0.05} = -0.015 \pm 0.045$ and $\tau = 0.0577 \pm 0.0056$, while considering only the B-mode $r_{0.05} = 0.025 \pm 0.064$ and τ is undetermined because of the noise.

The *Planck* temperature data are crucial to determine the other ΛCDM parameters and then, when combined with polarization data, to exhaustively verify if the limits on r depend on the other parameters. Furthermore, although *Planck* temperature data, when considered alone, are found to be about two times less sensitive than *Planck* polarization data in constraining r, the tensor contribution to temperature fluctuations allows to further tight the constraints on r derived from polarization data alone. In fact, including also *Planck* temperature data in the analysis using the *Planck* public low-ℓ temperature-only likelihood based on the PR3 CMB map recovered from the `Commander` and the High-ℓ Likelihood on Polarised Power-spectra (`HiLLiPoP`) at $\ell > 30$, and marginalizing over the nuisance and the other ΛCDM cosmological parameters, from the posterior distribution for r the authors[75] derive the currently most stringent upper limit based on *Planck* data alone: $r_{0.05} < 0.056$ at 95% CL.

Finally, in Ref. 75 the *Planck* temperature and polarization data analyzed as summarized above have been combined with the BK15 data, assuming their mutual independence, i.e. simply multiplying their likelihood distributions, as justified given their so different sky coverage, obtaining $r_{0.05} < 0.044$ at 95% CL which currently represents the most stringent upper limit.

[k]The primordial EB is expected to be null in the ΛCDM model. On the other hand, special rotation effects of the polarization field (such as birefringence) can produce some EB signal.

5. Future and alternative perspectives

5.1. *Lorentz invariance violation and CMB polarization*

The standard model of cosmology can explain the CMB radiation from the recombination epoch till today. As discussed above, it predicts the existence of some degrees of linear polarization known as E-modes and B-modes (see also Refs. 79–81). The linear polarization can be induced to the CMB by means of Compton scattering of CMB photons and cosmic electrons in presence of cosmological perturbations. However, the circular polarization for the CMB is a rare process in the standard model of cosmology, so that observation of any level of circular polarization can be a hint for the existence of new physics. The circular polarization for the CMB can be generated through Faraday conversion in which linear polarized light propagates through a medium resulting in different indexes of refraction along the two transverse axes.[82,83] Moreover, the CMB photons scattering from vector or fermionic DM can lead to circular polarization of the CMB.[84,85] Furthermore, circular polarization for the CMB can be induced by electron-photon Compton scattering in presence of a background field such as a magnetic field[82] or non-commutativity in space and time.[83,86]

In this study, we would like to explore the effects of Lorentz invariance violation (LIV) as a new background in the generation of circular polarization (see Ref. 87 for details). To do that we assume the CMB photon and cosmic electron scatter while the particle Lorentz symmetry is violated. To evaluate the LIV effect in the Compton scattering, we focus on an effective field theory approach known as standard model extension (SME). The minimal version of the SME contains every gauge invariant and observer-covariant operator, made by all the standard model (SM) fields which violate Lorentz invariance specified with new couplings.[88] In the SME, LIV is considered in a coordinate that the speed of light is constant c in all frames. The kinetic term in electron sector of electromagnetic quantum electrodynamics (QED) Lagrangian is modified with $c^{\mu\nu}$ tensor as[89]

$$\mathcal{L}_{\rm QED}^{\rm LIV} = \frac{1}{2} i\bar{\psi}(\gamma^{\nu} + c^{\mu\nu}\gamma_{\mu})\overleftrightarrow{D}_{\mu}\psi - \bar{\psi}m_e\psi\,, \tag{7}$$

where $\mathcal{D}_{\mu}$ represents the covariant derivative with $u\overleftrightarrow{D}^{\mu}v \equiv uD^{\mu}v - vD^{\mu}u$, ψ is the fermion field, γ_{μ} indicates the Dirac gamma matrices, and the mass of electron is m_e. We assume $c^{\mu\nu}$ to be symmetric and traceless tensor. The $c^{\mu\nu}$ tensor depends on the frame and it is estimated in the standard reference frame, i.e. Sun-centered, celestial equatorial frame (SCCEF).[90] All the available bounds on LIV parameters are given in SCCEF frame to be comparable with each other. Therefore, we also use correlation between components of laboratory frame and SCCEF given in Ref. 90 to transfer the result to SCCEF frame.

The polarization of the scattered CMB photon from cosmic electron in presence of LIV is characterized by four Stokes parameters:[79] $[I, Q, U, V]$. I indicates the overall radiation intensity, Q and U represent linear polarization and V is circular

polarization of the CMB radiation satisfying the inequality $I^2 \geq Q^2 + U^2 + V^2$. The time evolution of Stokes parameters, defining the CMB polarization, can be expressed through the quantum Boltzmann equation, schematically as[79]

$$\frac{df}{dt} = C[f]\,, \tag{8}$$

where the left-hand side involves time derivative of Stokes parameters which includes the gravitational effects and space time structure; besides, all possible interactions appear at the right-hand side of Boltzmann equation.

After expanding the intensity and polarization of the CMB radiation in terms of multipole moments in spin-weighted basis, the Boltzmann equations regarding to electron-photon Compton scattering in presence of LIV by considering only scalar perturbation in the metric, are obtained as

$$\begin{aligned}
&\frac{d}{d\eta}\Delta_I^{(S)} + iK\mu\Delta_I^{(S)} + 4[\dot{\psi} - iK\mu\varphi] = C_{e\gamma}^I \\
&\frac{d}{d\eta}\Delta_P^{\pm(S)} + iK\mu\Delta_P^{\pm(S)} = C_{e\gamma}^{\pm} - i\kappa_{\rm LIV}^{\pm}\,\Delta_V^{(S)} \\
&\frac{d}{d\eta}\Delta_V^{(S)} + iK\mu\Delta_V^{(S)} = C_{e\gamma}^V + \frac{i}{2}\Big[\kappa_{\rm LIV}^{+}\,\Delta_P^{-(S)} + \kappa_{\rm LIV}^{-}\,\Delta_P^{+(S)}\Big]\,;
\end{aligned} \tag{9}$$

here η is the conformal time, ψ and ϕ are the scalar perturbation corresponding to the potential of Newton and the spatial curvature perturbation, μ is the scalar product of the wave vector $\mathbf{K}$ and the CMB photon propagating direction, $\Delta_P^{\pm(S)} = Q^{(S)} \pm iU^{(S)}$ is a linear combination of linear polarizations, $C_{e\gamma}^I$, $C_{e\gamma}^{\pm}$ and $C_{e\gamma}^V$ indicate the involvement of the SM Compton scattering in $\Delta_P^{\pm(S)}$ and $\Delta_V^{(S)}$ parameters, respectively. In presence of LIV, the terms $\kappa_{\rm LIV}$ and $\kappa_{\rm LIV}^{\pm}$ in Eq. (9) are given by

$$\kappa_{\rm LIV} = -a(\eta)\,\frac{3}{4}\,\frac{\sigma_T}{\alpha}\,\frac{m_e^2}{k_0}\,\frac{\bar{n}_e}{m_e}\,,\;\; \kappa_{\rm LIV}^{\pm} = \kappa_{\rm LIV}\, c_{\{\alpha\beta\}}(\rho_Q^{\{\alpha\beta\}} \pm i\rho_U^{\{\alpha\beta\}})\,; \tag{10}$$

they define the Compton scattering contribution, k_0 being the momentum of the CMB photon. In general, the CMB polarization at the direction $\hat{\mathbf{n}}$ and at the present time η_0 is derived by integrating Eq. (9) along the line of sight and summing over all Fourier modes $\mathbf{K}$. The circular polarization due to LIV Compton scattering can finally be estimated in terms of linear polarization as follows

$$\begin{aligned}
\Delta_V^{(S)}(\mathbf{K},\mu,\eta_0) \approx \frac{1}{2}\int_0^{\eta_0} d\eta\,\dot{\eta}_{e\gamma}\,e^{ix\mu-\eta_{e\gamma}}\;\Big[&3\mu\Delta_{V1}^{(S)} + 2i\,\rho_Q^{\{\alpha\beta\}}c_{\{\alpha\beta\}}\,\frac{\kappa_{\rm LIV}}{\dot{\eta}_{e\gamma}}\,\Delta_P^{(S)} \\
&+ 2\,\frac{\kappa_{\rm LIV}^{-}\kappa_{\rm LIV}^{+}}{\dot{\eta}_{e\gamma}^2}\Delta_V^{(S)}\Big]\,,
\end{aligned} \tag{11}$$

where

$$\Delta_P^{(S)}(\mathbf{K},\mu,\eta) = \int_0^{\eta} d\eta\,\dot{\eta}_{e\gamma}\,e^{ix\mu-\eta_{e\gamma}}\;\Big[\frac{3}{4}(1-\mu^2)\Pi(K,\eta)\Big]\,, \tag{12}$$

$$\rho_Q^{\{\alpha\beta\}} = -\Big[\epsilon^1\cdot\hat{c}\cdot\epsilon^2 + \sum_{f=e,p}\frac{m_f v_b^2}{2k_0}(\hat{v}\cdot\epsilon^2\hat{v}\cdot\hat{c}\cdot\epsilon^1 + \hat{v}\cdot\epsilon^1\hat{v}\cdot\hat{c}\cdot\epsilon^2) - \frac{v_b}{2}(\hat{v}\cdot\epsilon^2\hat{k}\cdot\hat{c}\cdot\epsilon^1 + \hat{v}\cdot\epsilon^1\hat{k}\cdot\hat{c}\cdot\epsilon^2)\Big], \quad (13)$$

$\Pi = \Delta_{T2}^{(S)} + \Delta_{P2}^{(S)} + \Delta_{P0}^{(S)}$ and $\dot{\eta}_{e\gamma} = a(\eta)n_e\sigma_T$ and $\eta_{e\gamma} = \int_\eta^{\eta_0}\dot{\eta}_{e\gamma}(\eta)d\eta$ are the differential optical depth and total optical depth. For a detail calculation of Eqs. (9)-(13) see Ref. 87. The angular PS, C_ℓ^V, arisen from CMB-cosmic electron forward scattering in presence of LIV is obtained as

$$C_\ell^V \approx \frac{1}{2\ell+1}\int d^3K P_v(\mathbf{K})\times \sum_m \Big|\int d\Omega Y_{l\ell m}^*\int_0^{\eta_0} d\eta\,\dot{\eta}_{e\gamma}\,e^{ix\mu-\eta_{e\gamma}}\,2i\,\rho_Q^{\{\alpha\beta\}}c_{\{\alpha\beta\}}\,\frac{\kappa_{\rm LIV}}{\dot{\eta}_{e\gamma}}\,\Delta_P^{(S)}\Big|^2; \quad (14)$$

here $P_v(\mathbf{K})$ indicates the velocity PS which can be estimated as a function of primordial scalar spectrum $P_v(\mathbf{K},\tau)\sim P_\phi^{(S)}(\mathbf{K},\tau)$. Therefore, we can estimate the C_ℓ^V in terms of linearly polarized angular PS as follows:

$$C_\ell^V \approx (\tilde{\kappa}_{\rm LIV}^{\rm avg})^2 C_\ell^P, \quad (15)$$

with

$$\tilde{\kappa}_{\rm LIV} = c_{\{\alpha\beta\}}\,\rho_Q^{\{\alpha\beta\}}\frac{\kappa_{\rm LIV}}{\dot{\tau}_{e\gamma}}, \qquad \tilde{\kappa}_{\rm LIV}^{\rm avg} = \frac{1}{z_{lss}}\int_0^{z_{lss}} dz\;\tilde{\kappa}_{\rm LIV}(z)\simeq 10^{-3}, \quad (16)$$

where $\tilde{\kappa}_{\rm LIV}^{\rm avg}$ is average of $\tilde{\kappa}_{\rm LIV}(z)$ over redshift from last scattering surface, $z_{lss}\simeq 1100$, up to today, $z=0$. Based on recent experimental astrophysics bounds on different components of $c^{\alpha\beta}$ tensor,[91] we assume all component of $c^{\alpha\beta}$ tensor at the order of 10^{-15}. Considering the experimental value for the CMB linearly polarized angular PS of the order of[92] $C_\ell^P\equiv 0.1\mu{\rm K}^2$ for $\ell<250$, we can estimate the V-mode angular PS arisen from Compton scattering in presence of LIV as follows:

$$C_\ell^V \approx 0.8\ {\rm nK}^2\Big(\frac{c^{\alpha\beta}}{10^{-15}}\Big)^2. \quad (17)$$

The current experimental bound on the circular polarization coming from the Cosmology Large Angular Scale Surveyor (CLASS) experiment with the 40 GHz polarimeter ranging from $0.4\mu{\rm K}^2$ to $13.5\mu{\rm K}^2$ for $1\leq\ell\leq 120$. We expect that by improving the sensitivity of experiments in future, the constraint obtained in Eq. (17) would be comparable to experimental bounds.

5.2. *New gravitational degrees of freedom and the DM problem*

The nature of DM is the deepest problem of modern cosmology. Assuming GR, DM appears to be a necessary ingredient in theoretical models constructed for explaining astrophysical and cosmological observations on $\sim$ kpc scales or larger. This essentially boils down to a mismatch between the observed dynamics of visible matter and its gravitational influence. Many theories of what is DM have been proposed.[93]

The DM microphysical nature, however, is not crucial to explain many cosmological observations. This leads to a simple description so that the DM dynamics are effectively governed by the collisionless Boltzmann equation, coupled to gravity.

The less explored alternative is that DM is not the cause behind all these observed phenomena, but rather that GR (and also Newtonian gravity) breaks down at ultra-low curvatures and gravitational accelerations and a new description of gravity is necessary. Changing the law of gravity, however, is not as arbitrary as it may seem.[94] Lovelock's theorem[95] tells us that GR is the unique 4-dimensional theory based on a local and diffeomorphism-invariant action where the metric is the only dynamical degree of freedom. If a non-GR gravitational theory is then assumed to explain the DM phenomenon, it is inevitable that one or more of these assumptions must be broken, and this generically leads to new dynamical degrees of freedom, that is, new dynamical fields.

Milgrom proposed[96–98] that DM is only an apparent phenomenon and that one can instead fit galactic rotation curves via a modification of the inertia/dynamics of baryons or of the gravitational law, when accelerations become smaller than $a_0 \sim 1.2 \times 10^{-10}\,\mathrm{m/s^2}$. Modifying the gravitational law was further explored by Bekenstein & Milgrom[99] who proposed that when the gradients of the potential Φ are smaller than a_0, non-relativistic gravity is effectively governed by

$$\nabla \cdot \left(\frac{|\nabla \Phi|}{a_0} \nabla \Phi \right) = 4\pi G_{\mathrm{N}} \rho \,, \tag{18}$$

where G_{N} is the Newtonian gravitational constant, and ρ the matter density. These type of models are referred to as Modified Newtonian Dynamics (MOND).

MOND has enjoyed success in fitting galactic rotation curves and reproducing the baryonic Tully-Fisher relation, while on GC scales it is found that either a_0 must be larger by a factor of $4 \div 5$ or that some DM is still needed at GC cores; see Ref. 100 for a review. As MOND is inherently non-relativistic, it is difficult to test in cosmological settings, since systems such as the CMB require a relativistic treatment. Relativistic theories that yield MOND behavior have been proposed, the most well-known being the Tensor-Vector-Scalar (TeVeS) theory,[101,102] making clear predictions regarding gravitational lensing and cosmology. In cases where the CMB and matter power spectra (MPS) have been computed, no theory has been shown to fit *all* of the cosmological data while preserving MOND phenomenology in galaxies. TeVeS in particular can be compatible with the MPS of large scale structure[103,104] but fails to fit the CMB. Moreover, it leads to a tensor mode gravitational wave (GW) speed different than the speed of light,[105] in contradiction with the Laser Interferometer Gravitational-Wave Observatory (LIGO)/Virgo observations of GW along with an electromagnetic counterpart.

The non-relativistic equation (18) can only be an effective description, due to Lovelock's theorem. To make it into a fully fledged relativistic theory, one can introduce additional fields. Building on TeVeS and later developments,[105,106] Skordis & Zlosnik[107] proposed a simple relativistic theory which in addition to the metric

$g_{\mu\nu}$ has a scalar field ϕ and unit time-like vector field A^μ. Perturbing these fields on a Minkowski background, results in perturbations of ϕ and A_μ which mix with the metric perturbation via gauge transformations, i.e. the metric potentials mix with the perturbations of ϕ and A_μ. Thus, ϕ and A_μ are gravitational fields and not DM fields, because due to this mixing it is impossible to distinguish observationally which of the three is the cause behind the "DM phenomenon", in analogy to the electric/magnetic field mixing resulting in the electromagnetic field.

The theory contains a free function $\mathcal{F}(\mathcal{Y},\mathcal{Q})$ of two arguments: $\mathcal{Q} = A^\mu\nabla_\mu\phi$ and $\mathcal{Y} = q^{\mu\nu}\nabla_\mu\phi\nabla_\nu\phi$ where $q_{\mu\nu} = g_{\mu\nu} + A_\mu A_\nu$ is the 3-metric orthogonal to A^μ. It must obey certain conditions in order for the theory to serve its purpose and to be observationally viable. To recover MOND on galactic scales, it is necessary that the reduced function $\mathcal{J}(\mathcal{Y}) \equiv \mathcal{F}(\mathcal{Y},\mathcal{Q}_0)/(2-K_\mathrm{B})$ where $\mathcal{Q}_0$ is a non-zero constant, has the limit $\mathcal{J} \to \mathcal{Y}^{3/2}/a_0$ when $\mathcal{Y} \sim |\nabla\varphi|^2$ is small. Imposing that and considering virialized systems in the weak-field approximation, leads to linear equations involving the metric potential Φ and a scalar perturbation φ, sourced by the (baryonic) matter density. These contain an additional term which is not present in MOND, but looks like a mass term for the potential, $\mu^2\Phi$, where here $\mu^2 = 2\mathcal{K}_2\mathcal{Q}_0^2/(2-K_\mathrm{B})$. It is determined by the other parameters of the theory: $\mathcal{Q}_0$, appearing in as part of the free function, K_B, related to the coupling strength of the vector field and taking values in the range $0 < K_\mathrm{B} < 2$, and $\mathcal{K}_2$, related to the coupling strength of the scalar field. In addition, the resulting equations depend on Milgrom's constant a_0. Thus in the quasistatic weak-field situation, at least two parameter combinations are important: a_0 and μ, although, depending on how the GR limit is attained, there may be further parameters as part of the free function. Due to the presence of the mass term μ, the theory departs from MOND behaviour at ultra-low accelerations determined by μ.

Consider now setups involving the relativistic nature of the theory. The form of the action of the theory ensures that the right amount of gravitational lensing is ensured whenever Φ correctly determines the dynamics and the tensor mode GW speed is equal to the speed of light in all situations. Meanwhile, on Friedmann-Lemaître-Robertson-Walker (FLRW) $\phi = \bar{\phi}(t)$ while A^μ aligns trivially with the time direction so that $\mathcal{Y} \to 0$ and $\mathcal{Q} \to \dot{\bar{\phi}}$ and the action reduces to that of shift-symmetric K-essence[108] and the low-energy limit of the ghost-condensate theory.[109] Defining then the reduced function $\mathcal{K}(\mathcal{Q}) \equiv -\mathcal{F}(0,\mathcal{Q})/2$, we require that $\mathcal{K} \approx \mathcal{K}_2\left(\mathcal{Q}-\mathcal{Q}_0\right)^2 + \ldots$, with non-zero $\mathcal{Q}_0$ (same constants as what appear above), the energy density of ϕ scales precisely as a^{-3}, $a = 1/(1+z)$ being here the cosmic scale factor, i.e. like pressureless matter, plus small corrections. The equation of state and speed of sound of ϕ also scale as a^{-3} and depend on the constants $\mathcal{K}_2$ and $\mathcal{Q}_0$ of the action. In the late universe limit these tend to zero so that the linear perturbations of ϕ and A_μ can be re-casted by linear transformations into a density contrast δ and velocity divergence θ of pressureless matter. In this limit, the field equations of ϕ and A_μ and their contribution to the Einstein equations, become identical to

pressureless-dust equations, i.e. as for CDM. This ensures that the CMB and MPS spectra calculated within this theory, become parametrically close to those from ΛCDM, leading to excellent fits to the CMB angular PS from *Planck* and the MPS obtained from galaxy clustering.

To summarize, the theory is not a MOND extrapolation to cosmology. Rather, it recovers MOND in quasistatic situations on galactic scales, and it tends to ΛCDM behaviour on cosmological scales. It depends on a free function, which is, however, constrained so that these two limits are attained. Doing that, the theory depends on a minimum of 4 parameters, $K_{\rm B}$, $\mathcal{Q}_0$, $\mathcal{K}_2$ and a_0, while additional parameters could be part of the free function and be related to the GR limit or the early universe.

5.3. *Exploiting the magnification bias with high-z sub-mm galaxies*

Magnification bias is due to gravitational lensing and consists in the apparent excess in the number of high-z sources (the lenses sources) close to the position of low-z galaxies (the lenses). In fact, the gravitational lensing deflects the light rays of high-z sources causing the stretching of the apparent sky area in the region affected by the lensing. This also causes a boost in the flux density of the high-z sources, making them more likely to be detected above a given instrument flux density limit (see, e.g., Ref. 110). The magnification bias can be measured through the cross-correlation between the low and high-z objects. Given two source samples with non-overlapping redshift distributions, the excess signal when computing their cross-correlation with respect to the random case is due to the magnification bias. Being such signal related to lensing and thus to cosmological distances and the galaxy halo characteristics, it can be used to constrain cosmological parameters.

In order to get the best cross-correlation measurements, at the moment the optimal choice is to use as high-z sources (background samples) the high-z sub-mm galaxies (SMGs) first of all because of their steep number counts, shown with recent observations by the *Herschel* Space Observatory[111] and the South Pole Telescope[112] (SPT) strengthening their magnification. Moreover, the SMGs are faint in the optical which means that they do not get confused with the foreground lens sample, being such sample invisible at sub-mm wavelength. Lastly, the SMGs redshift are usually above $z > 1$ so that their selection as background sample ensures no overlap with the foreground objects. In fact, due to their extreme magnification bias, Dunne et al. (Ref. 113) make a serendipitous direct observation of high-z SMGs. While performing a study of gas tracers with Atacama Large Millimeter/submillimeter Array (ALMA) observation of galaxies targeting a statistically complete sample of twelve galaxies selected at 250 μm with $z = 0.35$, magnified SMGs appears around the position of half of them.

As shown in Refs. 114, 115, these advantages make the SMGs the perfect background sample for tracing the (baryonic and DM) mass density profiles of galaxies and GCs and their time-evolution and for constraining the free parameters of a

halo occupation distribution (HOD) model. In the adopted HOD model[116] all halos above a mass M_{min} host a central galaxy and those above a mass M_1 host satellites (galaxies in the halo) whose number is a power-law, $(M/M_1)^{\alpha}$, of the halo mass M. In particular, the results in Ref. 114 suggests that the lenses are massive galaxies or GCs, with a minimum mass of $10^{13} M_{\odot}$. Later on, Bonavera et al. (Ref. 115) study with the magnification bias the mass properties of a sample of quasars whose position signpost the lens at $0.2 < z < 1.0$ obtaining a $M_{min} = 10^{13.6^{+0.9}_{-0.4}} M_{\odot}$. This again suggests that the lensing is actually produced by halos of the size of GCs placed close to the quasar positions.

Moreover, some of the main cosmological parameters can be also estimated using the magnification bias, as in Ref. 117. They use the cross-correlation data measured between a foreground sample of Galaxy And Mass Assembly (GAMA) galaxies with spectroscopic redshifts in the range $0.2 < z < 0.8$ and a background sample of *Herschel* Astrophysical Terahertz Large Area Survey (H-ATLAS) galaxies with photometric redshifts $z > 1.2$ to constrain the HOD astrophysical parameters (M_{min}, M_1, and α) and some of the cosmological ones (Ω_M, σ_8, and H_0). These parameters are estimated through a Markov chain Monte Carlo analysis. They obtain a lower limit at 95% CL on $\Omega_M > 0.24$, a slight trend towards $H_0 > 70$ values and a tentative peak around 0.75 with an upper limit at 95% CL of $\sigma_8 < 1$. Such results are summarized in the $\Omega_M - \sigma_8$ plane in Fig. 7 (*left* panel).

Furthermore, magnification bias trough cross-correlation measurements can be used to constrain the halo mass function. In particular, Ref. 118 successfully tests such possibility according to two common parametrizations, the Sheth & Tormen[119] and the Tinker et al.[120] fits.

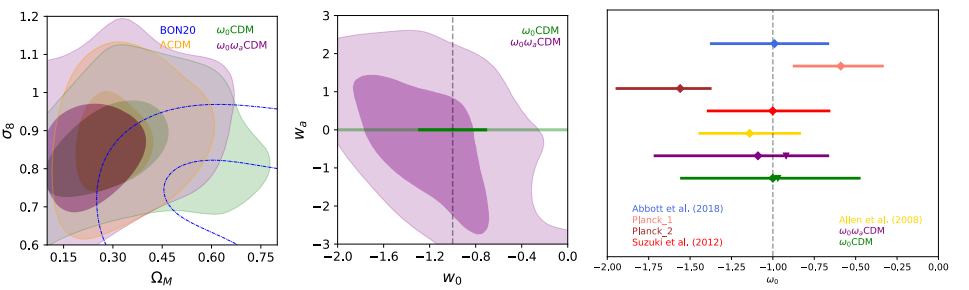

Fig. 7. *Left*: Ω_M and σ_8 contour plot for the non-tomographic case in Ref. 117 (dot-dashed blue line) and the tomographic runs in Ref. 122 for ΛCDM (in yellow), ω_0CDM (in green) and $\omega_0\omega_a$CDM (in purple) models. *Central*: ω_0 and ω_a contour plot for the $\omega_0\omega_a$CDM model. In both panels, the contours of the 2-dimensional posterior distributions are set to 0.393 and 0.865. *Right*: ω_0 results for the ω_0CDM (green) and $\omega_0\omega_a$CDM (purple) models compared with those by DES (blue), *Planck*_1 (base_w_wa_plikHM_TT_lowl_lowE_BAO, salmon), *Planck*_2 (base_w_plikHM_TT_lowl_lowE, brown), Supernovae (red), X-ray measurements (yellow). Adapted from Bonavera et al., A&A, in press, DOI 10.1051/0004-6361/202141521, 2021 (Ref. 122), reproduced with permission from Astronomy & Astrophysics, © ESO.

They find general agreement with traditional values for the involved parameters, with a slight difference in the Sheth & Tormen fit for intermediate and high masses, where the results suggest a hint at a somewhat higher number of halos. Given the large number of studies that can be performed with magnification bias through cross-correlation data, a systematic analysis of possible bias that might affect the estimation is being carried out. In particular, González-Nuevo et al. (Ref. 121) take into account different biases at cosmological scales in the source samples to carefully measure unbiased cross-correlation functions. More precisely, their background sample consists of H-ATLAS galaxies with $z > 1.2$ whereas they use two independent foreground samples with $0.2 < z < 0.8$: GAMA galaxies with spectroscopic redshifts and Sloan Digital Sky Survey (SDSS) galaxies with photometric redshifts. These independent samples allowed them to perform a pseudo-tomographic study that yields to constrain $\Omega_M = 0.50^{+0.14}_{-0.20}$ and $\sigma_8 = 0.75^{+0.07}_{-0.10}$. Such analysis also suggests that a tomographic approach might improve the results.

Driven by the conclusions mentioned above, adopting the unbiased sample by Ref. 121, Bonavera et al.[122] use magnification bias in tomography to jointly constrain the HOD astrophysical parameters in each selected redshift bin together with the Ω_M, σ_8, and H_0 cosmological ones in the ΛCDM scenario and for DE models in the ω_0CDM and $\omega_0\omega_a$CDM frameworks characterized by the ω_0 and ω_a parameters defining the DE barotropic index as $\omega(a) = \omega_0 + \omega_a(1 - a)$. The foreground sample has been divided into four redshift bins (0.1–0.2, 0.2–0.3, 0.3–0.5 and 0.5–0.8) and the sample of H-ATLAS galaxies has photometric redshifts $z > 1.2$. As for the HOD parameters, M_{min} shows a trend towards higher values at higher z confirming the findings in Ref. 114. For the ΛCDM model, they obtain a maximum posterior value [68% CL] of $\Omega_M = 0.26$ [0.17,0.41] and of $\sigma_8 = 0.87$ [0.75,1] (implying $S_8 \simeq 0.81$, in good agreement with the result in Sect. 4.1), being H_0 not yet constrained. For the ω_0CDM model, they find similar results on Ω_M and σ_8 and a maximum posterior value [68% CL] of $\omega_0 = -1$ $[-1.56, -0.47]$. For the $\omega_0\omega_a$CDM model, $\omega_0 = -1.09$ $[-1.72, -0.66]$ and $\omega_a = -0.19$ $[-1.88, 1.48]$. Fig. 7 shows the results in the $\Omega_M - \sigma_8$ plane for the ΛCDM, ω_0CDM and $\omega_0\omega_a$CDM models (*left* panel) and in the $\omega_0 - \omega_a$ plane (*central* panel). The results on ω_0 for the ω_0CDM and $\omega_0\omega_a$CDM cases are shown in Fig. 7 (*right* panel), together with a comparison with other results from literature. Moreover, the tomographic analysis presented in Ref. 122 confirms that magnification bias results do not show the degeneracy found with cosmic shear measurements and that, related to DE, do show a trend of higher ω_0 values for lower H_0 values (see Ref. 123 for details).

In conclusion, SMGs turn out to be a perfect background sample for magnification bias analyses, useful in astrophysical studies and as a further independent cosmological probe for ΛCDM and beyond ΛCDM models and this can be implemented adopting different foreground samples. Up to now ΛCDM compatible results have been found with tomographic and non-tomographic approaches and serendipitous direct observation of magnified SMGs have been performed with ALMA.

We initiate a new method for probing inflationary models that can produce primordial black hole populations, using only CMB physics at relatively large scales. In these scenarios, profile of the primordial scalar power spectrum exhibit a universal dip feature that is followed by a rapid growth towards small scales, leading to a peak responsible for PBH formation. Focusing on scales around the dip that are well separated from the peak, we first analytically compute expressions for the curvature bispectrum. We then show that the amplitude of the bispectrum is enhanced for the squeezed configuration around the position of the dip, and it acquires a characteristic scale dependence that can be probed by cross correlations between CMB μ-distortions and temperature anisotropies. We quantitatively study the properties of such cross-correlations and how they depend on the underlying model, discussing how they can be tested by the next generation of CMB μ-distortion experiments. This method allows one to experimentally probe inflationary PBH scenarios using well-understood CMB physics, without considering non-linearities associated with PBH formation and evolution.

Keywords: Inflation, Primordial Black Holes, CMB distortions

1. Introduction

Gravitational waves from merging black holes, in conjunction with other probes, can be used for testing our understanding of cosmology. There is the intriguing possibility that part of black holes from merging events have primordial origin, arising from the collapse of overdense regions in the early stages of our universe evolution.[1–3] The existence of such overdense regions might be attributed to the dynamics of inflationary cosmology. In this framework, it is well known that to produce primordial black holes (PBHs) (see *e.g.* reviews[4–7]) with astrophysically relevant masses, the primordial scalar power spectrum should increase by several orders of magnitude with respect to its values at large CMB scales. Within the context of single-field inflation, such an amplification can be realized during a short slow-roll violating non-attractor period during which the would-be decaying mode grows to influence evolution of super-horizon fluctuations. In this set-up, a peak in the curvature perturbation spectrum can be produced, and the non-linear process

of PBH production and subsequent evolution depends on the details of the peak, as first explicitly discussed in.[8]

The possible existence of primordial black hole (PBH) populations in our universe demands a detailed understanding of inflationary mechanisms that can give rise to them. Intriguingly, in inflationary scenarios capable of producing PBHs, the profile of the spectrum shows universal features such as the existence of pronounced dip, followed by a rapid growth with a well defined slope[9] towards its peak. The position of the dip is not random, but depends on other global properties of the spectrum, as well as on details of the non-attractor inflationary evolution.[10] It typically occurs at scales much larger than the peak, $k_{\rm dip}/k_{\rm peak} \simeq 10^{-2}$. Since the occurrence of dip seems to be a rather universal feature of power spectrum in single-field models of PBH formation, probing the physics associated with it offers an indirect way of testing these models, independently of the details of non-linear PBH formation and evolution mechanisms.

In this work, we ask whether we can probe the PBH formation mechanism by identifying large scale observables away from the scales associated with the peak of the spectrum.[11] For this purpose, we focus on scales around the dip feature to compute bispectrum of curvature perturbation analytically using the gradient expansion formalism[12,13] and show that it is generically amplified around the dip scale for squeezed configurations, exhibiting a characteristic scale dependence. We then show the influence of such a scale dependent squeezed bispectrum on the properties of cross-correlations between μ distortions and temperature T anisotropies and discuss the prospects of detectability of the $\langle \mu T \rangle$ signal with future spectral distortion experiments.

2. Curvature perturbation at super-horizon scales

Models of primordial black hole (PBH) formation based on single field inflation often include a short phase of non-attractor evolution, characterized by a transient growth of would be the decaying mode which influences the super-horizon evolution of cosmological scalar perturbations[a]. In this section, we review and utilize the *gradient expansion formalism*[b] – first introduced in[12] – to study the statistics of curvature fluctuations in scenarios including a transient non-attractor phase. In this framework, iterative solutions of the comoving curvature perturbation are generated at any desired order in a small-k expansion, in terms of analytic functions controlled by the background evolution. For example, the amplitude of curvature fluctuations at a fiducial late time $\tau = \tau_*$ (*e.g.* at the reheating surface) is mapped to its value at an initial time around horizon exit $\tau = \tau_k$ in terms of a complex-valued k-dependent

[a]Direct enhancement of tensor perturbations on super-horizon scales can be also achieved by devising an analogue non-attractor phase within the generalized scalar-tensor theories of single field inflation.[14,15]

[b]For a detailed account on the spectral profile of the scalar power spectrum that leads to PBH formation and its applications in the context of induced gravitational waves, we refer the reader to[13] where further developments of the gradient expansion formalism is discussed.

coefficient:

$$\mathcal{R}_k(\tau_*) = \alpha_k \mathcal{R}_k(\tau_k) = \left(\alpha_k^R + i\alpha_k^I\right) \mathcal{R}_k(\tau_k)\,, \tag{1}$$

where in the last equality we split the enhancement factor into its real and imaginary parts:

$$\alpha_k \equiv \alpha_k^R + i\alpha_k^I\,. \tag{2}$$

Once expanded up to second, k^2-order in the gradient expansion, the real and imaginary parts of α_k are given by

$$\alpha_k^R = 1 + D(\tau_k)\, v_{\mathcal{R}}^R - F(\tau_k)\, k^2, \tag{3}$$

$$\alpha_k^I = D(\tau_k)\, v_{\mathcal{R}}^I\,. \tag{4}$$

The quantity $v_{\mathcal{R}}^R$ and $v_{\mathcal{R}}^I$ denote the real and imaginary part of the k-dependent fractional velocity of the curvature perturbation, which is defined as

$$v_{\mathcal{R}}(\tau_k) = \left.\frac{\mathcal{R}_k'}{3\mathcal{H}_k\mathcal{R}_k}\right|_{\tau=\tau_k}\,. \tag{5}$$

The full k dependence of the expressions (3) and (4) on super-horizon scales is encoded in the quantities $v_{\mathcal{R}}^R$, $v_{\mathcal{R}}^I$ and in the functions $D(\tau_k), F(\tau_k)$ (see Appendix A and B), given by the following nested integrals of the pump field appearing in Eq. (15)[12, 13]:

$$D(\tau) = 3\mathcal{H}_k \int_{\tau}^{\tau_*} \mathrm{d}\tau' \, \frac{z^2(\tau_k)}{z^2(\tau')}\,, \tag{6}$$

$$F(\tau) = \int_{\tau}^{\tau_*} \frac{d\tau'}{z^2(\tau')} \int_{\tau_k}^{\tau'} \mathrm{d}\tau'' z^2(\tau'')\,. \tag{7}$$

Expressions (6) and (7) indicate that if the pump field increases with time – as in standard slow-roll inflation, where $z \propto a(\tau)$ – the functions D, F rapidly decrease to zero after horizon crossing (*i.e.* $\alpha_k \to 1$). Hence the curvature perturbation in (1) settles to a constant shortly after horizon exit ($\mathcal{R}_k(\tau_*) \simeq \mathcal{R}_k(\tau_k)$). On the contrary, in inflationary models containing phases of non-attractor evolution, $z(\tau)$ transiently decreases and the functions D, F can grow, amplifying the spectrum of curvature perturbation with $|\alpha_k| \gg 1$ at super-horizon scales: see Appendix B.

The curvature perturbation power spectrum. We define the late-time power spectrum evaluated at $\tau = \tau_*$ as

$$\langle \mathcal{R}_k(\tau_*) \mathcal{R}_{k'}(\tau_*) \rangle = (2\pi)^3\, P_{\mathcal{R}}(\tau_*, k)\, \delta\left(\vec{k} + \vec{k}'\right)\,. \tag{8}$$

Using Eq. (1), we can then relate the power spectrum at late times to the power spectrum evaluated at horizon crossing via

$$P_{\mathcal{R}}(\tau_*, k) \equiv \frac{2\pi^2}{k^3}\mathcal{P}_{\mathcal{R}}(\tau_*, k) = \frac{2\pi^2}{k^3}\left[\, |\alpha_k|^2\, \mathcal{P}_{\mathcal{R}}(\tau_k)\,\right] \equiv |\alpha_k|^2 P_{\mathcal{R}}(\tau_k), \tag{9}$$

where $\mathcal{P}_{\mathcal{R}}(\tau_k) \equiv k^3 P_{\mathcal{R}}(\tau_k, k)/2\pi^2$, and $|\alpha_k|^2 = (\alpha_k^R)^2 + (\alpha_k^I)^2$.

A non-linear expression for $\mathcal{R}$. We assume that $\mathcal{R}_k(\tau_k)$ is a Gaussian random variable: nevertheless, the super-horizon evolution typically introduces non-linearities. In fact, we can go beyond the linear theory used for Eq. (1) to compute the bispectrum of the late time curvature perturbation $\mathcal{R}_k(\tau_*)$. For the purpose of deriving an analytic expression for the bispectrum, we will use the following non-linear expression for the curvature perturbation, first derived in[16]

$$\mathcal{R}_k(\tau_*) = \alpha_k \mathcal{R}_k(\tau_k) + \frac{F(\tau_k)}{2}\left\{\int \frac{\mathrm{d}^3k'}{(2\pi)^3}\left[4k'^2 - \vec{k}'.(\vec{k}-\vec{k}')\right]\mathcal{R}_{k'}(\tau_{k'})\mathcal{R}_{|\vec{k}-\vec{k}'|}(\tau_{|\vec{k}-\vec{k}'|})\right\}. \tag{10}$$

where the last term represents the non-linear contribution parametrized by the convolution of the Gaussian variable $\mathcal{R}_k(\tau_k)$.

Bispectrum. We define the late-time bispectrum of curvature perturbations as

$$\langle \mathcal{R}_{k_1}(\tau_*)\mathcal{R}_{k_2}(\tau_*)\mathcal{R}_{k_3}(\tau_*)\rangle = (2\pi)^3 B_{\mathcal{R}}\left(k_1,k_2,k_3\right)\delta\left(\vec{k}_1+\vec{k}_2+\vec{k}_3\right), \tag{11}$$

and using (10), at leading order in the non-linear term, the bispectrum is given by[16,17]

$$B_{\mathcal{R}} = \frac{(2\pi^2)^2}{2(k_1k_2k_3)^3}\Big[\mathrm{Re}[\alpha^*_{k_1}\alpha_{k_2}]F(\tau_{k_3})\left\{5\left(k_1^2+k_2^2\right)-k_3^2\right\}k_3^3\,\mathcal{P}_{\mathcal{R}}(\tau_{k_1})\mathcal{P}_{\mathcal{R}}(\tau_{k_2}) + \text{ perms }\Big], \tag{12}$$

where the permutations are cyclic among the three external momenta $\{\vec{k}_1,\vec{k}_2,\vec{k}_3\}$. Correspondingly, we define the scale-dependent non-linearity parameter $f_{\rm NL}$ as

$$f_{\rm NL}\left(k_1,k_2,k_3\right) = \frac{5}{6}\frac{B_{\mathcal{R}}\left(k_1,k_2,k_3\right)}{\left[P_{\mathcal{R}}\left(\tau_*,k_1\right)P_{\mathcal{R}}\left(\tau_*,k_2\right)+\text{ perms }\right]}, \tag{13}$$

Using (9) and (12) in (13), we then obtain the scale-dependent $f_{\rm NL}$ as

$$f_{\rm NL} = \frac{5}{12}\frac{\left(\mathrm{Re}[\alpha^*_{k_1}\alpha_{k_2}]F(\tau_{k_3})\left\{5\left(k_1^2+k_2^2\right)-k_3^2\right\}k_3^3\,\mathcal{P}_{\mathcal{R}}(\tau_{k_1})\mathcal{P}_{\mathcal{R}}(\tau_{k_2})+\text{ perms }\right)}{\left[\left|\alpha_{k_1}\alpha_{k_2}\right|^2\mathcal{P}_{\mathcal{R}}\left(\tau_{k_1}\right)\mathcal{P}_{\mathcal{R}}\left(\tau_{k_2}\right)k_3^3+\text{ perms }\right]}. \tag{14}$$

Eq. (14) inform us that the size and the scale-dependence of the $f_{\rm NL}$ parameter depend on the function $F(\tau_k)$ and the enhancement factor α_k, whose behavior is tightly related with the background dynamics during inflation. We now turn to study the scale dependence of the power spectrum and bispectrum on a representative set-up capable of producing a large PBH population during inflation.

2.1. *Characteristics of the scalar power and bispectrum*

In order to study the spectral shape and enhancement in the power spectrum and bispectrum, we consider a representative scenario that instantly connects at $\tau = \tau_0$

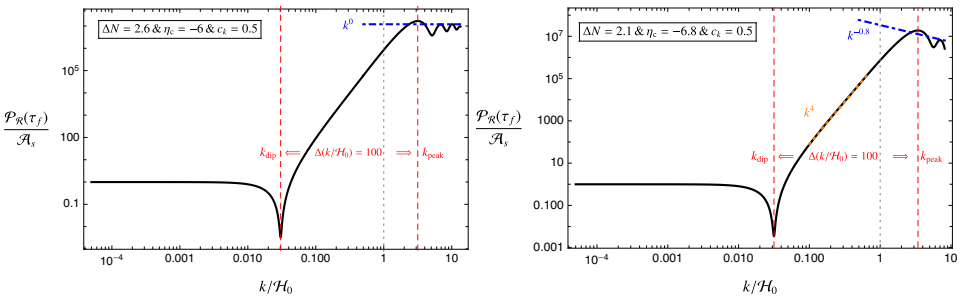

Fig. 1. Scale dependence of the power spectrum for an example ultra slow-roll model ($\eta_{\rm c} = -6$) (Left) and constant-roll model ($\eta_{\rm c} = -6.8$)(Right) as function of $k/\mathcal{H}_0$. The vertical gray-dotted lines separate the interval of wave-numbers leaving the horizon during the initial slow-roll era (left side) and the non-attractor era (right side). We define $\mathcal{A}_s = H^2/(8\pi^2\epsilon_{\rm sr}M_{\rm pl}^2)$.

an initial slow-roll era, with $\eta_{\rm sr} = 0$, to a slow-roll violating, non-attractor phase with constant $\eta_{\rm c} \leq -6$ lasting until $\tau = \tau_f$. Here η denotes the second slow-roll parameter, $H\,\eta \equiv d\ln\epsilon/dt$ and the first slow-roll parameter is given by $H\,\epsilon = -d\ln H/dt$. The pump field $z(\tau)$ appearing in the eqs. (6) and (7) is assumed to have a profile (we take $\tau < 0$):

$$z(\tau) = \begin{cases} z_0\,(\tau/\tau_0)^{-1} & \tau/\tau_0 \geq 1\,, \\ z_0\,(\tau/\tau_0)^{-(\eta_{\rm c}+2)/2} & \tau_f/\tau_0 \leq \tau/\tau_0 \leq 1\,, \end{cases} \tag{15}$$

describing collectively the initial slow-roll and the slow-roll violating phases, the latter being controlled by the negative $\mathcal{O}(1)$ "slow-roll" parameter η_c. The duration of the non-attractor phase can be parametrized as $\Delta N = \ln(\tau_0/\tau_f)$ in e-fold numbers. We relate the quantity z_0 with a constant slow-roll parameter $\epsilon_{\rm sr}$ via $z_0 = -a(\tau_0)\sqrt{2\epsilon_{\rm sr}}M_{\rm pl}$. For simplicity we parameterize the scale factor as in de Sitter space: $a = -1/(H\tau)$ with a constant Hubble rate H during inflation. We also indicate with $\mathcal{H}_0$ the size of the comoving horizon at the time of the transition to the non-attractor era.

Spectral profile of the power spectrum: We proceed with determining the corresponding growth rate of the power spectrum. For this purpose, we first re-write the dimensionless power spectrum as (see *e.g.* Eq. (9)),

$$\mathcal{P}_{\mathcal{R}}(\tau_f, k) \equiv |\alpha_k|^2\mathcal{P}_{\mathcal{R}}(\tau_k) = \left[(\alpha_k^R)^2 + (\alpha_k^I)^2\right]\mathcal{P}_{\mathcal{R}}(\tau_k)\,, \tag{16}$$

and we evaluate this quantity at the end of the non-attractor era $\tau_* = \tau_f$, to characterize the shape of the power spectrum using α_k^R (3), α_k^I (4) and $\mathcal{P}_{\mathcal{R}}(\tau_k)$ with the help of formulas we derived in Appendix A and B. In this way, we represent our results in Figure 1 for two different sets of parameters associated with the two-phase model of PBH formation characterized by the pump field profile of (15). For understanding the physical implications of our findings within the gradient expansion formalism, it is convenient to introduce a fixed quantity

$$c_k \equiv -k\tau_k \leq 1\,, \tag{17}$$

which determines the size of a mode k with respect to the horizon $(aH)^{-1}$ at time $\tau = \tau_k$, corresponding to the horizon crossing epoch. We stress that by virtue of the relation (17) and the super-horizon gradient formalism, all modes we consider in Figure 1 (and in general in this work) are outside the horizon at the initial time τ_k. We then distinguish modes whose momenta lie in the following ranges:

i) modes that become super-horizon during the initial slow-roll era, *i.e.* modes satisfying $\tau_k/\tau_0 > 1$ or equivalently $k/\mathcal{H}_0 < c_k \leq 1$, and
ii) modes that leave the horizon during the non-attractor $\eta_c \leq -6$ phase, $c_k < k/\mathcal{H}_0$.

Focusing on these regimes separately, we discuss below the spectral behavior of $\mathcal{P}_\mathcal{R}$ and some of its global features.

The behaviour of late time $\mathcal{P}_\mathcal{R}$ shown in Figure 1 reflects the accuracy of the gradient expansion formalism in capturing characteristic features of the power spectrum in inflationary backgrounds that transiently violates slow-roll conditions which is required to generate PBHs.[18] In particular, we notice a pronounced dip feature occurring at relatively large scales, associated with modes that still leave the horizon in the initial slow-roll era (*i.e.* $k_{\rm dip} \ll \mathcal{H}_0$) far away from the peak, which occurs at $k_{\rm peak} \simeq 3\mathcal{H}_0$.[19] The presence of such a pronounced dip in the spectrum is a universal feature, being virtually present in all single field models based on non-attractor evolution that are aiming to generate a sizeable peak in the power spectrum for producing PBH, say of order 10^7 (see e.g.[20–29]).

The dip and its properties. It is worth mentioning that such dip feature arise due to competing contributions that appear in the power spectrum that are weighted by opposite signs.[35] The properties of the dip feature turn out to be related with global features of the spectrum profile. As shown in a recent work,[10] the location of the dip position $k_{\rm dip}$ in momentum space can be related with a characteristic pivot scale $k_\star$ associated with the duration of non-attractor evolution by the expression $k_{\rm dip}/k_\star \simeq \mathcal{O}(1) \times (\Delta\mathcal{P}_\mathcal{R}/\mathcal{P}_\mathcal{R})^{-1/4}$. For the scenarios we consider with a pronounced peak in the power spectrum, we expect $k_\star$ to be related with $k_{\rm peak}$, and $(\Delta\mathcal{P}_\mathcal{R}/\mathcal{P}_\mathcal{R})^{-1/4} \simeq \left(10^7\right)^{-1/4} \simeq 10^{-2}$. A close examination of Figure 1 confirms these arguments and shows that

$$k_{\rm dip} \simeq 10^{-2}\, k_{\rm peak} \tag{18}$$

is a robust relation, valid in all single field inflationary scenarios that can produce a pronounced peak in the power spectrum. In light of these considerations, we assume (18) for the rest of this work.

Spectral profile of the bispectrum: Let us concentrate on modes that exit during the initial slow-roll era, $k/\mathcal{H}_0 < c_k$, to investigate the scale-dependence of the bispectrum. We expect the bispectrum to have features and be amplified around the scale $k_{\rm dip}$ corresponding to the position of the dip in the power spectrum: in fact, non-linearities are usually enhanced at the location of rapid changes in the

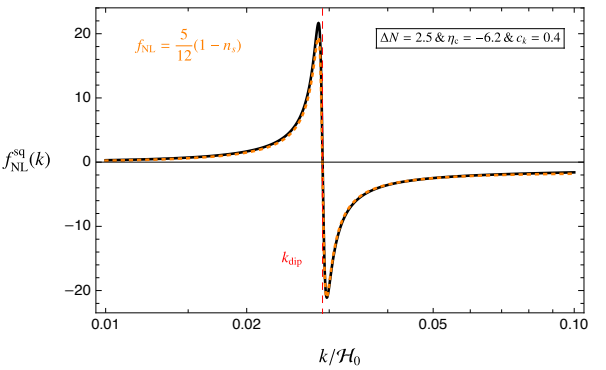

Fig. 2. Scale dependence of the non-linearity parameter $f_{\rm NL}$ around $k_{\rm dip}$ for the squeezed configuration for a transient constant-roll model that can generate a 10^7 enhancement in the power spectrum: $\{\Delta N = 2.5, \eta_c = -6.2, c_k = 0.4\}$. In the right panel, we represent the accuracy of the consistency relation $f_{\rm NL} = 5(1 - n_s)/12$ in capturing the behavior of the $f_{\rm NL}$ in the squeezed limit, using (16) and $n_s - 1 \equiv {\rm d}\ln\mathcal{P}_{\mathcal{R}}(\tau_f, k)/{\rm d}\ln k$.

power spectrum.[30] In what follows, we confirm this expectation for the system under consideration.

We now analyze the squeezed limit of the scale dependent non-linearity parameter[c]. For scales that exit the horizon during the initial slow-roll era, noting the scale invariance of $\mathcal{P}_{\mathcal{R}}(\tau_k)$ factors, we take the squeezed limit $\vec{k}_3 \to 0$ ($k_1 \simeq k_2 \equiv q$) of (14) which yields as[11,16]

$$f_{\rm NL}(q, q, k_3 \to 0) \equiv f_{\rm NL}^{\rm sq} = \frac{5}{12}\left(\frac{4\ {\rm Re}[\alpha_q^* \alpha_{k_3}]\, F(\tau_{k_q}) q^2}{|\alpha_q \alpha_{k_3}|^2}\right). \tag{19}$$

Focusing on a representative choice of parameters that can generate an enhancement of order 10^7 in the power spectrum, in Figure 2 we plot the profile of $f_{\rm NL}$ in the squeezed configuration $k_3 \ll k_1 = k_2$ around the dip scale $k_{\rm dip}$ using (19) and with the help of formulas derived in Appendix B. We observe that the squeezed limit $f_{\rm NL}$ initially grows positive, to then rapidly decrease to negative values around $k_{\rm dip}$, and to finally increase again from negative values, almost in a symmetrical fashion. Intriguingly, as can be seen from the overlap of orange dotted curve with the black solid one in the right panel of Figure 2, the scale dependence of $f_{\rm NL}$ in the squeezed limit agrees very well with the one inferred from Maldacena's consistency condition: $f_{\rm NL} = 5(1-n_s)/12$. The typical magnitude for the squeezed limit of $|f_{\rm NL}|$ around $k_{\rm dip}$ results of order $\mathcal{O}(10)$, compatible with the large value for the spectral tilt around the dip region.[13]

It is worth stressing that the findings we present here agree well with previous literature[34–36] that numerically studied non-Gaussianity in inflationary setups that

[c]A scale-dependent $f_{\rm NL}$ arises in a variety of other inflationary contexts, see e.g. the early works.[31–33]

include a transient non-attractor era. However, the main advantage of our formulas (16) and (19) is the analytic control they provide us to study features in the power and bispectrum in a model independent way without restoring to numerical techniques. In particular, these formulas are flexible enough to ensure an accurate description of the power and bispectrum in various inflationary backgrounds that exhibit a transient, slow-roll violating phase(s) characterized by two essential parameters: the duration ΔN of the non-attractor phase and the value of the slow-roll parameter $\eta_c < 0$ in this phase.

3. μT correlations as a probe of the PBH generation mechanism

In the previous section we studied scale dependence of the squeezed bispectrum around the scales corresponding to the dip scale of the power spectrum. If the dip feature occurs at relatively large scales, say $10\,\mathrm{Mpc}^{-1} \leq k_{\rm dip} \leq 10^4\,\mathrm{Mpc}^{-1}$, the properties of the resulting curvature spectrum can be probed through CMB $\mu-$distortions, using well controlled CMB physics in the linear regime.[37–39] Building on the ideas first introduced by Pajer&Zaldarriaga,[40] this possibility was suggested in our recent work.[11] We stress that the range of scales we identified for $k_{\rm dip}$ above is well motivated for PBH populations with astrophysical masses. For example, given that $k_{\rm dip}/k_{\rm peak} \simeq 10^{-2}$ with a dip scale located around $k_{\rm dip} \simeq 10^3 - 10^4\,\mathrm{Mpc}^{-1}$ corresponds to a peak scale $k_{\rm peak} \simeq 10^5 - 10^6\,\mathrm{Mpc}^{-1}$ that correspond to the formation of PBH in the mass range[6,41] $M_{\rm pbh} \simeq 1 - 100\,M_\odot$.

We now discuss how to use the cross-correlation among CMB spectral μ distortions and temperature anisotropies for probing the statistics of curvature perturbation in inflationary scenarios capable of generating PBHs. The method we propose allows one to indirectly probe the inflationary PBH formation mechanism at relatively large scales, away from the scales where the curvature spectrum grow and has a peak. For a detailed discussion on the formulas we will introduce below, we refer the reader to the works.[11,40,42,43]

We begin by relating the initial curvature perturbation $\mathcal{R}_k$ to the spherical harmonic coefficients of the CMB temperature anisotropies $\Theta(\hat{n}) = \sum_{lm} a^T_{lm}\, Y_{lm}(\hat{n})$ and μ distortion anisotropies $\mu(\hat{n}) = \sum_{lm} a^\mu_{lm}\, Y_{lm}(\hat{n})$ which are are given by[40,42]

$$a^T_{lm} = \frac{12\pi}{5}(-i)^l \int \frac{\mathrm{d}^3k}{(2\pi)^3}\, \mathcal{R}_k\, \Delta_l(k)\, Y^*_{lm}(\hat{k}), \tag{20}$$

$$a^\mu_{lm} \simeq 18.4\pi(-i)^l \int \frac{\mathrm{d}^3k_1\, \mathrm{d}^3k_2}{(2\pi)^6} Y^*_{lm}\left(\hat{k}_+\right)\, \mathcal{R}_{k_1}\, \mathcal{R}_{k_2}\, W\left(\frac{k_+}{k_s}\right) j_l\left(k_+\chi_*\right) \times \left\langle \cos\left(c_s k_1 \tau\right) \cos\left(c_s k_2 \tau\right)\right\rangle_p \left[e^{-\left(k_1^2+k_2^2\right)/k_D^2}\right]^{z_i}_{z_f}, \tag{21}$$

where p denotes time averaging over the period acoustic oscillations; $\vec{k}_+ \equiv \vec{k}_1 + \vec{k}_2$; c_s is the sound speed of the radiation perturbations; $\chi_* = \tau_0 - \tau_* \simeq 14\,\mathrm{Gpc}$ is the comoving distance between the last scattering surface and today; and

$\Delta_l(k)$ is the transfer function during radiation domination. Furthermore, in (21), $W(k) = 3k^{-3}[\sin(k) - k\cos(k)]$ is a top-hat filter function in Fourier space that smears the dissipated energy over a volume of radius $k_s^{-1} \gtrsim k_D(z_f)^{-1}$ where k_D denotes the diffusion damping scale during a radiation dominated universe. It depends on redshift as $k_D(z) \simeq [(1+z)/10^5]^{3/2}\ 130\,\mathrm{Mpc}^{-1}$ where the range of redshifts associated with the μ distortions are given by

$$z_f \equiv 5 \times 10^4 < z < 2 \times 10^6 \equiv z_i. \tag{22}$$

We then define angular correlators involving anisotropies labeled by $\{i, j\}$ as

$$\left\langle \left(a^i_{lm}\right)^* a^j_{l'm'} \right\rangle = \delta_{ll'}\delta_{mm'} C^{ij}_l\,, \qquad i\,=\,\mu, T. \tag{23}$$

In the following discussion, we make use of the definition (23) to study angular correlations $\langle \mu T\rangle$ and to relate them to scale dependent bispectrum present around the dip scale of the PBH forming inflationary scenarios.

Using the definition (11) of the bispectrum together with (20) and (21), the cross correlations $C_l^{\mu T}$ for a squeezed bispectrum ($\vec{k}_+ = \vec{k}_1 + \vec{k}_2 \to 0$) can be expressed as,[40,42]

$$C_l^{\mu T} \simeq \frac{27.6}{20\pi^3} \int \mathrm{d}\ln k_+\, \Delta_l(k_+)\, j_l\left(k_+\chi_*\right) \times \int \mathrm{d}\ln q \left[k_+^3 q^3 B_{\mathcal{R}}\left(q, q, k_+ \to 0\right)\right] \left[e^{-2q^2/k_D^2(z)}\right]_{z_f}^{z_i}, \tag{24}$$

where we take the filter function $W \to 1$ in the squeezed limit $k_+ \ll k_s \simeq k_D(z_f)$, and relabel $|\vec{k}_1| \simeq |-\vec{k}_2| \equiv q$. Using the general definition (13) of the non-linearity parameter, the squeezed limit bispectrum inside the $\mathrm{d}\ln q$ integral in (24) can be expressed as

$$B_{\mathcal{R}}\left(q, q, k_+ \to 0\right) \simeq \frac{12}{5} \underbrace{f_{\mathrm{NL}}^{\mathrm{sq}}(q)|\alpha_q|^2|\alpha_{k_+}|^2}_{\equiv f_{\mathrm{NL}}^{\mathrm{eff}}(q)}\ P_{\mathcal{R}}(\tau_q) P_{\mathcal{R}}(\tau_{k_+}). \tag{25}$$

In (25), we defined the bispectrum in terms of the two copies of the power spectrum evaluated at around horizon crossing τ_k in the initial slow-roll era. Notice that with this parametrization, (25) represent the scale dependent generalization of the purely local bispectrum through the scale dependent $f_{\mathrm{NL}}^{\mathrm{eff}}(q)$.

Noticing that $P_{\mathcal{R}}(\tau_p) = 2\pi^2\mathcal{P}_{\mathcal{R}}(\tau_p)/p^3$ and $\mathcal{P}_{\mathcal{R}}(\tau_p) \simeq 2.1 \times 10^{-9}$ for mode exit during the initial slow-roll era (see e.g. (A.3)), we insert (25) in (24) to express the angular cross correlation as

$$C_l^{\mu T} \simeq 2.7 \times 10^{-17}\, \frac{2\pi}{l(l+1)}\ b_{(\mathrm{pbh})}(l), \tag{26}$$

where we define

$$b_{(\mathrm{pbh})}(l) \equiv \frac{6l(l+1)}{\ln\left(\frac{k_D(z_i)}{k_D(z_f)}\right)} \int \mathrm{d}\ln k_+\ \Delta_l(k_+)\ j_l\left(k_+\chi_*\right) \int \mathrm{d}\ln q\ f_{\mathrm{NL}}^{\mathrm{eff}}(q) \left[e^{-2q^2/k_D^2(z)}\right]_{z_f}^{z_i}, \tag{27}$$

as the key quantity that determines the multipole dependence and the size of the $\langle \mu T \rangle$ correlator of Eq. (26). Notice that this quantity depends on the transfer function $\Delta_l(k)$ which we decompose as[43]

$$\Delta_l(k) = \rho(l)\Delta_l^{(\mathrm{SW})}(k)\,. \tag{28}$$

$\Delta_l^{(\mathrm{SW})}(k)$ is the transfer function in the large-scale Sachs-Wolfe (SW) limit $l \to 0$,

$$\Delta_l^{(\mathrm{SW})}(k) \;=\; \frac{1}{3} j_l(k\chi_*), \tag{29}$$

and

$$\rho(l) \simeq 1.08\left[1 - 0.022l - 1.72\times 10^{-4} l^2 + 2\times 10^{-6} l^3 - 4.56\times 10^{-9} l^4\right], \tag{30}$$

is an analytic fit that includes high-l corrections to the SW approximation.[43] Using (28) and (29), we can then simply take the integral over the long momenta k_+ in (27) and factorize the outcome as

$$b_{(\mathrm{pbh})}(l) = \rho(l)\, b_{(\mathrm{pbh})}^{(\mathrm{SW})}, \tag{31}$$

with

$$b_{(\mathrm{pbh})}^{(\mathrm{SW})} = \left[\ln\left(\frac{k_D\,(z_i)}{k_D\,(z_f)}\right)\right]^{-1} \int \mathrm{d}\ln q\; f_{\mathrm{NL}}^{\mathrm{eff}}(q)\left[e^{-2q^2/k_D^2(z)}\right]_{z_f}^{z_i}. \tag{32}$$

Notice that for a purely local spectrum with constant non-linearity parameter, *i.e.* $f_{\mathrm{NL}}^{\mathrm{eff}}(q) \to f_{\mathrm{NL}}^{(\mathrm{p})}$, we get $b_{(\mathrm{pbh})}^{\mathrm{sw}} = f_{\mathrm{NL}}^{(\mathrm{p})}$ and hence reproduce the standard results derived for $C_l^{\mu T}$ in the SW limit.[40,42] However, $b_{(\mathrm{pbh})}^{\mathrm{sw}}$ can not influence the l dependence of the angular correlator $C_l^{\mu T}$(26) but it can significantly influence its overall amplitude through a non-trivial scale dependence of $f_{\mathrm{NL}}^{\mathrm{eff}}$. We will concretely see an example of this fact in the PBH forming inflationary scenarios below.

Using the analytic formulas we provide in Appendix A, B, we derive an analytic expression for the scale dependence of the effective non-linearity parameter $f_{\mathrm{NL}}^{\mathrm{eff}}$ (25) in Appendix C. In this way, we compute the expression (32) analytically to obtain

$$\frac{b_{(\mathrm{pbh})}^{(\mathrm{SW})}}{f_{\mathrm{NL}}^{(\mathrm{p})}} = 1 + \frac{1}{\ln\left(\frac{k_D(z_i)}{k_D(z_f)}\right)} \sum_{n=2}^{6} c_{\mathrm{NL}}^{(n)} \frac{\Gamma(n/2)}{2^{(n+2)/2}} \left(\frac{k_D(z)}{\mathcal{H}_0}\right)^n \Bigg|_{z_f}^{z_i}, \tag{33}$$

where the dependence of the coefficients $c_{\mathrm{NL}}^{(n)}$ on the background parameters in the non-attractor era, *i.e.* $\{\eta_{\mathrm{c}}, \Delta N\}$ can be obtained from the formulas we provide in Appendix C, B and A. Armed with (33), we can quantify the extent of which the scale dependence in the bispectrum can influence the μT angular correlator $C_l^{\mu T}$. For this purpose, we use (33) to compute $b_{(\mathrm{pbh})}^{(\mathrm{SW})}$ in terms of the location of the dip in momentum space k_{dip} by noting the relationship $\mathcal{H}_0 \simeq 100 k_{\mathrm{dip}}/3 \simeq 33\, k_{\mathrm{dip}}$ we derived in Section 2.1. The resulting dependence of $b_{(\mathrm{pbh})}^{(\mathrm{SW})}$ on the location of the dip feature k_{dip} is shown in Figure 3 for two different choices of parameter set that describes an inflationary model including a transient non-attractor era. We observe

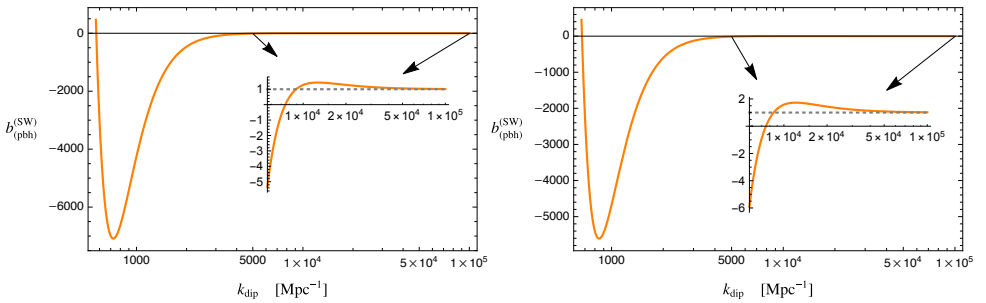

Fig. 3. Parameter $b^{(\mathrm{SW})}_{(\mathrm{pbh})}$ (33) for $f^{(\mathrm{p})}_{\mathrm{NL}} = 1$ as a function of the location of the dip feature $k_{\mathrm{dip}} \simeq 3\mathcal{H}_0/100$ in an inflationary model that contains a transient non-attractor phase parametrized by the parameter sets $\{\Delta N = 2.6, \eta_{\mathrm{c}} = -6, c_k = 0.5\}$ (Left) and $\{\Delta N = 2.5, \eta_{\mathrm{c}} = -6.2, c_k = 0.4\}$ (Right).

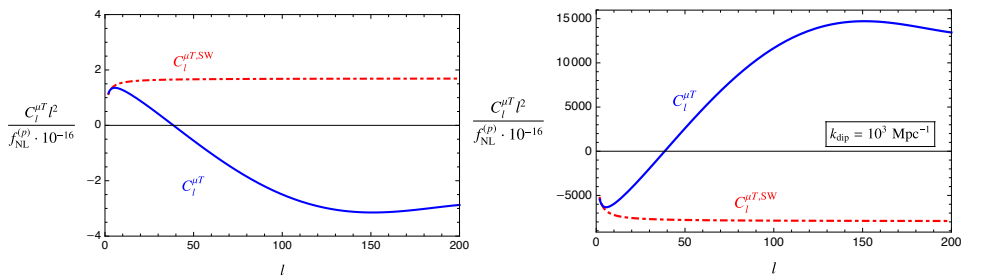

Fig. 4. Multipole dependence of $C_l^{\mu T}$ for a purely local type bispectrum (Left) and for a PBH forming inflationary scenario that contains a transient constant-roll era ($\eta_{\mathrm{c}} = -6.2$) that has a duration of $\Delta N = 2.5$ e-folds and with a dip feature that is located at $k_{\mathrm{dip}} = 10^3\,\mathrm{Mpc}^{-1}$(Right).

that for phenomenologically interesting values of k_{dip}, $b^{(\mathrm{SW})}_{(\mathrm{pbh})}$ obtains *large negative* values and hence can alter the *overall amplitude* and *sign* of the $\langle \mu T \rangle$ correlator significantly, in particular compared to a inflationary scenario endowed with a purely local type bispectrum where $b^{(\mathrm{SW})} \to f^{(\mathrm{p})}_{\mathrm{NL}}$.[40]

To further illustrate these points, in Figure 4 we present the multipole dependence of $C_l^{\mu T}$ (26) for a purely local bispectrum and for an inflationary model that contains an intermediate non-attractor phase where we show the resulting angular correlator for both within the Sachs-Wolfe approximation (dot-dashed line), and by taking into account full transfer effects (solid line). We observe that compared to the scale independent local bispectrum case (left panel in Figure 4), the overall amplitude of the angular correlator is enhanced significantly and its behavior from large to small scales is inverted due to the large negative $b^{(\mathrm{SW})}_{(\mathrm{pbh})}$ acquires for the $k_{\mathrm{dip}} = 10^3\,\mathrm{Mpc}^{-1}$. In other words, for a PBH forming inflationary scenario, μ distortions become anti-correlated with temperature anisotropies at large scales contrary to the case arise for a scale independent local bispectrum. It is worth stressing that this behavior arise because in PBH forming inflationary scenarios,

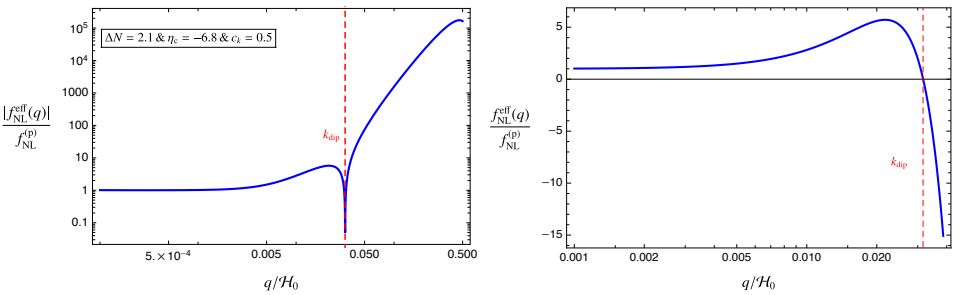

Fig. 5. Scale dependence of the effective non-linearity parameter $f_{\rm NL}^{\rm eff}$ (25) in the squeezed limit $k_3/q \to 0$ for an inflationary model that exhibit an intermediate constant-roll phase $\eta_{\rm c} = -6.8$ that lasts $\Delta N = 2.1$ e-folds.

the effective scale dependent bispectrum changes sign around the dip feature and grows large in the negative direction as we show in the right panel of Figure 5. This result is interesting on its own as one can in principle distinguish between these scenarios by just looking at the sign of the $C_l^{\mu T}$ at large scales at small l. In summary, our results imply that phases of non-attractor inflation can qualitatively and quantitatively change the properties of the cross-correlations between CMB temperature anisotropies and μ-type distortions.

3.1. *Prospects of detectability for* $\langle \mu T \rangle$

To assess the prospects of detectability for the μT correlator, we now estimate the cumulative signal-to-noise ratio, S/N using[42]

$$\left(\frac{S}{N}\right)^2 = \sum_{l=2}^{l_{\rm max}} (2l+1) \frac{\left(C_l^{\mu T}\right)^2}{C_l^{TT} C_l^{\mu\mu,N}} \,, \tag{34}$$

where C_l^{TT} is the CMB temperature anisotropy power spectrum and $C_l^{\mu\mu,N}$ is the noise level for μ distortions. For an experiment as PIXIE[44] the noise is given by $C_l^{\mu\mu,N} \simeq 4\pi\, \mu_{\rm min}^2\, e^{l^2/84^2}$ [40] where $\mu_{\rm min}$ denotes the minimum detectable μ distortion signal. Using (20), we denote the TT correlator in (34) as

$$C_l^{TT} = \frac{36\pi}{25} \int {\rm d}\ln k\, \mathcal{P}_{\mathcal{R}}(k) \Delta_l^2(k). \tag{35}$$

Therefore to estimate the S/N, we require the full knowledge the of the transfer function Δ_l in (35). Taking these effects into account, it was found that the signal to noise ratio can be estimated as 40% of the result that one would obtain by adopting the SW limit,[42,43] adopting $\rho_l \to 1$, $C_l^{TT,{\rm SW}} = 2\pi \mathcal{P}_{\mathcal{R}}^{(0)}/(25\, l(l+1))$ [d]. Following the

[d]Note that the smallest scales we are interested corresponds to $l_{\rm max} = 200$, so we can safely assume the scale indepedent part of the power spectrum in (35) although it has non-trivial scale dependence (enhancement) at much smaller scales for inflationary scenarios we are interested in this work.

discussion above, we carry the sum in (34) up to $l_{\rm max} = 200$ using (26) and (31) to obtain[11]

$$\left(\frac{S}{N}\right) \simeq 0.35 \times 10^{-3} |f_{\rm NL}^{\rm (p)} b_{\rm (pbh)}^{\rm (SW)}| \left(\frac{10^{-8}}{\mu_{\rm min}}\right). \tag{36}$$

This result implies that $|f_{\rm NL}^{\rm (p)} b_{\rm (pbh)}^{\rm (SW)}| \gtrsim 2892$ should be observable for a PIXIE like experiment. On the other hand, for a spectrometer comparable to PRISM[45] with $\mu_{\rm min} = 10^{-9}$, $|f_{\rm NL}^{\rm (p)} b_{\rm (pbh)}^{\rm (SW)}| \gtrsim 290$ is required for the detectability. At this point, it is worth mentioning that for a local type $f_{\rm NL}^{\rm (p)} \sim 10^{-2}$ at CMB scales as predicted by standard slow-roll backgrounds, such a signal would be challenging to detect.

On the other hand, considering the 2σ limits on the local type bispectrum by Planck[46] at CMB scales: $-11.1 < f_{\rm NL}^{\rm (p)} < 9.3$ ($f_{\rm NL}^{\rm (p)} = -0.9 \pm 5.1$, 68%CL) and the typical values of $|b_{\rm (pbh)}^{\rm (SW)}| \simeq$ a few $(10^2 - 10^3)$ that can be obtained in inflationary scenarios that can generate PBH populations (See figure 3), we conclude that the impact of the scale dependent non-Gaussianity on the $\langle \mu T \rangle$ correlator should be observable by PIXIE or PRISM for an interesting range of $k_{\rm dip}$ values relevant for the formation of PBHs within the mass range $M_{\rm pbh} \simeq 1 - 100\, M_\odot$.

4. Discussion

We presented a method for probing inflationary scenarios of PBH formation, using only CMB physics at relatively large scales. We based our arguments on the characteristic properties of the spectrum of curvature perturbation in single-field inflationary models that can generate a large population of PBHs. In these models, the curvature perturbation spectrum is characterized by a pronounced dip followed by a rapid growth towards a peak responsible for PBH formation. By making use of the gradient expansion formalism,[12] we analytically computed the properties of the power spectrum and for the first time of the bispectrum around the dip position, which occurs at scales well larger than the peak. Focussing our attention to the squeezed configuration, we found that the bispectrum can be enhanced around the position of the dip; it also acquires a characteristic momentum dependence that is controlled by the underlying inflationary mechanism. Here, we propose to probe such an enhanced squeezed bispectrum through the correlations it induces between CMB μ-distortions and CMB temperature fluctuations. For this purpose, we extended the methods first explored in[40] to include the case of scale-dependent non-Gaussianity from PBH formation mechanisms, finding analytical expression for quantities controlling μT correlations, and discussing how future CMB μ-distortion experiments can test this observable. Interestingly, the method we propose would allow one to experimentally probe inflationary PBH scenarios using well-understood CMB physics at scales much larger than the peak of the spectrum, without considering non-linearities associated with PBH formation and evolution. In particular, owing the relation between relevant scales associated with μ distortions and the

features present in the PBH forming inflationary scenarios, our findings are relevant for PBH masses within the $M_{\rm pbh} \sim 1 - 100 M_\odot$. These finding suggest that μT correlations can be used as a useful tool to distinguish between astrophysical vs primordial origin of BHs.

Appendix A. The power spectrum $\mathcal{P}_{\mathcal{R}}(\tau_k)$ and fractional velocity $v_{\mathcal{R}}$

For the initial slow-roll phase, the solution for the curvature perturbation that reduces to the standard Bunch Davies vacuum can be written as[13]

$$\mathcal{R}_k^{\rm sr} = \frac{iH}{M_{\rm pl}} \frac{e^{-ik\tau}}{\sqrt{4\epsilon_{\rm sr} k^3}} \, (1 + ik\tau), \qquad \tau_k/\tau_0 > 1, \tag{A.1}$$

where $\epsilon_{\rm sr} \ll 1$ is the slow-roll parameter in the initial slow-roll stage which we assume to be constant. Using the solution (A.1) in the definition, the real and imaginary part of the fractional velocity (evaluated at $\tau = \tau_k$) can be obtained as

$$v_{\mathcal{R}}^R(c_k) = -\frac{c_k^2}{3(1+c_k^2)}, \quad v_{\mathcal{R}}^I(c_k) = -\frac{c_k^3}{3(1+c_k^2)}, \qquad \tau_k/\tau_0 > 1, \tag{A.2}$$

where c_k is defined in (17). It is clear from (A.2) that the imaginary part of $v_{\mathcal{R}}$ includes an extra factor of c_k compared to the real part. We note that unless $c_k = 1$, this translates into an extra suppression for the imaginary part of the fractional velocity.

On the other hand, using (A.1), the power spectrum evaluated at around horizon crossing is given by

$$\mathcal{P}_{\mathcal{R}}(\tau_k) = \frac{k^3}{2\pi^2} |\mathcal{R}_k(\tau_k)|^2 = \frac{H^2}{8\pi^2 \epsilon_{\rm sr} M_{\rm pl}^2} \left(1 + c_k^2\right), \qquad \tau_k/\tau_0 > 1. \tag{A.3}$$

Next, we need to develop an expression for $\mathcal{R}(\tau_k)$ and the fractional velocity continuous through the transition at $\tau = \tau_0$. This was done using a matching procedure for $\mathcal{R}_k$ and its derivative in[11] which gives

$$\mathcal{R}_k = \frac{iH}{M_{\rm pl}} \frac{(\tau/\tau_0)^{\eta_{\rm c}/2}}{\sqrt{4\epsilon_{\rm sr} k^3}} (-k\tau)^{3/2} \left[c_1 H_\nu^{(1)}(-k\tau) + c_2 H_\nu^{(2)}(-k\tau) \right], \qquad \tau_k/\tau_0 < 1. \tag{A.4}$$

where $\nu = (3+\eta_c)/2$. The scale dependent coefficients are given by

$$c_1 = y_0^{3/2} e^{iy_0} \frac{y_0\left(H_\nu^{(2)}(y_0) + iH_{\nu-1}^{(2)}(y_0)\right) - H_{\nu-1}^{(2)}(y_0)}{H_{\nu-1}^{(1)}(y_0)H_\nu^{(2)}(y_0) - H_\nu^{(1)}(y_0)H_{\nu-1}^{(2)}(y_0)}, \tag{A.5}$$

$$c_2 = y_0^{3/2} e^{iy_0} \frac{(y_0)\left(H_\nu^{(1)}(y_0) + iH_{\nu-1}^{(1)}(y_0)\right) - H_{\nu-1}^{(1)}(y_0)}{H_\nu^{(1)}(y_0)H_{\nu-1}^{(2)}(y_0) - H_\nu^{(2)}(y_0)H_{\nu-1}^{(1)}(y_0)}. \tag{A.6}$$

where we defined $y \equiv -k\tau$. Then for $\tau_k/\tau_0 < 1$, the real and the imaginary part of the fractional velocity can be obtained as

$$v_{\mathcal{R}}^R(\tau) = -\frac{y}{3}\left[\frac{f_1 f_3 - y_0\left(f_1 f_4 + f_2 f_3\right) + y_0^2\left(f_1 f_3 + f_2 f_4\right)}{f_3^2 - 2y_0 f_3 f_4 + y_0^2\left(f_3^2 + f_4^2\right)}\right], \tag{A.7}$$

$$v_{\mathcal{R}}^I(\tau) = -\frac{y}{3}\left[\frac{y_0^2\left(f_1 f_4 - f_2 f_3\right)}{f_3^2 - 2y_0 f_3 f_4 + y_0^2\left(f_3^2 + f_4^2\right)}\right], \tag{A.8}$$

where we define the functions $f_n = f_n(y, y_0, \nu)$, for $n = 1, 2, 3, 4$ in terms of the Bessel function of the first and second kind as

$$\begin{aligned} f_1(y, y_0, \nu) &= J_{\nu-1}(y_0)Y_{\nu-1}(y) - Y_{\nu-1}(y_0)J_{\nu-1}(y), \\ f_2(y, y_0, \nu) &= J_\nu(y_0)Y_{\nu-1}(y) - Y_\nu(y_0)J_{\nu-1}(y). \end{aligned} \tag{A.9}$$

Furthermore, we note the following relations $f_4 = f_1(y, y_0, \nu+1)$, $f_3 = -f_2(y_0, y, \nu)$. The continuity of the real and the imaginary part of the fractional velocity can be confirmed explicitly from the eqs in (A.7) and (A.8) as they reduce to their slow-roll counterparts provided in (A.2) at the transition point $\tau_k = \tau_0$. Using the relations we noted earlier, power spectrum evaluated at $\tau = \tau_k$ for modes that leave the horizon during the non-attractor phase ($\tau_k/\tau_0 < 1$) can be obtained as

$$\mathcal{P}_{\mathcal{R}}(\tau_k) = \frac{H^2}{8\pi^2\epsilon_{\rm sr}M_{\rm pl}^2}\frac{c_k^{2\nu}\pi^2}{4}\left(\frac{k}{\mathcal{H}_0}\right)^{2-2\nu}\left[f_3^2 - 2y_0 f_3 f_4 + y_0^2(f_3^2 + f_4^2)\right]_{\tau=\tau_k} \tag{A.10}$$

Similarly, the continuity of the power spectrum can be confirmed explicitly by evaluating (A.10) at the transition point $\tau_k = \tau_0$ at which it reduced to (A.3).

Appendix B. The functions $D(\tau_k)$, $F_k(\tau_k)$

For the two phase background model parametrized by the pump field profile in Eq. (15), scale dependent functions $D(\tau_k)$, $F(\tau_k)$ (see Eqs. (6) and (7)) are calculated in[13] for modes that exit during the initial slow-roll era ($k/\mathcal{H}_0 < c_k$) and in[11]

for mode exit during the non-attractor era ($e^{\Delta N} > k/\mathcal{H}_0 > c_k$). Below, we present the explicit formulas for these functions for both stages of inflationary evolution.

$$D(\tau_k) \equiv \mathcal{C}_0^D + \mathcal{C}_3^D \left(\frac{k}{\mathcal{H}_0}\right)^3, \tag{B.1}$$
$$\frac{F(\tau_k)}{\tau_0^2} \equiv \mathcal{C}_{-2}^F \left(\frac{k}{\mathcal{H}_0}\right)^{-2} + \mathcal{C}_0^F + \mathcal{C}_1^F \left(\frac{k}{\mathcal{H}_0}\right), \qquad \frac{k}{\mathcal{H}_0} < c_k,$$

where the coefficients are given by

$$\mathcal{C}_0^D = 1, \qquad \mathcal{C}_3^D \simeq -\frac{3\, e^{-(\eta_c+3)\Delta N}}{(\eta_c+3)c_k^3}, \qquad \mathcal{C}_{-2}^F = \frac{c_k^2}{6},$$
$$\mathcal{C}_0^F \simeq -\frac{\eta_c\, e^{-(\eta_c+3)\Delta N}}{(\eta_c+3)(\eta_c+1)}, \qquad \mathcal{C}_1^F \simeq \frac{e^{-(\eta_c+3)\Delta N}}{c_k(\eta_c+3)} \tag{B.2}$$

where $\tau_f/\tau_0 \equiv x_f = e^{-\Delta N}$ with ΔN denoting the duration of the slow-roll violating ($\eta_c \leq -6$) era. On the other hand, for modes that leave the horizon during the non-attractor era, we have

$$D(\tau_k) \equiv \tilde{\mathcal{C}}_{\eta_c+3}^D \left(\frac{k}{\mathcal{H}_0}\right)^{\eta_c+3} + \tilde{\mathcal{C}}_0^D \tag{B.3}$$
$$\frac{F(\tau_k)}{\tau_0^2} \equiv \tilde{\mathcal{C}}_{\eta_c+1}^F \left(\frac{k}{\mathcal{H}_0}\right)^{\eta_c+1} + \tilde{\mathcal{C}}_{-2}^F \left(\frac{k}{\mathcal{H}_0}\right)^{-2} + \tilde{\mathcal{C}}_0^F, \qquad c_k < \frac{k}{\mathcal{H}_0} < e^{\Delta N}$$

where

$$\tilde{\mathcal{C}}_{\eta_c+3}^D = -\frac{3\, e^{-(\eta_c+3)\Delta N}}{(\eta_c+3)c_k^{\eta_c+3}}, \qquad \tilde{\mathcal{C}}_0^D = -\frac{3}{\eta_c+3}, \qquad \tilde{\mathcal{C}}_0^F = \frac{e^{-2\Delta N}}{2(\eta_c+1)},$$
$$\tilde{\mathcal{C}}_{-2}^F = \frac{c_k^2}{2(\eta_c+3)}, \qquad \tilde{\mathcal{C}}_{\eta_c+1}^F = \frac{e^{-(\eta_c+3)\Delta N}}{(\eta_c+1)(\eta_c+3)c_k^{\eta_c+1}}. \tag{B.4}$$

Appendix C. $f_{\rm NL}^{\rm eff}$ in the squeezed limit

Using the definition (25) with (19), for mode exit during the initial slow-roll era, the squeezed limit effective non-linearity parameter is given by

$$f_{\rm NL}^{\rm eff} = \frac{5}{3}\left(\mathrm{Re}[\alpha_q^* \alpha_{k_3}]\, F(\tau_{k_q}) q^2\right). \tag{C.1}$$

From (C.1), one can show that in the large scale tail of the squeezed limit, *i.e.* $q > k_+$ as $q \to 0$, $f_{\rm NL}^{\rm eff}$ obtains an "initial" value $f_{\rm NL}^{(0)} = 5c_{\rm NL}^{(0)}(c_q)/3$ where $c_{\rm NL}^{(0)} \simeq (1 + v_{\mathcal{R}}^R - \mathcal{C}_{-2}^F)^2 \mathcal{C}_{-2}^F$. Since, we send $q \to 0$ to reach this initial value, we do not expect that $f_{\rm NL}^{(0)}$ can reflect an accurate initial value for the squeezed configuration of (C.1). To keep our discussion on the observability of $\langle \mu T \rangle$ (see Section 3.1) as general as possible, we therefore replace this initial value with a fiducial primordial $f_{\rm NL}^{(\rm p)}$ to characterize the effective non-linearity parameter at large scales, *i.e.* at CMB scales. Using the formulas we derived for the functions $D(\tau_k), F(\tau_k)$ above and the

definitions of the enhancement factor α_k in eqs.(3) and (4), at leading order in the $k_+/q \ll 1$ expansion, we can then express $f_{\rm NL}^{\rm eff}$ in terms of simple power law expansion as[11]

$$f_{\rm NL}^{\rm eff} \simeq f_{\rm NL}^{\rm (p)} \left[1 + \sum_{n=2}^{6} c_{\rm NL}^{(n)}(\eta_{\rm c}, \Delta N, c_q) \left(\frac{q}{\mathcal{H}_0} \right)^n \right] + \mathcal{O}\left(\frac{k_+}{q} \right). \tag{C.2}$$

The coefficients $c_{\rm NL}^{(n)}$ of this expansion can be expressed in terms of the coefficients $\mathcal{C}$ of the F, D functions of Appendix B and the fractional velocities $v_{\mathcal{R}}^R, v_{\mathcal{R}}^I$ we defined in (A.2) as

$$c_{\rm NL}^{(0)} \simeq (1 + v_{\mathcal{R}}^R - \mathcal{C}_{-2}^F)^2 \mathcal{C}_{-2}^F, \qquad c_{\rm NL}^{(2)} \simeq \frac{\mathcal{C}_0^F}{\mathcal{C}_{-2}^F}, \qquad c_{\rm NL}^{(3)} \simeq \frac{\mathcal{C}_1^F}{\mathcal{C}_{-2}^F} \tag{C.3}$$

$$c_{\rm NL}^{(4)} = -\frac{(\mathcal{C}_0^F)^2}{\mathcal{C}_{-2}^F(1 + v_{\mathcal{R}}^R - \mathcal{C}_{-2}^F)}, \qquad c_{\rm NL}^{(5)} \simeq (1 + v_{\mathcal{R}}^R - \mathcal{C}_{-2}^F) \left[v_{\mathcal{R}}^R \mathcal{C}_3^D - 2\mathcal{C}_1^F \right] \mathcal{C}_0^F, \tag{C.4}$$

$$c_{\rm NL}^{(6)} \simeq (1 + v_{\mathcal{R}}^R - \mathcal{C}_{-2}^F) \left[v_{\mathcal{R}}^R \mathcal{C}_3^D - \mathcal{C}_1^F \right] \mathcal{C}_1^F, \tag{C.5}$$

where we neglected terms proportional to $v_{\mathcal{R}}^I$ for $c_k \ll 1$ because in this regime $v_{\mathcal{R}}^R \gg v_{\mathcal{R}}^I$ as can be realized from (A.2).

Compton scattering of photons with thermal electrons is one of the most ubiquitous phenomenon in nature. Numerical approaches to solve the evolution of photons in such situations typically assume the energy exchange to be much smaller compared to the temperature of electrons. In this work, we solve the photon evolution in its full generality, without the diffusion approximation, and show the differences between the exact solution and approximate solutions. We point out the importance of solving exact kinematics of Compton scattering for the computation of Cosmic Microwave Background (CMB) spectral distortions at redshifts $(z) \lesssim 3 \times 10^4$.

Keywords: Cosmology; Cosmic Microwave background; CMB spectral distortions.

1. Photon evolution equation

The Boltzmann equation for the evolution of photon spectrum in contact with a thermal electron bath can be written as,[1]

$$\frac{\mathrm{d}n_0}{\mathrm{d}\tau} = \int P^{\mathrm{th}}(\omega_0 \rightarrow \omega) \left[\mathrm{e}^{\frac{\omega-\omega_0}{\theta_e}} n(1+n_0) - n_0(1+n)\right] d\omega, \tag{1}$$

where n_0 and n are the photon occupation number at frequency ω_0 and ω respectively, $\theta_e (= \frac{T_e}{m_e})$ is the non-dimensional electron temperature, $d\tau (= \mathrm{c} N_e \sigma_{\mathrm{T}} dt)$ is the optical depth of Compton scattering of photons with the electrons. The exact

kinematics of Compton scattering is stored in the kernel $P^{\rm th}(\omega_0 \rightarrow \omega)$ which can be computed using `CSpack`[a] .[2] The kernel satisfies the detailed balance relation,

$$P^{\rm th}(\omega \rightarrow \omega_0) = \frac{\omega_0^2}{\omega^2} {\rm e}^{\frac{\omega-\omega_0}{\theta_e}}\, P^{\rm th}(\omega_0 \rightarrow \omega), \tag{2}$$

which ensures that the Planck spectrum is the equilibrium solution of photon evolution equation.

In literature, one often uses the diffusion approximation[1] which assumes that the energy exchange between photons and the electrons is much smaller than the electron temperature. Then one can do a Taylor series expansion in $\frac{\omega-\omega_0}{\theta_e}$ in Eq. 1. Further assuming Compton scattering to be non-relativistic, we obtain Kompaneets equation,[3,4]

$$\frac{{\rm d}n_0}{{\rm d}\tau} = \frac{\theta_e}{x_0^2}\frac{\partial}{\partial x_0} x_0^4 \left[\frac{\partial}{\partial x_0} n_0 + n_0(1+n_0)\right], \tag{3}$$

where $x_0 (= \frac{\omega_0}{\theta_e})$ is the dimensionless frequency. The photon equilibrium solution is given by,

$$\frac{\partial}{\partial x_0} n_0 + n_0(1+n_0) = 0 \tag{4}$$

We can obtain a relativistically exact equation within diffusion approximation by using the Ansatz (without stimulated scattering terms),[5,6]

$$\frac{{\rm d}n_0}{{\rm d}\tau} = \frac{1}{\omega_0^2}\partial_{\omega_0}\left[\mathcal{D}(\omega_0)\,\partial_{\omega_0}\Delta n_0 + \mathcal{A}(\omega_0)\Delta n_0\right], \tag{5}$$

where $A(\omega_0)$ and $D(\omega_0)$ are tuned to match the relativistically exact first and second moment of photon evolution equation.[5] We call this the improved Fokker-Planck (FP) approximation. Note that the zeroth moment which is the photon number conservation equation is automatically satisfied by Eq. 5. Since the coefficients of Eq. 5 are a function of photon energy ω_0, the equilibrium solution will not be unique and will be a function of photon energy which is unphysical. Therefore, we expect that Eq. 5 can not be a reliable substitute of Eq. 1. We will confirm it with numerical test problems in the next section.

2. Numerical solutions for test problems

As a test problem, we consider monochromatic photon injection at frequency x_{inj}. In Fig. 1, we plot the first and second moment of the evolving photon spectrum as a function of $y = \int \theta_e d\tau$, which can be thought of as a time variable. With time, the photon spectrum spreads out. Therefore, the absolute value of the moments increases until equilibrium is reached at which point there is no more evolution. Since the injected photon energy is higher than the electron temperature ($x = \omega/\theta_e$),

[a] `CSpack` is available at `www.chluba.de/CSpack`

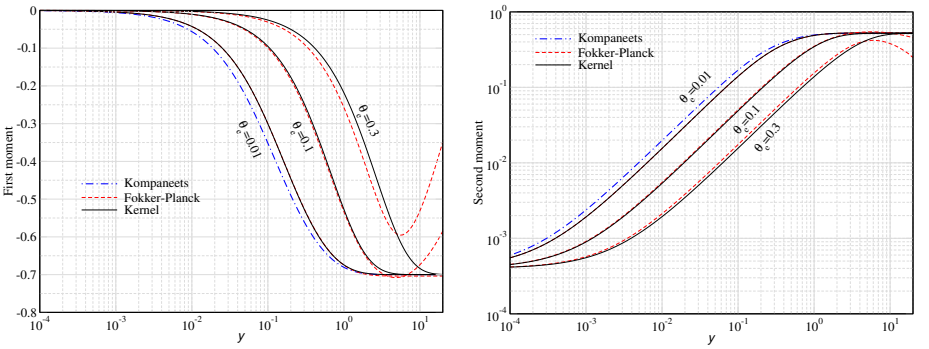

Fig. 1. Evolution of first (left panel) and second (right panel) moments of photon field for injection at $x_{\rm inj} = 10$. Stimulated terms were neglected. The electrons are kept at a constant temperature $\theta_e = 0.1$. We compare the solutions of the Kompaneets equation and the improved FP approach (Eq. 5) with the solution for the exact scattering kernel (Eq. 1). The Kompaneets solutions are independent of the temperature. The temperature dependence is captured well by the improved FP approach at low value of the y parameter. However, this approach fails as expected once equilibrium is reached.

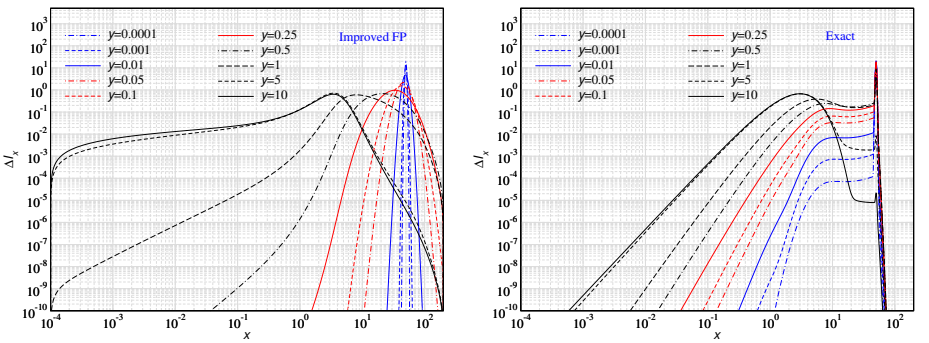

Fig. 2. Snapshots of solution for photon field as a function of frequency for different y parameters and numerical approaches as annotated. On the y-axis, we plot the dimensionless intensity, $I_x = x^3\, n$. Photon were injected at $x_{\rm inj} = 50$ at $y = 0$.

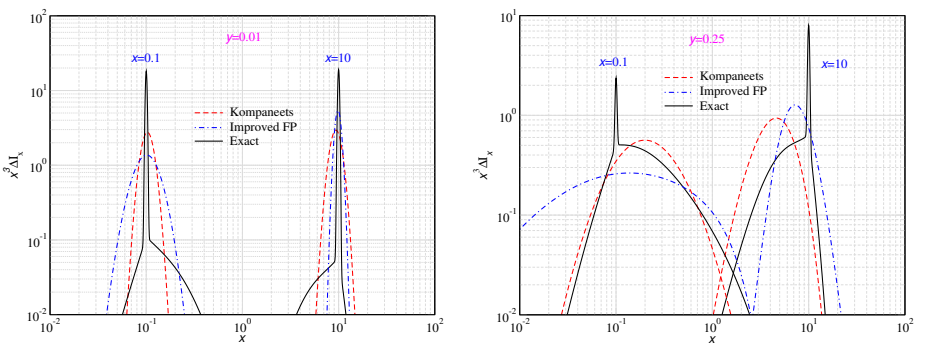

Fig. 3. Comparison of solutions with different approximations and the exact solution with $\theta_e = 0.1$ and various values of injection frequency (x) and y as shown in the figure.

photons lose energy to the electrons on average. This makes the first moment negative for this particular choice of initial photon energy. The second moment which captures the dispersion of the photon spectrum is always positive. The improved FP solution captures the evolution of moments much better than the Kompaneets equation but they do not approach the equilibrium solution for reasons as already explained before.

In Fig. 2, we plot the snapshots of photon evolution and compare the improved FP and the exact solution for a few values of y. The different solutions look significantly different from each other even if the moments of the spectrum are similar. The improved FP solution is much smoother due to the diffusion approximation while in case of the exact solution, we still see a signature of photon injection at $x_{inj} = 50$ at $y \sim 10$. In Fig. 3, we compare Kompaneets, improved FP and the exact solution for few different cases to further illustrate the differences of different approximations.

3. Implications for CMB spectral distortions

The CMB spectrum is accurately described by the Planck spectrum up to a level of 10^{-5}.[7] Injection of non-thermal photons at $z \lesssim 2 \times 10^6$ gives rise to CMB spectral distortions as the CMB can not relax to the Planck spectrum as photon number changing processes become inefficient.[8] As opposed to the test problems considered in the previous section in which electrons were at a constant temperature, in the expanding universe, both the CMB photons and the background electrons evolve together. Therefore, in this scenario, we solve two equations which are the photon evolution equation (Eq. 1) and the temperature of the electrons.[5] We evolve the photon spectrum from the redshift of photon injection up to today when the CMB photons reach us. Here, we consider photon injection at a single redshift.

In Fig. 4, we plot the CMB spectral distortion solutions for photons with energy and redshifts as shown and compare the exact solution with the Kompaneets

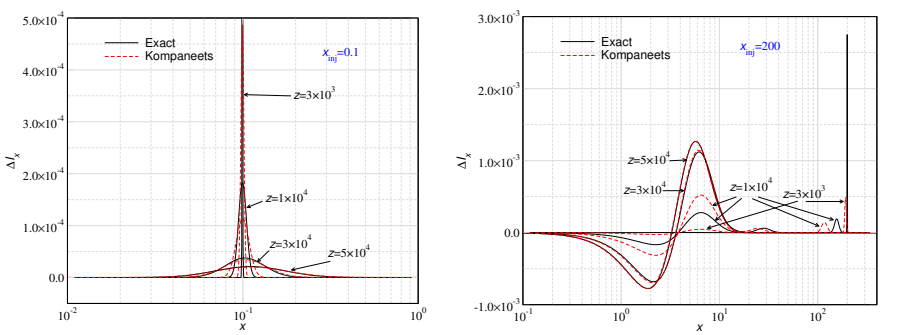

Fig. 4. Spectral distortion solution for energy injection at different redshifts with frequency of injection as denoted. The Kompaneets solution generally overestimates the broadening and mean shifts in the photon distribution. For injection at $x = 200$, the exact solution falls back with respect to the Kompaneets treatment, which overestimates the energy exchange with electrons.

approximation. The electron temperature at these redshifts are of the order of few eV, therefore, relativistic corrections are not important, and the improved FP approximation is identical to Kompaneets approximation. The Kompaneets approximation overestimates the broadening of photon spectrum. At higher frequencies, the Klein-Nishina corrections reduce the energy exchange from the energetic photons to the background electrons which is not captured by the Kompaneets solution. The energy gain by the electrons shows up as y-distortion[4] which, consequently, is not predicted correctly in Kompaneets approximation.

4. Conclusions

In this work, we solve the evolution of photons in contact with a thermal bath of electrons via Compton scattering and compare the exact solutions with various approximations found in literature. We point out and explain the differences between these solutions and show that the various approximations do not capture the physics correctly for the whole photon evolution history. We study CMB spectral distortions from photon injections and show that the exact solution differs significantly from Kompaneets solution and will be important for determining CMB spectral distortion constraints for photon injection scenarios.

The BISOU (Balloon Interferometer for Spectral Observations of the Universe) project aims to study the viability and prospects of a balloon-borne spectrometer, pathfinder of a future space mission dedicated to the measurements of the CMB spectral distortions. We present here a preliminary concept based on previous space mission proposals, together with some sensitivity calculation results for the observation goals, showing that a 5-σ measurement of the y-distortions is achievable.

Keywords: CMB, Spectral distortions, Balloon project.

1. Introduction

With the success of the ESA Planck mission, the concordance cosmological model is established as the reference framework. However, outstanding questions about this model are still unanswered. In particular the simplest inflationary model proposed as the origin of the initial matter perturbations is favoured by Planck measurement of the spectral index and low non-Gaussianity. Nevertheless, it still needs to be confirmed through the measurement of its smoking gun signature: the relic background of primordial gravitational waves. The latter can only be observed through the Cosmic Microwave Background (CMB) polarisation: namely B-modes. The CMB frequency spectrum is another key observable to probe the cosmological model. Its intensity was precisely measured by COBE/FIRAS almost three decades ago,[1,2] with deviations limited to $\Delta I/I \approx 10^{-5}$. Since then, not much progress has been achieved in measuring its deviation from a true blackbody. However, while the space mission proposals PIXIE[3] and PRISTINE (to ESA F-mission call) have not been successful, following two white papers,[4,5] the ESA Voyage 2050 programme has selected this topic amongst its three themes.

The BISOU (Balloon Interferometer for Spectral Observations of the Universe) project aims to study the viability and prospects of a balloon-borne spectrometer, pathfinder of a future space mission dedicated to the absolute measurement of the CMB spectrum. While PIXIE and PRISTINE were targeting both the measurement of the CMB polarisation, namely a first detection of the CMB B-mode polarisation, and the absolute measurement of the CMB spectral distortions, BISOU's main goal is to perform a first measurement of the later. However, secondary science will also include measurement of the Cosmic Infrared Background (CIB) emission, and potentially the polarisation of the dust up to 2 THz together with Galactic emission lines such as CI, CII, NII and OI.

Taking into account the specificity of a balloon flight in term of requirements and conditions (i.e. residual atmosphere, observation strategy for instance), this CNES Phase 0 study will evaluate if such a spectrometer is sensitive enough to measure at least the Compton y-distortion while consolidating the instrument concept and improving the readiness of some of its key sub-systems.

2. Science goals

While the CMB has a nearly perfect blackbody emission spectrum, deviations from it, referred to as spectral distortions, are expected. These distortions encode information about the full thermal history of the Universe from the early stages (primordial distortions from inflation and cosmological recombination lines) until today (star formation and galaxy clusters). Many of these processes are part of our standard cosmological model and are detailed in several publications.[4,6]

Spectral distortions result from processes that affect the thermal equilibrium between matter and radiation. One of the standard distortions, known as the Compton y-distortion, is created in the regime of inefficient energy transfer (optically

thin scattering) between electrons and photons, relevant at redshifts $z < 5 \times 10^4$. Processes creating this type of distortion are dominated by the inverse-Compton scattering of CMB photons off hot electrons during the epoch of reionization and structure formation, also known as the thermal Sunyaev-Zeldovich (tSZ) effect.

Chemical potential or μ-type distortions, on the other hand, are generated by energy release at earlier stages ($z > 5 \times 10^4$), when interactions are still extremely efficient (optically thick scattering) and able to establish kinetic equilibrium between electrons and photons under repeated Compton scattering and photon emission processes.

The COBE-FIRAS limit, $|y| < 1.5 \times 10^{-5}$ (95% C.L.), is roughly one order of magnitude larger than the expected signal,[7] $y \approx 2 \times 10^{-6}$. Signal from μ-type distortions will be even fainter. It is therefore crucial to have reliable models of all the emissions that will be much stronger than these signals in order to properly subtract them.

2.1. *Modeling the signals*

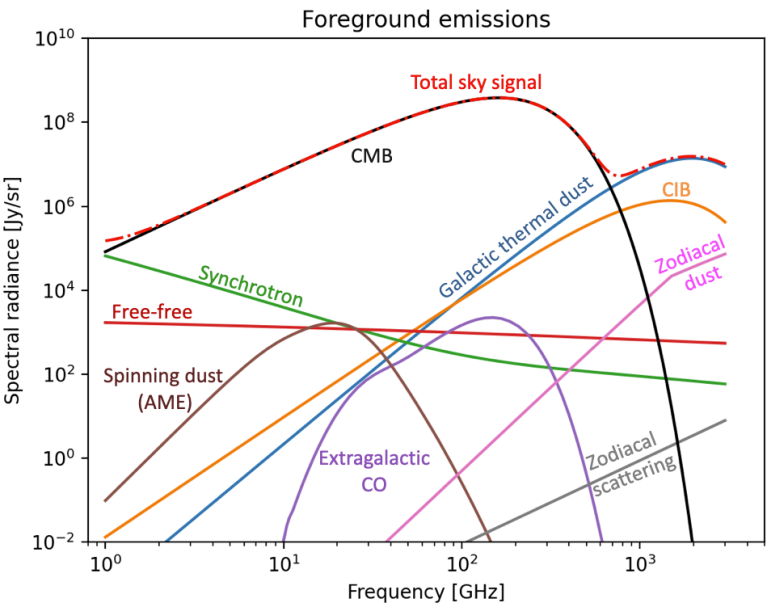

Fig. 1. Foreground emission contributions with respect to the CMB blackbody emission, together with the sum of all astrophysical signals (CMB + foregrounds).

Several astrophysical foregrounds contribute meaningfully to the sky signal at frequencies relevant to CMB spectral distortions. In addition to the ones already modeled[6] from Planck data,[8] additional components from the zodiacal dust have

been included. Figure 1 shows the individual contributions together with the sum of all sky signals, including the CMB. At low frequencies (below 70 GHz), the brightest foregrounds are from the synchrotron, the free-free and the so-called anomalous microwave emissions. High frequencies foregrounds (above 100 GHz) are mainly due to the emission of the Galactic thermal dust, the cumulative redshifted emission from thermal dust in distant galaxies, called the cosmic infrared background (CIB), and the zodiacal thermal dust emission. Additional foregrounds contributing to the total sky signal are the cumulative CO emission from distant galaxies at intermediate frequencies and the zodiacal scattering at high frequencies.

2.2. *CMB spectral distortions modeling*

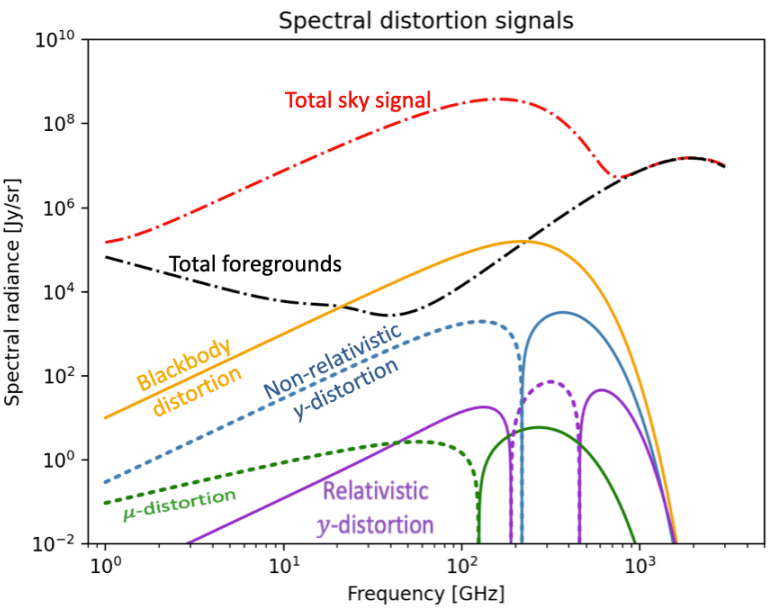

Fig. 2. Models of the spectral distortions: Black body distortion ΔT_{CMB} (orange), non-relativistic y-distortion (blue), relativistic y-distortion (purple) and μ-distortion (green). This is compared to the total foreground signal (dashed black) and the total sky signal - Foregrounds + CMB (dashed red).

Following the same assumptions and processes as the ones presented in Abitbol et al.,[6] figure 2 shows the signals associated with the various distortions of the spectrum, with respect to the total emission of the foregrounds and the total sky signal (including the CMB emission).

Four contributions are considered and modeled. First a blackbody distortion that represents a first order temperature deviation ΔT_{CMB} to the true CMB blackbody

spectrum. Then a cumulative thermal SZ y-distortion, including both standard non-relativistic and relativistic contributions (from Hill et al.[7]). The intracluster medium (ICM), the intergalactic medium and reionization contributions are included in the Compton-y signal. A relativistic correction to thermal SZ distortion[7,6] is modeled using the moment-based approach. Finally the chemical potential μ-distortion is generated assuming only signals from acoustic damping and adiabatic cooling. The r-type distortion, sometimes called "residual" distortion, is expected to have a contribution smaller than the μ-type distortion and is not represented in figure 2.

3. Instrument concept

The initial concept is based on a similar one that had been proposed by the PIXIE team[3] (shown in figure 3 left) and also used for the PRISTINE F-class ESA mission proposal. The instrument is a Fourier Transform Spectrometer (FTS) with two inputs and two outputs. Both inputs are going through a separate telescope, both sets of optics being identical in order to minimise the systematics. Because PIXIE has several observation modes, an external calibrator (cooled blackbody) could be located in front of one of the apertures at any one time. In the "spectral distortion" mode, for which the absolute spectrum needs to be measured, one input is directed towards the sky, the second towards a blackbody whose temperature is set to the CMB one, 2.726 K, so that a differential measurement can be achieved. This process can be alternated in order to cancel any asymmetry in both optical systems. After going through a set of polarisers, each of the two outputs is focused on a dual-polarisation multimoded bolometric detector, so that each of the four detectors measures an interference fringe pattern between orthogonal linear polarizations from the two input beams. In order to limit the photon noise, the whole instrument is cooled to about 3 K, the detectors being at sub-K temperature.

3.1. *Balloon specificity*

The previous studies for the instrument concept were performed on the basis of a space mission. For the case of a balloon project, the conditions, the requirements and therefore the instrument concept will be different. Stratospheric balloon projects might be considered to be in near-space conditions, but there are still many differences, some of these being the potential flight time, access to the sky, thermal environment, etc...

A few will have strong impacts on the payload concept. First the residual atmosphere at an altitude of about 40 km will be of the order of 3 mbar with a temperature of the order of 270 K. This will not only lead to an additional photon noise contribution, but also to the necessity of hosting the overall instrument inside a dewar in order to keep it at a temperature of the order of 3 K under vacuum. Even with a small pressure difference, the dewar will then need to have a window through which the telescope will point towards the sky (see figure 3 right). The

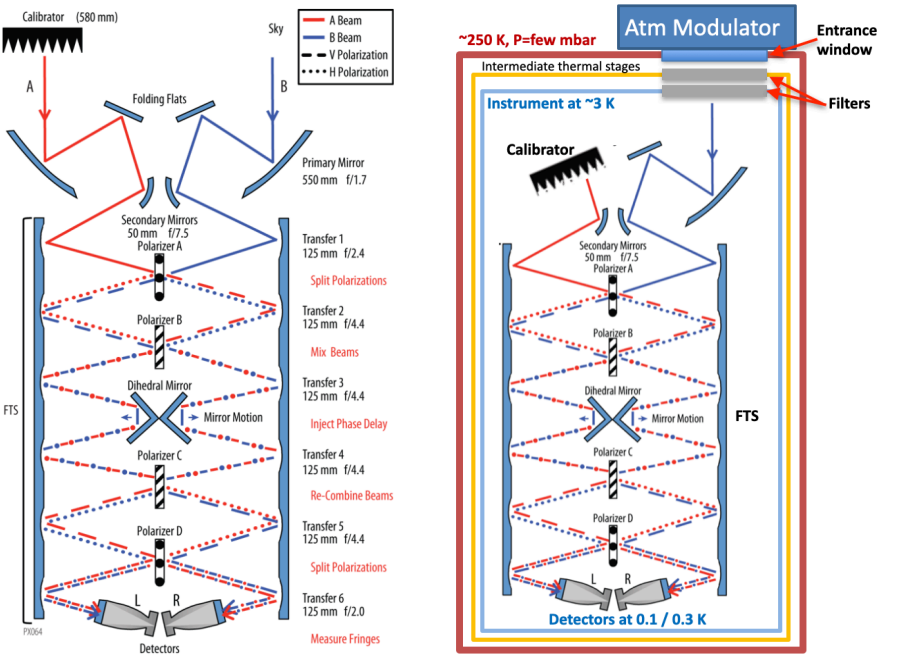

Fig. 3. Left: Original instrument concept from the PIXIE space mission proposal.[3] Right: BISOU instrument scheme.

outside dewar shell being at ambient temperature, intermediate thermal stages will be necessary with thermal filters in order to limit the thermal background load and potential straylight.

This is also preventing the calibrator to be outside the dewar and will then have to be located inside in order to keep it at a very steady temperature of about 3 K.

Due to the mass, power and dimensions constraints of a typical balloon payload, it is unlikely that two sets of optics can be used with a telescope primary diameter of 35 to 40 cm allowing for a multi-moded beam FWHM of about 1.5 deg.

3.2. *Gondola, dewar and cooling chain*

Assuming that the balloon flight will be provided by CNES, our study is based on the use of the CARMEN gondola[9] design that has been used lately for the PILOT balloon project[10] for instance, allowing for a maximum all-included payload mass of 750 kg (including ballast). While CNES has so far flown these types of payload for a typical 35-hour flight duration, it is planned that a first 5-day test-flight will happen in 2022. We will therefore base our sensitivity calculations on the assumption that this type of flight will be available in the future.

The whole instrument needs to be cooled to about 3 K, where the detectors only will be cooled to a sub-K temperature. A trade-off is being made in order to

define the optimum one, but it is highly likely that 300 mK will be low enough (section 4.1) for the focal plane, allowing for the use of a ^{3}He sorption cooler. Due to mass and power limitations, mechanical coolers for balloon platforms are not yet mature enough, even if some developments are being investigated, most notably by NASA. We chose a proven cooling solution using liquid helium to cool the overall instrument, between 4 and 2 K depending on the bath pressure, using the natural low pressure at high altitude. Several intermediate thermal stages and shields cooled with the helium vapour retrieved from the bath will allow for heat load reduction on the 3 K stage. Typical intermediate temperature stages are 150 K, 80 K and 20 K.

3.3. *Atmosphere*

As already mentioned, the residual atmosphere at 40 km altitude will still create a large photon noise contribution with respect to the extremely faint signal that we are trying to observe. For instance, atmospheric effects at ground level and even at balloon altitudes are shown in Masi et al.[11] with respect to spectral distortion signals. The signal level due to the atmosphere is still 2 to 3 orders of magnitude higher that the non-relativistic y-distortion signal depending on the frequency. In theory, assuming a reliable model, this contribution could be removed.

More important, will be the variations of the atmosphere with altitude, observation elevation and time. This cannot be modelled and will therefore need an atmosphere modulation strategy at a high enough frequency to be compatible with the variation timescale. Such a modulator is already used for COSMO,[11] but for BISOU, another modulator, such as a cold internal beam stirrer is also being considered.

For the time being, at that stage of the study, the atmosphere is not yet considered in our sensitivity and systematic effects calculations.

3.4. *The instrument*

Following the conditions of a balloon project (section 3.1), several points had to be adapted and trade-offs have already been made. With emphasis on the spectral distortions, these measurements will always be performed against the calibrator. Due to the fact that we are using only one telescope to save mass (with therefore an unbalanced optical system), the calibrator will be kept fixed in front of one of the FTS inputs for simplicity and risk mitigation.

With the help of an instrument model being developed, and assuming some initial parameters such as telescope diameter, flight duration and observation efficiency, or again spectral resolution, calculations presented in section 4 are showing that the sensitivity is strongly dependant on three key parameters: the temperature and emissivity of the window, and the maximum frequency of observation as the photon noise is increasing with frequency. The implications of these issues will be

discussed in the following sections. However, we see straight away that the dewar window, the warmest optical element, needs to have a very low emissivity, a temperature as low as possible and be as thin as possible to minimise the systematics.

In order to use a very thin window, a valve at the entrance of the dewar, opening only when the pressure difference is small (at a certain altitude), could be used. Such a technique was used for the Archeops[12] balloon project for instance.

The emissivity of the window could be reduced by the application of a copper/gold grid as was done on the ArTéMiS[13] ground based camera.

Finally while the dewar will be at a temperature ranging from 300 to 270 K, the window could have a mount thermally isolated from the structure and actively cooled with the vapour coming from the helium bath. Such a development will be studied with a dedicated R&D programme. This should bring the window temperature below 200 K.

4. Preliminary sensitivity estimates

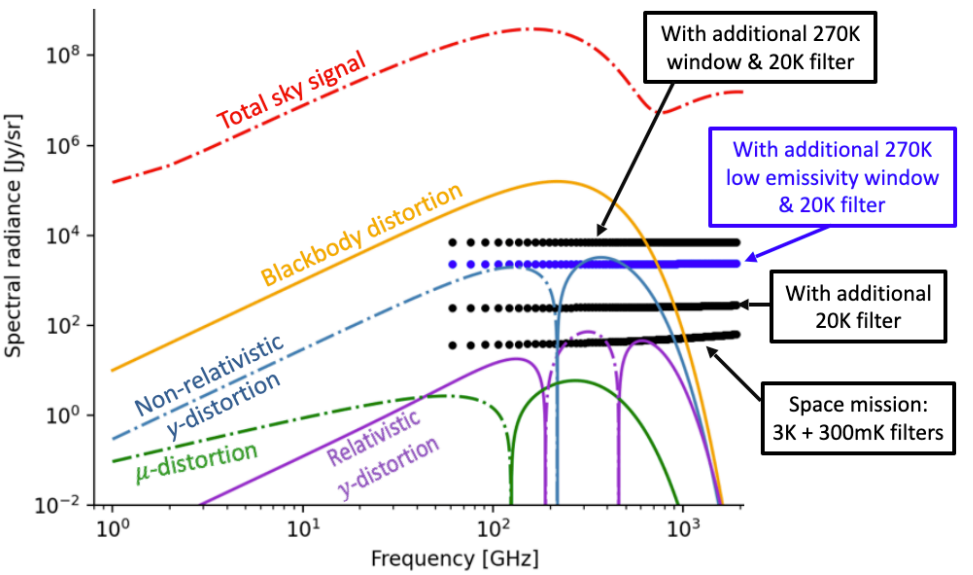

Fig. 4. Estimated instrument sensitivity for different concepts, compared to various spectral distortion signals. All calculations are assuming a 5-day flight. The highest sensitivity assumes a space mission, while the lowest sensitivity is for a balloon flight for which the noise is limited by the emission of the dewar window with pessimistic characteristics.

4.1. *Photometric model*

A preliminary photometric model has been developed, taking into account only the dewar window and a minimum of two spectral filters on the lowest temperature

stages (supposed to be at 20 and 3 K and with a top-hat transmission profile) for the optical input. The emission of all the components in the optical path is modeled as blackbody emission (at the temperature of the component) multiplied by the emissivity of that component at the specified temperature. The load on the detector is estimated by adding the power contributions of the optical components as well as the contribution from the sky, using for each:

$$P(\nu, T) = \int_{\nu_{min}}^{\nu_{max}} eff(\nu) A\Omega(\nu) \epsilon(\nu, T) B(\nu, T) d\nu$$

where $A\Omega$ is the throughput of the multi-moded optics, eff the transmission/efficiency of the optical system, B the blackbody function, and for this first version of our model, the emissivity ϵ is taken as a constant for each component.

We integrate the power received by the detector over the full range of frequencies. In order to assume the worst case scenario for the detector load, when the optical path difference of the Fourier Transform Spectrometer is null, the power is integrated over the full frequency range that we will observe.

The total Noise Equivalent Power (NEP) is then calculated by adding in quadrature the photon NEP from the signal arriving on the detector and the detector NEP which is assumed to be about four times lower than the photon NEP. For the time being, we assume that the other contributions to the total NEP are small in comparison to the photon one. Depending on the assumptions made, for the temperature and emissivity of the optical components for instance, the total NEP is of the order of a few 10^{-16} W Hz$^{-1/2}$ for a space mission to about 10^{-14} W Hz$^{-1/2}$ for a balloon configuration, high enough to allow for the use of detectors at a temperature of about 300 mK.

4.2. *Results*

Following classic calculations,[3] from the total NEP, the detected noise for a fixed integration time τ is given by:

$$\delta P = \frac{NEP_{total}}{\sqrt{\tau/2}}$$

where τ is taken to be 90 hours, corresponding to a flight duration of 5 days with 75% observation efficiency. From this, the noise at the detector may in turn be referred to the specific intensity, leading to an equivalent instrumental sensitivity that can be compared to spectral emissions. These results are shown on figure 4 for different instrument configurations. For all these configurations, a FTS spectral resolution of 15 GHz, a lowest frequency ν_{min}=60 GHz, and a linear tapered filter to limit the high frequency contribution above 600 GHz have been used.

Figure 4 shows the impact of the window on the sensitivity as it will be the warmest element on the optical chain. Starting from a "space configuration" where

the warmest element might be around 3 K (filter at 3 K and 300/100 mK with 0.1% emissivity each), which will be the most sensitive configuration, followed by a configuration with an added filter at T=20 K, then the same configuration with the window at T=270 K added, this with 2 emissivity assumptions for the window, one with ϵ=0.1% like all other filters, and a lower one with $\epsilon = 3 \times 10^{-4}$ (in blue), something that we hope to achieve.

We then conclude that in order to have a first detection of the y-parameter with a decent signal-to-noise ratio, the window will need to be cooled further as previously discussed.

Another parameter which is also crucial, is the maximum observation frequency ν_{max}. All the photon contributions being higher with increasing frequency, the overall sensitivity will drop with increasing ν_{max}. On the other hand, in order to retrieve the "easy" science goals, such as the y-parameter spectral distortions, ΔT_{CMB} and T_{CIB} for the measurement of the Cosmic Infrared Background, measurements have to go to high frequencies. Therefore a trade-off needs to be reached in order to optimise the S/N for each parameter.

This work has started and will be presented in future publications. However, we can already say that, not taking into account the atmosphere, S/N ratios of 5 for the y-distortions, about 30 for ΔT_{CMB} and about 10 for T_{CIB}, can be reached if ν_{max} were to be 1200 GHz.

Obviously a more detailed study will need to take place for a better optimisation, including more sophisticated models and better parameter knowledge.

5. On-going and future work

Aside from more detailed model of the instrument and sensitivity calculations, several points need to be addressed by the end of the Phase 0 study.

The next important hurdle to cross is understanding how to deal with the atmosphere. More accurate models and data for high altitude are being gathered within the consortium but as already stated, a modulator seems inevitable. Concept work and the study of the associated effects of this modulator will be paramount.

Other points to be developed (not exhaustive) can be listed as:

- Observation plan and scanning strategy;
- Calibration strategy, together with the accurate characterisation and control of the calibrator;
- Study on how to increase the sensitivity, by increasing the number of detectors for instance, or having two channels;
- A first cut to the study of the systematic effects, in order to answer at least if the unbalanced optical system between the two inputs will not be a limiting factor;
- Updated science case.

6. Conclusion

So far, assuming that the atmospheric problem can be solved, it seems that according to our preliminary estimates, such a balloon borne instrument will be able to have valid scientific outputs, and not be limited to a technological demonstrator for future space missions. Namely, a measurement of the CIB, a better constraint on ΔT_{CMB}, and more importantly a first 5-σ measurement of the y-distortions if not better.

If these results are confirmed by the end of Phase 0, a proposal to CNES and other funding bodies will be submitted to start a more detailed Phase A study, for a first test-flight on the horizon 2026.

Cosmic microwave background spectral distortions constraints on decaying dark matter particles and axion-like particles using *COBE/FIRAS* and *EDGES*

Boris Bolliet

Department of Physics, Columbia University, New York, NY 10027, USA
E-mail: boris.bolliet@gmail.com

We present new cosmic microwave background (CMB) spectral distortions constraints on low mass (10^{-10}-10^{4} eV) dark matter particles that decay into photons. The constraints are first presented in a model-independent manner and then applied to axions and decaying excited states. For the first time, we place constraints using the full distortion spectra compared to the *COBE/FIRAS* and *EDGES* measurements. This proceeding summarizes results obtained with Jens Chluba and Richard Battye, and published in MNRAS 507 (2021)[a].

Keywords: Cosmology: cosmic microwave background – theory – observations; Dark Matter.

1. Introduction

Spectral distortions are a powerful probe of the thermal history of the universe.[1] They can constrain dark matter candidates with coupling to the electro-magnetic sector, since these typically inject energy into the photon-baryon plasma, generating departure of the CMB spectrum from the black body law. In the past decade, a number of studies have derived constraints on the dark matter cross-section, the mass lifetime and abundance of the decaying or annihilating dark matter particles[e.g.].[2–5] Spectral distortions are often characterized by the chemical potential μ and the Compton-y parameter, which are directly proportional to the injected energy and compared with the COBE/FIRAS bounds, $\mu < 9 \times 10^{-5}$ and $y < 1.5 \times 10^{-5}$ (95%CL). However, the μ and y distortions are generally not sufficient to characterize the full distortions. This is the case when the injected photons do not have time to undergo many scatterings, i.e., *comptonize*. For instance, for distortions from decaying particles with a lifetime comparable to the age of the universe, there may be a y distortion but also a peak in intensity located at the rest mass energy of the decaying particle. Here, we present the first constraints that use such features in the distortion spectra.

This is a challenging task: it requires to solve the Boltzmann equation for photons, simultaneously with the time evolution of the electron temperature and the ionisation history. To do so, we use the code `Cosmotherm` as well as packages recently

[a] https://arxiv.org/abs/2012.07292

developed at the University of Manchester, namely `CSpack` for computing energy exchange from Compton scattering[6] and `BRpack` to compute Bremsstrahlung emission coefficients.[7] We use a standard reionization modeling[8] and a refined treatment of helium and hydrogen recombination initially based on Recfast.[9,10] To run these codes we developed a python package, named `specdist`[b], so that we could compute in parallel many distortion spectra and the corresponding ionisation histories.

2. Photon injection from decaying particles

We focused on a dark matter particle that decays into two photons, each carrying half of the rest mass energy of the decaying particle. We also considered dark matter excited states where one photon carries the energy difference between the excited and ground state of the decaying particle. The time evolution of the dark matter particle population is described by the exponential decay law with a decay rate Γ that is the inverse of the lifetime. The decay rate determines the time of energy injection and consequently the type of distortion. For short lifetimes we expect a μ-distortion until redshift $z \approx 5 \times 10^4$, and a y-distortion at lower redshift. For photon injection happening after recombination, we expect a more complicated shape due to photons that do not have time to scatter and instead simply redshift as the universe expands.

For the spectrum of the injected photons we used a narrow gaussian that approximates a delta function centered at the rest-mass energy of the decaying particle. The normalization of the spectrum is directly proportional to the abundance of decaying particles which we can write in term of the dark matter fraction $f_{\rm dm}$, that we constrain. To do this, once the distortion is computed we proceed with the exercise of comparing it with CMB frequency spectra measurements such as the measurements from *COBE/FIRAS*[11] and the *EDGES* brightness temperature at 78 MHz.[12]

3. Complementary constraints from ionization histories

We also use complementary constraints from the perturbed ionisation histories that affect the CMB temperature and polarization anisotropy power spectra. The left panel of figure 1 shows several ionisation histories for a particle that decays during the end of recombination, with different masses labelled in dimensionless unit. For some of these we found an interesting time evolution with periodic spikes when we switched on collisional ionisation.

In principle these ionisation histories can be fed to Boltzmann codes such as `class`[16] or `camb`[17] to compute the CMB anisotropy power spectra and extract constraints using, e.g., the *Planck* likelihood.[18] A faster method is to use the projection methods developed by Luke Hart and Jens Chluba:[13] the ionisation histories are

[b] https://github.com/CMBSPEC/specdist

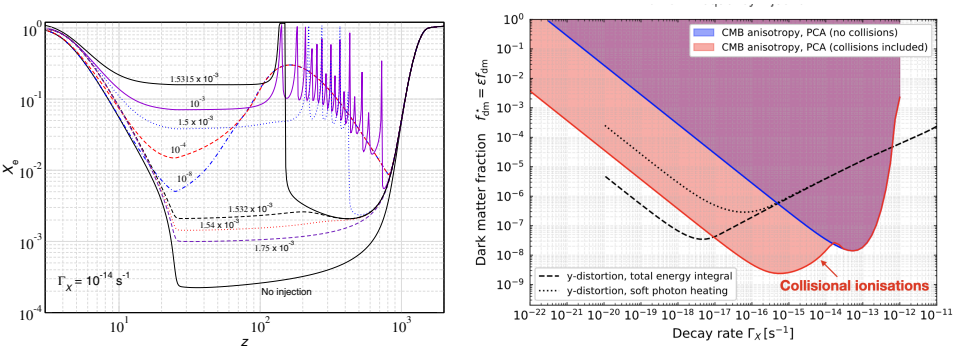

Fig. 1. **Left:** Non-linear responses in the ionization history around critical injection frequencies for $\Gamma = 10^{-14}\,\mathrm{s}^{-1}$ and $\Delta\rho_\gamma/\rho_\gamma = 3\times10^{-5}$. For $10^{-3} \lesssim x_{\rm inj,0} = h\nu_{\rm inj,0}/k_{\rm B}T_{\rm CMB} \lesssim 1.53\times10^{-3}$ the free electron fraction shows intermittent bursts due to photon injection, free-free absorption and collisional processes. **Right:** Derived 95% CL dark matter fraction limit, $f^*_{\rm dm} = \epsilon f_{\rm dm}$, for a range of lifetimes and $x_{\rm inj,0} \lesssim 10^{-8}$. The CMB anisotropy limits were obtained with the projection method,[13] while the other two are derived assuming $4y \lesssim 6\times10^{-5}$ (95% CL) from *COBE/FIRAS*. The dotted curve corresponds to soft photon heating, and the solid dashed line to the total energy integral with the y-era visibility function. For the CMB anisotropy constraints we considered a case where collisional ionisations are not included (blue region) and a case where these are included (red region). As can be seen, atomic collisions are driving post-recombination decay constraints ($\Gamma \lesssim 10^{-14}\,\mathrm{s}^{-1}$). We emphasize that these constraints are for very low mass decaying particles ($m \ll 1$eV) where all the injected energy in the form of photons is converted into heat, in contrast with scenario where the energy is deposited and leads to direct ionisation.[14, 15]

projected onto eigenmodes obtained from a principal component analysis, allowing to derive constraints with a simple root-finding routine.

As shown in the right panel of figure 1, benefiting from the exquisite measurements of *Planck* and *WMAP*, constraints from CMB anisotropy are the strongest for dark matter candidates that decay near recombination, when the CMB is emitted. Nonetheless, *COBE/FIRAS* spectrometer measurements actually beat imager constraints for particles that decay far from recombination, since spectral distortions probe nearly the entire thermal history. Note that the figure illustrates this point with the y-distortion constraints only, while we can now make use of the full distortion spectra.

4. Constraints from the full distortion spectra

In a forthcoming work we will be using machine learning methods in order to build an optimal spectral distortion emulator. For this work, we computed a vast library of distortions so that at any point in the parameter space spanned by the lifetime, mass and abundance of the decaying particle we can interpolate the precomputed spectra and compute the likelihood values given the *COBE/FIRAS* and *EDGES* measurements. A subset of the distortion spectra is shown in figure 2. Our model independent constraints are shown on figure 3. On the left panel, we see the maximally allowed dark matter fraction as a function of the injection energy in eV.

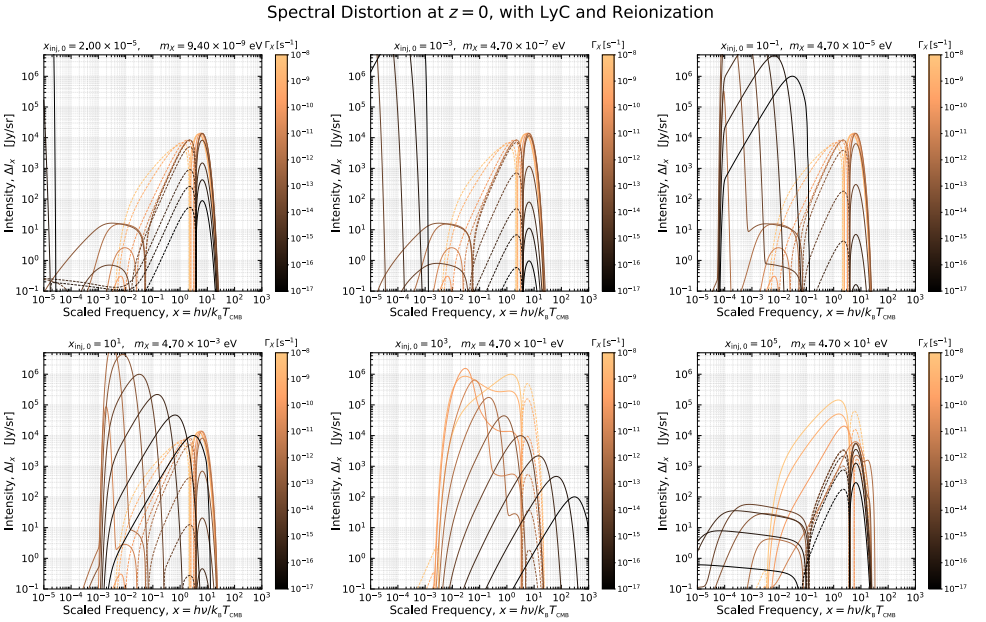

Fig. 2. Solutions for the spectral distortion created by photon injection from decaying particles for several masses, m, and lifetimes, Γ, including simple modelling for reionization in addition to H I, He I and He II photo-ionization (LyC stands for Lyman continuum absorption). All spectra are normalized such that $\Delta\rho/\rho|_{\rm inj} = 3 \times 10^{-5}$. Negative parts of the signal are shown as dashed lines.

The thick line correspond to a a short lifetime, for a particle that decays at early time, towards the end of the μ-era. It is essentially the constraints that one would obtain with a simple μ-estimate calculation by integrating the injected energy over time. There are two differences though: a region near 0.1-10 eV where the chemical potential is actually negative, and a small bump near 1meV associated with photons that have redshifted down to 78MHz where we impose that the CMB brightness temperature should not exceed the *EDGES* measurements. For longer lifetimes, the straight horizontal line constraints corresponding to μ or y estimates is nearly absent: the constraints are driven by the extra redshifted photons that do not scatter efficiently and end up in the *COBE/FIRAS* or *EDGES* frequency range. For decays happening near or after recombination (dotted and dashed-dotted lines respectively), we see strong constraints on the dark matter fraction for energy higher than the ionisation threshold of Hydrogen and Helium (the vertical dashed line on the figure). These constraints are driven by the y-distortion caused by heating from Lyman continuum absorption, and analogous processes for Helium. On the right panel of figure 3, we show the full constraints in the lifetime, injection energy plane with darker colors corresponding to more excluded regions. One piece of modeling that is absent in the constraints of figure 3 are quantum effects associated with the

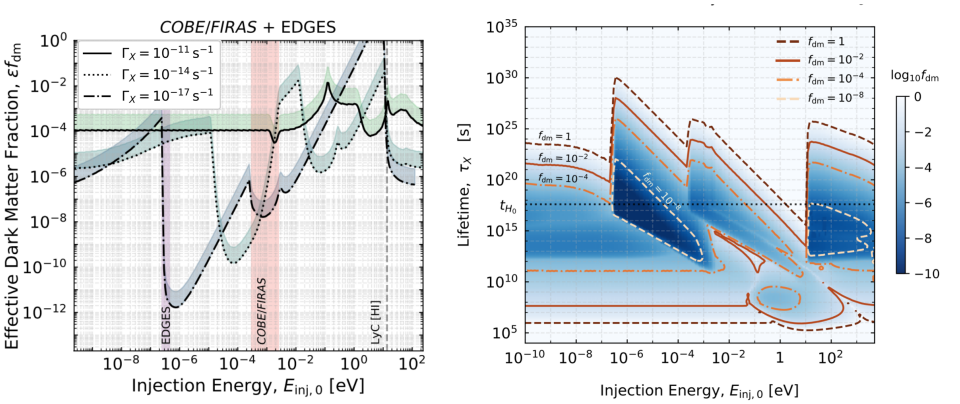

Fig. 3. **Left:** Constraints on the effective DM fraction for decaying particle scenarios (95% CL) for various combinations of data from *COBE/FIRAS*, *EDGES* and *Planck*. The upper panels show the constraints for lifetimes $\Gamma \leq 10^{-11}\,{\rm s}^{-1}$ and various combinations of datasets when assuming decay to occur in vacuum. The lower panels show several examples when including stimulated decay. See main text for discussion. **Right:** Constraints (95% CL) on decaying particle models when subsequently including data from *COBE/FIRAS*, *EDGES* and *Planck*. The addition of *EDGES* affects the constraints at $E_{\rm inj} \simeq 3 \times 10^{-7} - 3 \times 10^{-4}\,{\rm eV}$, while the addition of *Planck* has the largest effect at high energies above $E_{\rm inj} \simeq 13.6{\rm eV}$.

bosonic or fermionic nature of the decaying particle. We treated the case of bosons, for which the emission is stimulated by the ambient CMB photon bath.[19] The effect of stimulated decay is relatively simple: the decay rate becomes frequency dependent with a term that includes the photon occupation number, evaluated at the injection frequency. One has

$$\Gamma_{\rm stim} \approx [1 + 2n(x_{\rm inj})]\,\Gamma \tag{1}$$

where $\Gamma_{\rm stim}$ is the decay rate in the stimulated case and Γ the would be decay rate without stimulated emission, and where we use the Planck black body law to compute $n(x_{\rm inj})$ with $x_{\rm inj} \equiv h\nu_{\rm inj}/k_{\rm B}T_{\rm CMB}$. For large injection frequencies $\nu_{\rm inj}$, both the stimulated decay rate and standard decay rate are equal because $n(x_{\rm inj}) \approx 0$, but for low injection frequencies the difference between $\Gamma_{\rm stim}$ and Γ is proportional to $1/\nu_{\rm inj}$ and is larger at higher redshifts. For instance, for a decay with lifetime roughly the age of the universe today, we expect a small y-distortion and an emission peak centered around the injection frequency. With stimulated decay accounted for, such decaying particle would already have completely decayed a long time ago, in the μ-era, generating a standard μ-distortion. This also implies that with stimulated decay, in the case of low $\nu_{\rm inj}$, one needs much more particles to yield the same amount of energy injection for a fixed lifetime. With this extra piece of modelling we can revisit the constraints of figure 3.

Constraints with stimulated decay accounted for are presented in figure 4 and are the main model independent results of our work. By *model independent*, we mean that at this stage we have not chosen a specific type of particles (other than

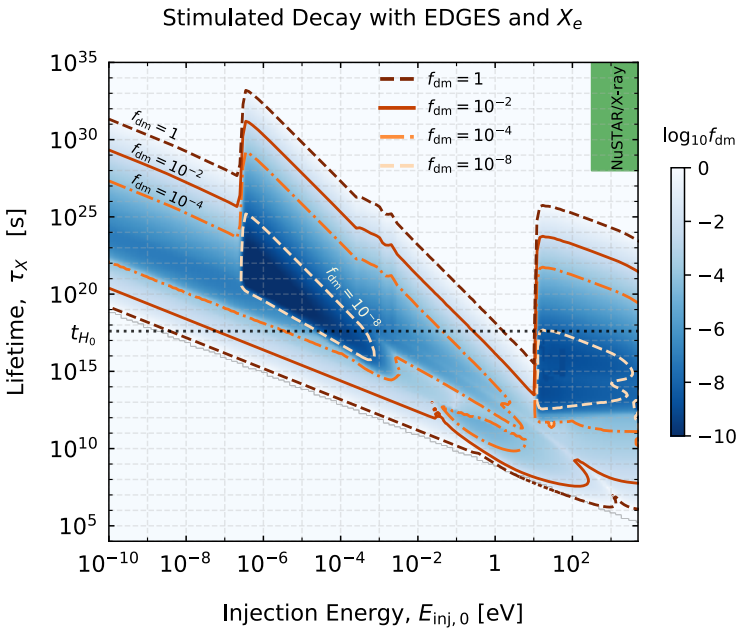

Fig. 4. Same as in figure 3 but with stimulated decay accounted for. The dominant effect of simulated decay is to shift and compress the limits along the τ_X axis for low injection energies/frequencies. We also mark the lifetime corresponding to the age of the Universe ($\tau_X \equiv t_{H_0} \simeq 4.4 \times 10^{17}$ s). For comparison, we have added the current level of constraints of sterile neutrino decay in the X-ray frequency range, namely the lifetime has to be longer than 10^{28} s for masses between $5 - 50$keV (green area labeled 'NuSTAR/X-ray'), see Fig 5 of Roach et al.[20]

being bosons). At high injection frequency, namely above 10 eV, the contours are unaffected by the stimulated decay, as expected. But at lower frequency we see an upward tilt of the constraint regions compared to the vacuum decay case of figure 3, towards longer lifetimes, consistent with the discussion above. For comparison, on the top right corner of figure 4 we have added a green exclusion region which comes from the non-detection of X-ray lines expected in radiative decay of sterile neutrinos.[20]

5. Constraints on axion-like particles

We translated our constraints to axion-like particles (ALPs) models. ALPs are pseudo Nambu-Goldston bosons proposed as dark matter candidates and motivated by solutions to the strong CP problem.[21] For these types of particles there is a fundamental relationship between the mass and the decay rate, parameterized the coupling constant $g_{a\gamma\gamma}$.[22] Then, we can replace the x-axis of figure 4 by the ALPs mass, and map the y-axis, which was the lifetime, to the coupling constant. Constraints on ALPs are shown in figure 5. The top right corner of the plot is not constrained

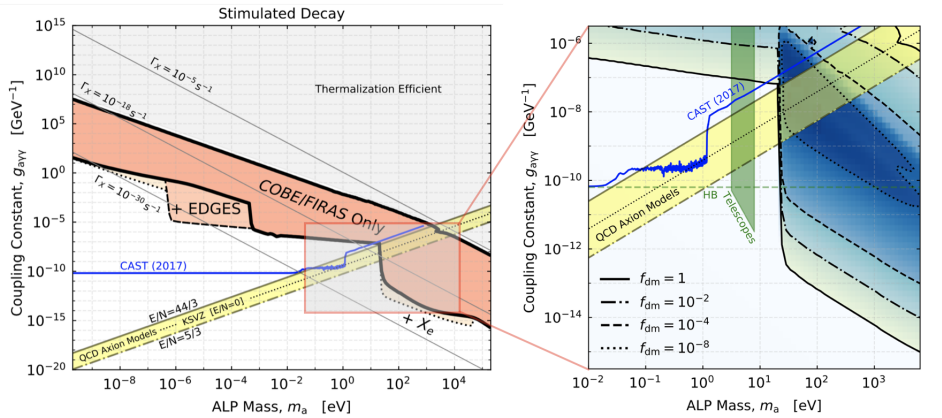

Fig. 5. **Left:** Cumulative *COBE/FIRAS*, *EDGES* and *Planck* constraints (95% CL) on ALPs models and $f_{\rm dm} = 1$. These constraints include blackbody-induced stimulated decay. For reference, we also show that constraint from *CAST*[23] and the physically-motivated region valid for the KSVZ axion model over a range of anomaly coefficients E/N (yellow region). Spectral distortions provide competitive constraints at axion masses of $m_a c^2 \gtrsim 27\,$eV. **Right:** Same as left panel but zoomed in on the high-mass end and for various values of $f_{\rm dm}$. Stimulated decay is unimportant in this domain. Axions with masses $m_a c^2 \gtrsim 27$eV are heavily constrained even if they only constitute a small fraction of the DM. For comparison we have added constraints from Horizontal Branch Stars (green dashed line labeled 'HB') and optical telescopes searches focused on Abell clusters (green shaded area).[24,25] We refer to Fig 91.1 of PDG18[26] for further details on these optical constraints and to Regis et al[27] for the most recent updates.

because it corresponds to very short lifetimes, and all injected energy and photons are thermalized thanks to efficient double Compton and Bremsstrahlung scatterings. The upper part of the pink band is constrained by the μ and y-distortion limits, and the lower part with the peaks correspond to constraints driven by the full spectra. The thick line shows the constraints using *COBE/FIRAS* residuals and the dashed line is the extended constraints when we add the 78 MHz *EDGES* data. The dotted lines are the constraints when we add CMB anisotropy from perturbed recombination. On the right we show a zoomed in region of the plot and we also show the constraints assuming ALPs make up only a fraction of the dark matter. Most of this part of the constraint plot is determined by the y-distortion due to heating from Lyman continuum absorption and it shows that spectral distortion constraints are competitive against other astrophysical constraints on axions, e.g., constraints from *Horizontal Branch* (HB) stars (the green dashed line) and *optical telescopes* (the green area).

6. Conclusion

Here we have presented the first constraints on photon injection processes using the full distortion spectra and ionisation histories. Our work shows that we are still harvesting insights into dark matter from the 30 years old *COBE/FIRAS* spectrometer

data. There is little doubt that the next spectrometer mission will be game changing for dark matter models. Our next steps will be to build a spectral distortion emulator to alleviate the computationally expensive calculations of distortion spectra and ionisation histories, and provide a forecast analysis for a next spectrometer mission such as Voyage 2050.[28]

The COSmic Monopole Observer (COSMO) is an experiment to measure low-level spectral distortions in the isotropic component of the Cosmic Microwave Background (CMB). Deviations from a pure blackbody spectrum are expected at low level (< 1 ppm) due to several astrophysical and cosmological phenomena, and promise to provide important independent information on the early and late phases of the universe. They have not been detected yet, due to the extreme accuracy required, the best upper limits being still those from the COBE-FIRAS mission. COSMO is based on a cryogenic differential Fourier Transform Spectrometer, measuring the spectral brightness difference between the sky and an accurate cryogenic blackbody. The first implementation of COSMO, funded by the Italian PRIN and PNRA programs, will operate from the Concordia station at Dome-C, in Antarctica, and will take advantage of a fast sky-dip technique to get rid of atmospheric emission and its fluctuations, separating them from the monopole component of the sky brightness. Here we describe the instrument design, its capabilities, the current status. We also discuss its subsequent implementation in a balloon-flight, which has been studied within the COSMOS program of the Italian Space Agency.

Keywords: Cosmic Microwave Background; Spectral Distortions; Fourier Transform Spectrometer.

1. Introduction

Spectral distortions of the CMB represent a research path orthogonal and synergic to CMB polarization studies. Their detection can shed light on cosmic reionization, on the physics of recombination, on dark matter and in general on any energy release in the primeval fireball, and even on the very early universe and cosmic inflation. See[1] and references therein for a comprehensive review. The expected deviations are very small, < 1 ppm, but have characteristic spectral signatures, allowing, in principle, their separation from overwhelming foreground emission and the CMB monopole itself. In figure 1 we compare the largest spectral distortions of the CMB in the mm-wave region to the most important foregrounds.

Current upper limits for spectral distortions are at a level of 0.01% of the peak brightness of the CMB, and were obtained more than 20 years ago by COBE – FIRAS.[2,3] Current technologies promise to achieve much higher sensitivity, the limiting factor remaining the control of instrumental systematic effects and the emission of astrophysical foregrounds. In order to avoid the very large background produced by the earth atmosphere at CMB frequencies, the final measurement must be carried out from space. To this purpose, several proposals for space-based experiments have been submitted, like the PIXIE,[4] CORE[5] and PRISTINE missions. Meanwhile,

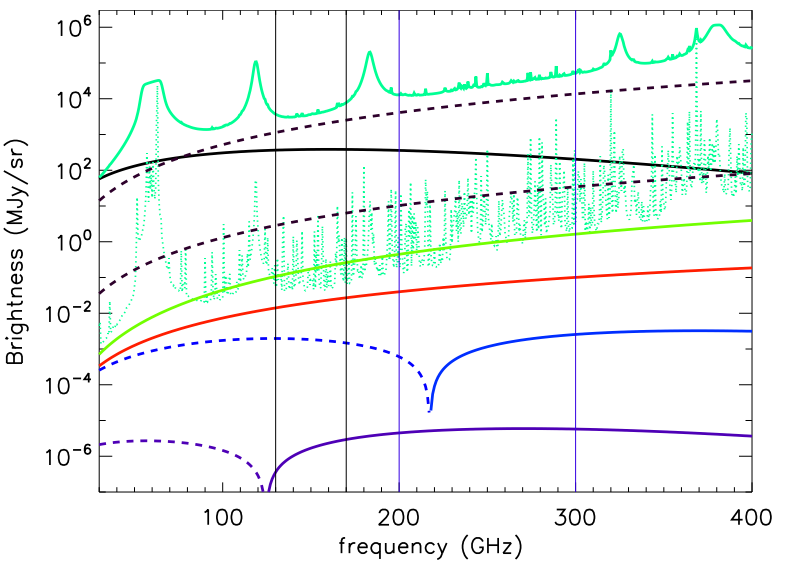

Fig. 1. Plot of isotropic brightness from (top to bottom, continuous lines): Antarctic atmosphere in Dome-C (zenith), CMB, interstellar dust (Galactic average), far infrared background (FIRB) from unresolved galaxies, absolute value of the y-distortion ($y = 1.77 \times 10^{-6}$, negative branch dashed), absolute value of the μ-distortion ($\mu = 2 \times 10^{-8}$, $\beta = 2.19$, negative branch dashed). The two dashed lines represent the emission of the window of the receiver, for the ground based (upper) and the balloon-borne (lower) implementations of COSMO. The dotted line represents atmospheric emission at stratospheric balloon altitude (zenith). The two couples of vertical lines define the observation bands of COSMO in its ground-based implementation.

ground-based and near-space efforts are necessary to test and refine methods, and possibly to detect the largest spectral distortions. Here we focus on the COSMO project, a pathfinder, staged effort to be carried out in Dome-C (Antarctica) first, and then on a stratospheric balloon.

The problem of spectral distortions of the CMB monopole, as evident from figure 1, is that they are very small with respect to other isotropic backgrounds, including instrument emission, atmospheric emission (if present), astrophysical foregrounds from the interstellar medium and the other galaxies along the line of sight, and the CMB monopole itself. Moreover the instrument has to be cryogenic to reduce its own emission, and operate where atmospheric emission is very small and/or can be measured and subtracted. For sure, advanced strategies for components separation are in order (see e.g.[6]).

In the following section we focus on the COSMO experiment, attempting sub-orbital measurements of spectral distortions.

2. The COSMO experiment

2.1. *Measurement method and general design*

COSMO is a cryogenic differential Fourier Transform Spectrometer (FTS) in Martin Puplett Interferometer (MPI) configuration:[7] a two input ports differential instrument comparing the brightness of the sky (port A) to the brightness of an accurate internal blackbody (port B), exactly like in COBE-FIRAS.[8] A simplified instrument model is described by equation 1:

$$I_{sky}(x) = \mathcal{R} \int_0^\infty A\Omega(\sigma)[B_{sky}(\sigma) - B_{ref}(T_{ref}, \sigma)]e(\sigma)[1 + cos(4\pi\sigma x)]d\sigma \quad (1)$$

where $I_{sky}(x)$ is the signal measured by the detector as a function of the optical path difference x between the two arms of the interferometer, which is scanned by means of a moving roof-mirror; σ is the wavenumber, $A\Omega(\sigma)$ is the optical throughput of the detector, $B_{sky}(\sigma)$ is the sky brightness present at input port A, $B_{ref}(T_{ref}, \sigma)$ is the brightness of the reference blackbody at temperature T_{ref} present at input port B, $e(\sigma)$ is the spectral efficiency of the instrument, the constant $\mathcal{R}$ is the responsivity of the instrument. During the calibration phase, an external blackbody at a known temperature T_{ext} fills input port A: in these conditions the measured signal is

$$I_{cal}(x) = \mathcal{R} \int_0^\infty A\Omega(\sigma)[B_{ext}(T_{ext}, \sigma) - B_{ref}(T_{ref}, \sigma)]e(\sigma)[1 + cos(4\pi\sigma x)]d\sigma. \quad (2)$$

Antitransforming equation 2 one gets the quantity $\mathcal{R}A\Omega(\sigma)e(\sigma)$, which can then be used in the antitransform of equation 1 to estimate $B_{sky}(\sigma)$.

Both B_{ref} and B_{ext} should be at cryogenic temperatures, close to T_{CMB}, in order to avoid saturation or non-linearity effects in the detectors, and extreme requirements on the knowledge of T_{ref}, T_{ext} and the blackbody emissivities.

Since the COSMO instrument operates in environments (Dome-C or the stratosphere) where atmospheric emission is present, special care must be taken to measure the emission from the atmosphere, and the emission of the vacuum window separating the cryogenic instrument from the external environment. Both these emissions are not present in a space-based instrument, while they contribute very significantly to the measured B_{sky} in the case of a suborbital experiment like COSMO. Moreover, the cryogenic external blackbody will necessarily have a vacuum window, adding its emission to B_{ext}.

2.2. *Coping with atmospheric emission*

In the ground-based implementation, COSMO will operate from the French-Italian Concordia base, in Dome-C (Antarctica). This is likely to be one of the best sites on Earth for mm-wave astronomical observations, being extremely cold and dry. But still atmospheric emission is present. The first defense against atmospheric emission is the selection of the frequency interval. In its ground-based implementation, COSMO uses two frequency channels matching mm-wave atmospheric windows, covering the frequency bands 110-170 GHz and 200-300 GHz. Each frequency channel is detected by an independent focal plane array. In this way radiation from the high frequency band does not overload the low-frequency detectors, so that higher sensitivity can be achieved in the low frequency channel.

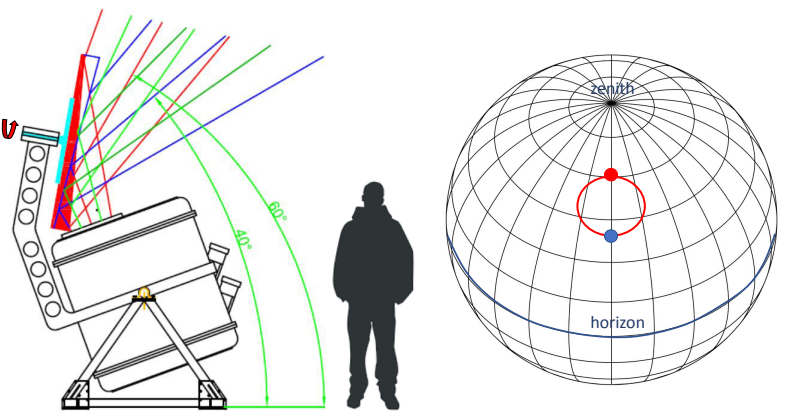

Fig. 2. Geometry of the sky scan for the COSMO experiment. **Left:** The COSMO instrument with the external spinning wedged flat mirror, steering the instrument beam in the sky while spinning. The arrow identifies the spin axis, while the mirror is sketched in two positions (red and blue) corresponding to maximum and minimum elevation of the beams, respectively. The central and marginal beams are also shown in the same colors. **Right:** Resulting scan of the beam (in red) over the celestial sphere. The two spots mark the maximum and minimum elevations explored by the beam. The circular scans, combined with Earth rotation, result in the coverage of several sky patches at different Galactic latitudes.

COSMO uses fast Kinetic Inductance Detectors (KID) and fast elevation scans to separate atmospheric emission and its long-term fluctuations from the monopole of the sky brightness. A fast spinning, wedged flat mirror (>1000 rpm) steers the boresight direction on a circle, 20^o in diameter, scanning a range of elevations (and the corresponding optical depths of the atmosphere) while the cryogenic interferometer scans the optical path difference (see figure 2).

In this way the recorded interferogram (equation 1) will be the one due to the sky monopole (constant during the sky scan) plus the one due to atmospheric emission, which is modulated by the beam elevation variations during the sky scan. A sample expected interferogram is reported in figure 3 for the low-frequency band of COSMO.

By properly sampling the measured interferograms, the interferograms corresponding to the different elevations e scanned by the instrument can be retrieved. These can be antitrasformed to estimate the measured brightness spectra for the different elevations. For each frequency, a cosec(e) law can be used to estrapolate to zero air-mass, thus estimating the isotropic component of the sky brightness (see figure 4).

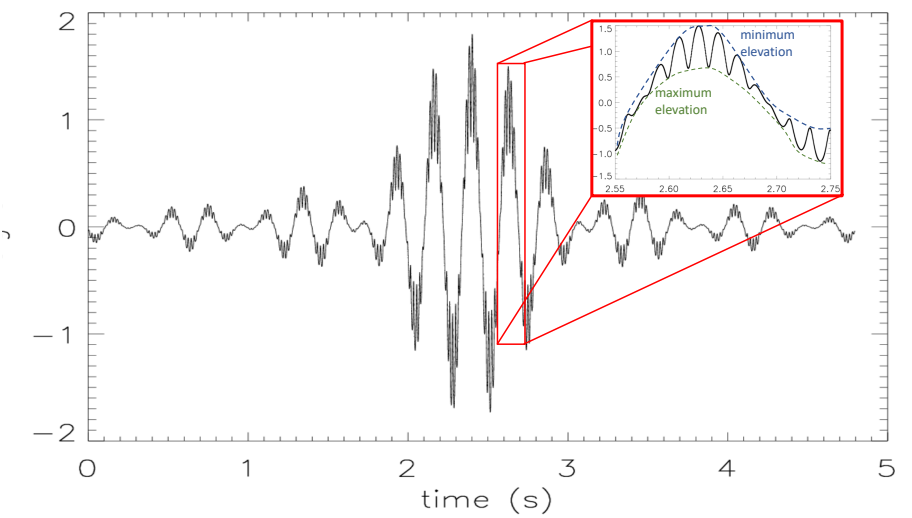

Fig. 3. Example of expected interferogram obtained while the flat wedged mirror is spinning. For each position x of the roof mirror in the MPI (corresponding to a different time on the abscissa), the signal changes due to the fast variation of the observed elevation. Fast (KID) detectors are used to follow these variations. In this example one full scan of the roof mirror is shown (at a mechanical speed of $\sim$ 0.25 cm/s, from -1.27 cm to +1.27 cm of optical path difference). The zoomed inset shows how the interferograms corresponding to the maximum and minimum elevations can be obtained by properly resampling the measured interferogram. Millions of interferograms like this one will be measured during an observation campaign.

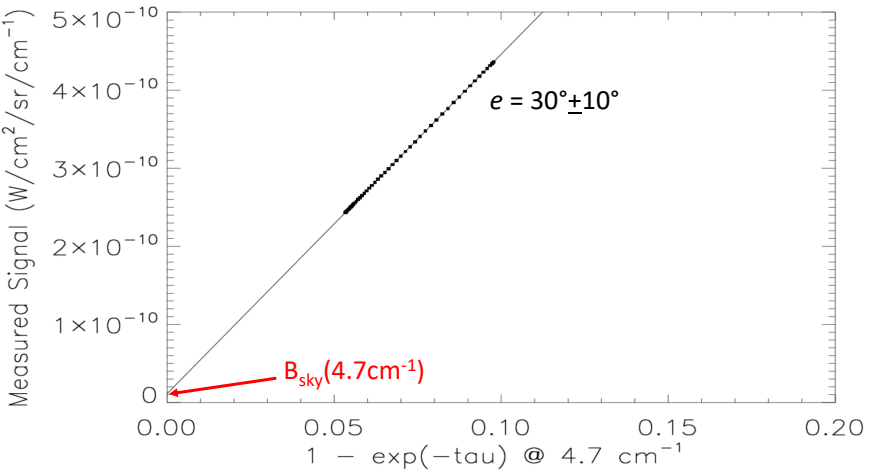

Fig. 4. Extrapolation to zero air-mass to estimate the isotropic component of the sky brightness for each frequency.

Since the instrument measures one interferogram every few seconds, slower atmospheric fluctuations are removed in the process, mitigating the effects of $1/f$ noise, which is characteristic of atmospheric fluctuations.

This measurement method is allowed by the use of fast ($\tau \sim 60\mu s$) KIDs, similar to the ones developed for the OLIMPO experiment.[9] In table 1 we report a possible scanning configuration of the COSMO instrument in its first ground-based implementation.

2.3. *Coping with window emission*

Both the cryogenic reference blackbody and the FTS of COSMO are enclosed in a vacuum shell, necessary for the cryogenic operations. External radiation enters the vacuum jacket through a vacuum window, made from a transparent material for mm waves. The best solution is to use a slab of polypropylene, which has to be ~ 1 cm thick in the ground based implementation, to withstand atmospheric pressure. This can be significantly thinner at balloon altitude: we assume a 25 μm thick window for that implementation. As visible in figure 1, the emission of the receiver window is very important in both cases. The way we cope with it is to measure spectra keeping the internal reference and the external calibrator at the two input ports and steady, for different, well controlled temperatures of the window. This procedure will produce a calibration of the contribution from window emission in the measured spectra as a function of the temperature of the window. This will be monitored during the sky measurements, so that will be possible to subtract

Table 1. Scanning characteristics of the COSMO instrument[a]

circle radius	5	deg
beam FWHM	0.5	deg
wedged mirror spin	600	rpm
time per beam	200	μs
time for one forward plus one reverse sky dip	0.1	s
maximum wavenumber	20	cm^{-1}
sampling step	125	μm
resolution	5-15	GHz
time to complete one interferogram	25.6	s
sky dips per interferogram element	2	

Note: [a]Example of certainly feasible combination of wedge and roof mirror scans; faster scans are currently under consideration.

window emission using the calibration. The expected accuracy of this process has been investigated: preliminary results show that the residuals after subtraction are subdominant when targeting at the measurement of the y distortion.

3. Implementation of the ground-based COSMO experiment

3.1. *Selection of the site and installation*

Due to the high altitude, extremely low temperatures in the winter, and absence of solar illumination for several months in a row, the Dome-C (Antarctica) site offers unmatched excellent conditions for astronomical observations in the mm-wave atmospheric windows (see e.g.[10,11]). Its latitude (75^oS) allows for crosslinked sky scans at constant elevation (which are not possible from the South Pole), similar to those obtained in circumpolar stratospheric balloon flights (see e.g.[12]). The presence of the French-Italian Concordia station provides high quality logistics support (power, communications, resident personnel) for the operations of a modern CMB experiment. The instrument will be hosted in a thermally insulated ISO20 shipping container, with retractable roof, and mounted on a palafitte on top of a hardened snow berm, following a consolidated tradition for medium-size astronomical instruments in Antarctica. The container and the instrument will be oriented so that the elevation movement steers the boresight along the local meridian. As described below (see §4), this simple sky scan strategy allows to observe both high and intermediate Galactic latitudes, totalizing a coverage of $\sim 5\%$ of the sky.

3.2. *The optical system*

3.2.1. *Generalities*

Angular resolution is not the main driver of this experiment, which is aimed at measurements of the *isotropic* monopole component of the CMB brightness. We designed

the instrument with and optical aperture of 22 cm in diameter, producing a diffraction limited beam at the longest wavelength (2.4 mm) of $\sim 0.7^o$ FWHM. This is the result of a tradeoff between the size of the optical aperture and the need of monitoring the effect of *anisotropic* foregrounds. The telescope and the Fourier Transform Spectrometer are located inside the cryostat to minimize their radiative background. A sketch of the optical setup, based on polyethylene lenses, is shown in the left panel of figure 5, while the main data are reported in table 2.

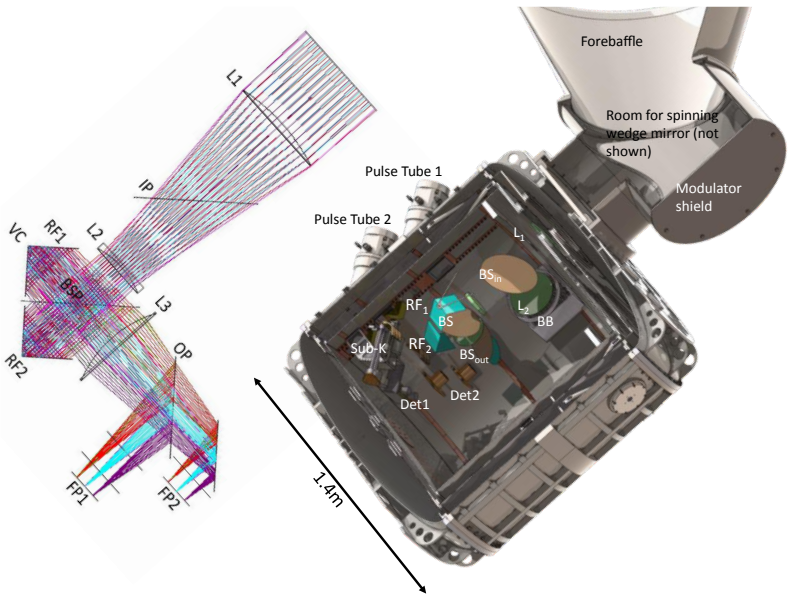

Fig. 5. **Left:** Ray tracing and optical design of COSMO. L1 is the light collector lens, L2 produces a nearly parallel beam for the FTS, L3 focuses radiation of the focal planes FP1 and FP2. The Differential Fourier Transform Spectrometer is costituted by the input polarizer IP, the beam-splitter polarizer BSP, the roof mirrors RF1 and RF2, the output polarizer OP. The input polarizer transmits radiation from the sky and reflects radiation from the cryogenic reference blackbody. **Right:** rendering of the accommodation of the COSMO instrument inside its cryogenic system.

Table 2. Optical parameters of the COSMO instrument.

optical aperture diameter	220	mm
effective focal length	726	mm
multimode pixel antenna aperture diameter	20	mm
focal planes	2	
number of detectors per focal plane	9	
projected pixel to pixel distance (x and y)	0.75	deg
beam FWHM	0.75	deg

3.2.2. *The cryogenic Fourier Transform Spectrometer*

The cryogenic FTS is a MPI, with two delay lines terminated with roof-mirrors. The interferogram is obtained introducing a variable difference in the lengths of the two delay lines. This is obtained with the linear movement of one of the two roof-mirrors (RF1 in figure 5). The maximum optical path difference introduced by the motion of the moving roof mirror is +/- 2 cm, corresponding to a coarse spectral resolution of ∼10 GHz. Since the FTS operates at cryogenic temperature, we have to minimize the friction produced by the motion of the roof-mirror. We have designed a cryomechanism based on harmonic steel flexure blades, operating in the elastic regime. The actuator is a coil moving in the radial magnetic field of a strong permanent magnet (figure 6). The position is sensed by a LVDT. Preliminary room-temperature tests confirm the frictionless operation of the device.

3.2.3. *The detectors*

The output beam from the FTS is naturally split in two exit ports by the output polarizer. In each output port we place a focal plane array, consisting of multimode horn antennas feeding multimode lumped elements kinetic inductance detectors (LEKIDs), on a 4 inch Si wafer. The reflected beam serves the high frequency band array, while the transmitted one serves the low frequency band array.

The design of the COSMO LEKIDs was optimized starting from the experience gained with the LEKID arrays realized for the OLIMPO experiment.[25,26] COSMO detectors are 30 nm thick Aluminum LEKIDs, each of which has a front–illuminated V order Hilbert curve absorber/inductor. The large absorber area, $\sim 8\,\mathrm{mm} \times 8\,\mathrm{mm}$ for both channels, serves to guarantee the efficient absorption of all the modes

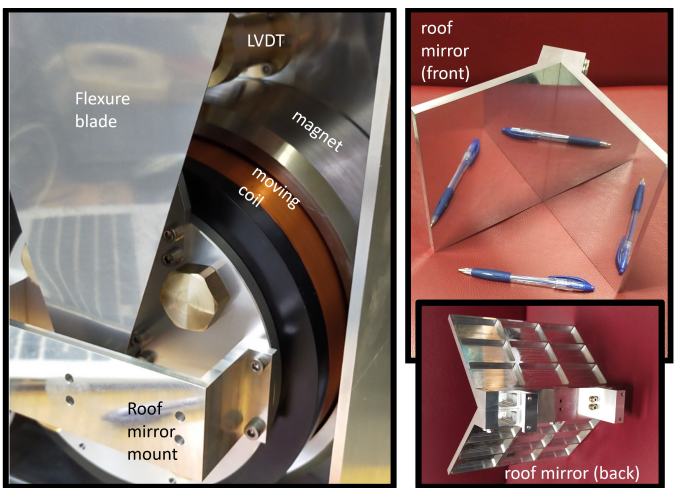

Fig. 6. **Left:** photo of the cryogenic roof-mirror scanner for the MPI FTS. **Right:** the roof mirror. Its projected size is 200 × 200 mm.

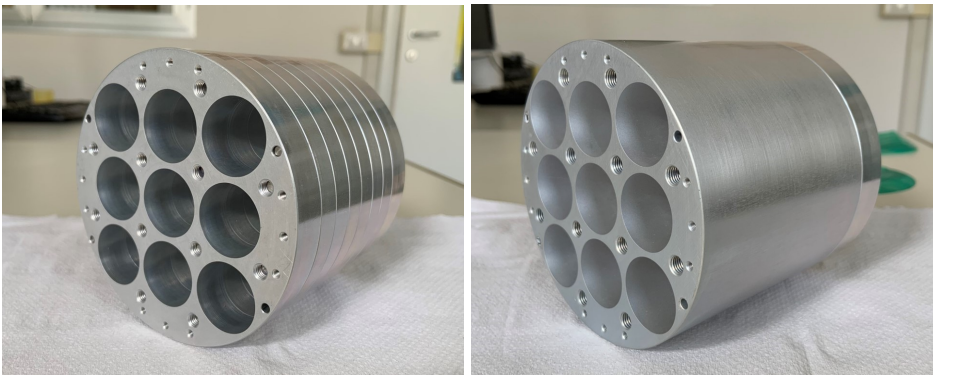

Fig. 7. **Left:** photo of the low-frequency array, made of seven antenna plates and a bottom plate with circular waveguides. **Right:** photo of the high-frequency array, which is made as one piece, with a separate bottom plate of circular waveguides.

which propagate through the multimode waveguides. In particular, the size of the waveguide diameter, 4.5 mm for the 150 GHz channel and 4 mm for the 255 GHz channel, allows the propagation of 10 to 19 modes in the 120-180 GHz range and of 23 to 42 modes in the 210-300 GHz range. Because of the size of the focal planes and the horn apertures, each detector array hosts 9 pixels.

The forecast performance for such detectors, in terms of detector noise equivalent power (NEP) is $\mathrm{NEP_{det}} \sim 3.8 \times 10^{-17}\,\mathrm{W}/\sqrt{\mathrm{Hz}}$, with a response time $\tau \sim 60\,\mu\mathrm{s}$, when operated at about 300 mK. These estimations take into account the absorber volume, the superconductor critical temperature, and the simulated absorber efficiency. This performance is more than adequate for the ground-based implementation of COSMO, which is likely to be dominated by atmospheric noise and systematic effects rather than by detector sensitivity.

3.2.4. *The detector feedhorns*

The radiation coming from the FTS is coupled to the detectors by two arrays of nine multimoded feed-horns working in the $120 - 180$ GHz and $210 - 300$ GHz range, respectively. Since COSMO will perform only total intensity measurements, we chose a smooth-walled profile which is easier to manufacture than a corrugated one.

The low-frequency array consists of Winston cone antennas while the high-frequency array hosts linear profiled antennas. The antenna design is the result of a trade-off between the multimode requirement on the antenna waveguide, the mechanical constraint on the antenna aperture and the optimization of the antenna directivity within the cryostat aperture window. The forecasted FWHM of the main beam is around 20°, the first side-lobe level is below -15 dB and the far side-lobe level is below -30 dB.

The arrays are machined with CNC milling by Pasquali SRL in Milan, and are obtained by superimposing metal plates through dowel-pins and tightening them with screws, as shown in figure 7. The arrays are cylindrical with a diameter of 101 mm to minimize the mass to be cooled as much as possible; the feed-horns are arranged on a square footprint with a 26 mm center-to-center distance.

Both the arrays are made in ergal (Al7075) to conform to the focal plane and avoid differential thermal contractions during the cryogenic cooling of the experiment. They are mechanically coupled to a band-pass filter on the front (aperture) side and to an interface to the focal plane wafer holder on the back. To this purpose, we used the experience gained with the LSPE-SWIPE experiment[15] to design a flared waveguide interface to directly illuminate the KIDs detectors.

3.2.5. *The reference blackbody*

One of the two inputs of FTS looks at a cryogenic reference blackbody. This is a cavity with the inner surface covered by a microwave absorber. The cavity structure is in copper, to achieve a very uniform temperature. We have optimized the shape of the cavity both through geometrical ray tracing (maximizing the number of internal reflections) and via finite elements electromagnetic simulations (minimizing the S_{11} parameter). The performance in the ray-tracing approximation is assessed assuming a reflectance of the coating as a function of the wavenumber $\bar{\nu}$ as in ref.,[16] $r(\bar{\nu}) = 0.08 + \frac{0.06[cm^{-1}]}{\bar{\nu}}$. The number of internal reflections is always $N > 6$, corresponding to the cavity reflectance $R = r^N < 10^{-6}$ over the band 100-300 GHz. This indirectly provides the cavity emissivity as $(1 - R)$.

Due to the size of the calibrator, much larger than the wavelengths of interest, we used *HFSS* electromagnetic analysis only to simulate the performance of a thin cut section of the cavity. This is a few wavelengths thick, and is representative in terms of the absorbing properties of the cavity. However it is not representative of the direction of the damped outgoing radiation. The simulations have been run for the lowest frequencies of the 150 GHz band, and the corresponding dielectric properties of the absorbing coating (relative permittivity $\epsilon_r = 3.50$ and dielectric loss tangent $tg(\delta) = 0.032$ at 100 GHz at 4 K) have been taken from.[17] The input radiation is set as an *Incident Gaussian Beam*, determined by the lens L1 feeding the blackbody cavity. The reflectance, computed as the ratio of the Poynting vector fluxes of the scattered and incident radiation, is $R(120\,\mathrm{GHz}) = 3.2 \cdot 10^{-6}$. Diffractive effects and reflection coefficients at non-normal incidence, not included in the ray tracing approach, produce discrepancies between the two models.

Finite elements thermal simulations have been performed, considering a perfect thermal contact between the copper external structure and the internal absorbing coating, and including an irradiating internal surface of the cavity to a 4 K background. The external structure temperature was set to 2.725 K, from a starting

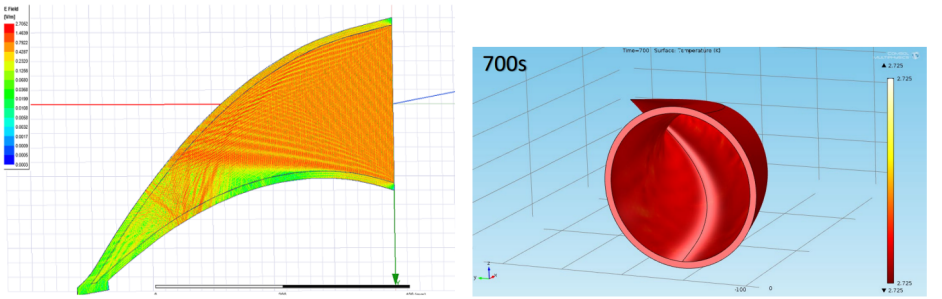

Fig. 8. **Left:** Results of an HFSS simulation of the total electric field propagating within the blackbody cavity, demonstrating its gradual attenuation (colors correspond to a logarithmic scale for field amplitudes. **Right:** Results of a finite elements thermal simulation displaying the temperature at the surface of the internal absorbing coating 700s after cool-down. The temperature gradients are <0.1 mK.

point of 4 K. The thermal properties of the coating are taken from.[18] Preliminary results show a maximum thermal gradient <0.1 mK (see fig.8).

3.2.6. *The atmospheric modulator*

The other input of the FTS looks at the sky through an optical window and a beam-steering mirror, which is used to modulate atmospheric emission and measure it as described in §2.2. The atmospheric scan has to be very fast (up to 2800 rpm) to measure atmospheric emission and subtract it in real time, so that 1/f noise from atmospheric emission is efficiently removed. A light-weighted, all 6061 Aluminum design for the mirror has been optimized to minimize the inertia. The off-axis inertia moments are null using optimized counterweights, allowing us to use simple and reliable electrical motors and shaft bearings.

One of the most dangerous problems in this kind of measurements is the pickup of ground radiation. A custom forebaffle has been designed as the first defense against ground spillover. This forebaffle moves together with the receiver, and will be complemented by much larger steady ground shields. The internal surface will be fully covered with eccosorb absorber. The forebaffle is largely oversized, and has been shaped so that the spillover from its inner surface is not modulated by the spin of the wedge mirror. Heaters and temperature sensors will allow to test any residual spillover contribution to the measured signal by means of custom calibration measurements.

3.3. *The cryogenic system*

A large cryogenic system, based on pulse-tubes and a ^{3}He evaporation cooler is used to cool the optical system and the detector arrays. The system is similar to the one

developed for the QUBIC experiment (see[13]), adapted for operation in the harsh Antarctic environment. To this purpose, we used the experience gained with the BRAIN refrigerator, successfully operated in Dome-C more than 10 years ago.[14] In the right panel of figure 5 we show the implementation of the COSMO instrument inside its cryogenic system. Using pulse tube refrigerators, the cryogenic system can operate continuously and does not rely on the delivery of cryogenic liquids, which would be very difficult in dome-C. Of course, continuous power is required, which amounts to about 10 kW, most of which are used for the pulse tube compressors and to warm-up the environment inside the experiment shelter to above 0 Celsius.

3.4. *Readout electronics*

The arrays of KIDs are read applying a comb of frequencies tuned to the resonances of the different pixels, and reading the S21 parameter for each pixel. A FPGA-based electronic system generates a set of tones corresponding to the KIDs' resonances. The combination of tones is sent to the detectors; the return signal is acquired and analyzed by means of a transceiver which detects the change in amplitude and phase of the tones. The system is based on a commercial architecture (Xilinx Virtex-5 NI7966R). The Virtex5 architecture was selected because it is the most powerful of the family being available as a rad-hard component. This specification not necessary for Antarctica, but is strategic in the perspective of the implementation of COSMO on a stratospheric balloon . We have prepared a state machine which, in the first state, performs a sweep to find the resonance tones of the KIDs. In the second state, a lookup table is generated with the values of the resonances found. With a CORDIC algorithm these tones are generated to compose a comb, which the third state of the machine transmits to the KIDs and acquires in amplitude and phase to measure the variation of the working point of the detectors. We have already tested the functionality of the state machine in the lab by means of Nb kids, fit for a 4 K cryostat. We are currently working to move the entire process of modulation and demodulation on board of the FPGAs, to reach the target rate of acquisition, fit for the operation with the FTS.

4. Performance forecast for the the ground-based COSMO experiment

The performance of the instrument is assessed via ILC[19] (Internal Linear Combination) based simulations. Absolutely-calibrated maps are used as input, containing the superposition of the PySM[20] maps of CMB anisotropies and thermal dust, as the main galactic foreground. The isotropic distortion maps are added as a y-distortion map with $y = 1.77 \cdot 10^{-6}$ and a μ-distortion map with $\mu = 2.0 \cdot 10^{-8}$. The input multi-frequency maps, with a spectral resolution $\Delta\nu = 15\,\mathrm{GHz}$, are smoothed with a FWHM=1°. The noise realization, added as Gaussian noise, is dominated by the photon noise from the cryostat window, whose emission is modeled as a 240 K

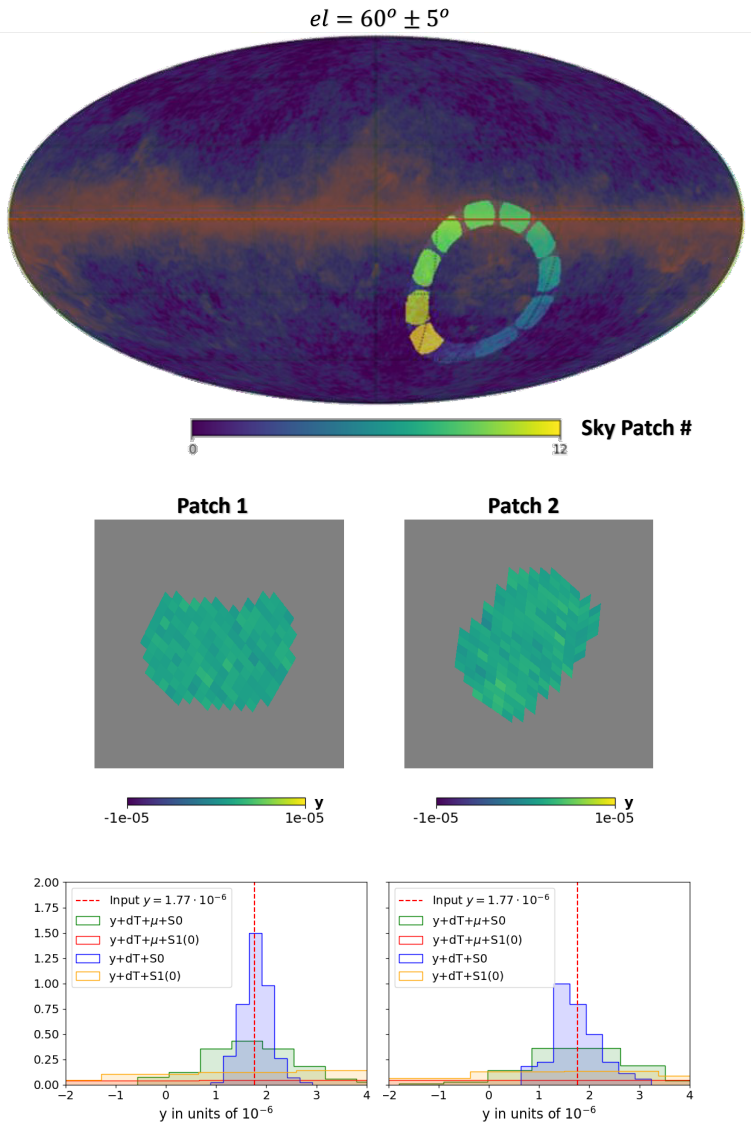

Fig. 9. **Top:** Sky coverage map divided in 11 patches, overlapped to the 270GHz PySM map which includes thermal dust emission and CMB anisotropy. **Middle:** Simulated measured maps for the y distortion sky component, extracted using the ILC method, in two sample sky patches at high Galctic latitude. **Bottom:** Histograms of the simulated estimates for the y values, for the two sky patches above.

grey-body with 1% emissivity, and by the atmospheric emission (modeled based on the *a.m.* software with PWV=0.15mm).

The ILC machinery allows to extract the y-distortion map from the dominant components. Different orders of the thermal dust emission are subtracted from the

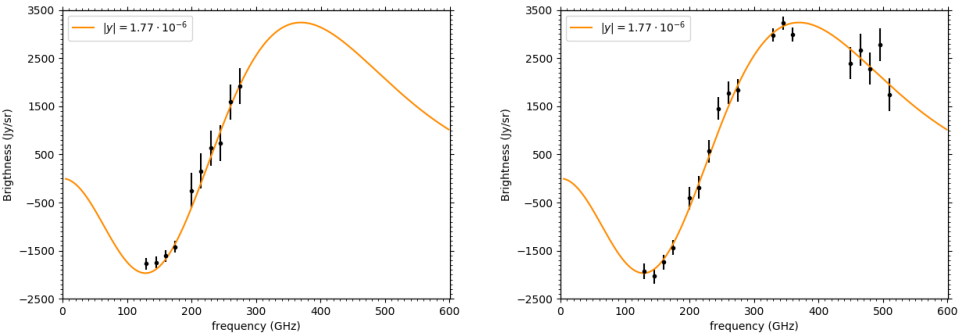

Fig. 10. **Left:** Simulated measurement of the spectral distortion of the CMB after one year of integration in Dome-C, assuming photon noise limited performance dominated by the emissions of the cryostat window and the atmosphere and assuming 15 GHz resolution. **Right:** Simulated measurement of the spectral distortion of the CMB after 15 days of integration on a stratospheric balloon, assuming photon noise limited performance dominated by the CMB, residual atmosphere and warm mirror, and assuming 15 GHz resolution.

solution as in.[21] Histograms of the output Compton-y maps, reported in Fig.9, show that the best ILC solution is provided by subtracting the 0^{th} order of the thermal dust, in combination with the CMB anisotropy.

Assuming a scanning strategy at fixed central elevation, combined with the spinning wedge mirror modulation, 5% of the sky is observed every day, which can be divided for the analysis in 11 sky-patches at different Galactic latitudes (see fig.9). The ILC is independently applied to the patches and the weighted average of the output Compton-y maps provides the estimate of the isotropic y distortion as $y = (1.70 \pm 0.28) \cdot 10^{-6}$.

In figure 10 (left panel) we show the expected spectrum of the spectral distortion we expect to measure after 1 year of integration in Dome-C.

5. Implementation of the balloon-borne COSMO experiment

The spectrum of the CMB at mm wavelengths has been measured from stratospheric balloon platforms in the past (see e.g.[22]). Here we plan to exploit the recent advaces in detector sensitivity and speed, and the atmospheric modulation technique validated with the ground based implementation of COSMO, to take advantage of the very low residual atmospheric emission present at stratospheric altitude (see fig.1). With an atmospheric emission ∼300 times dimmer than in the ground based case, we expect that possible atmospheric residuals, which in the ground based implementation might escape the removal method described in §2.2, will be negligible. In these conditions we expect that the limiting factor will become the emission of the warm components of the instrument, i.e. the room temperature sky scan mirror and the cryostat window. Due to the reduced atmospheric pressure at balloon altitude,

the latter can be made very thin (order of 25 μm), implying a factor $\sim$100 reduction of its thermal emission. We have a long-term plan to reuse the LSPE-SWIPE gondola and cryostat ([23]) to fly a modified COSMO instrument in the stratosphere in a time-scale of 4 years. This activity is synergic to the development of the BISOU experiment.[24] Due to the reduced atmospheric load, we can extend our spectral coverage to significantly higher frequencies, in order to easy the separation of spectral distortions from local foreground emission. We rerun our simple simulation (§4) for the case of an observation in a 15-days flight, with photon-noise limited detectors (here the radiative background is dominated by the CMB, the thin window and the sky modulator mirror) obtaining the performance forecast shown in figure 10 (right panel). The S/N ratio for the extraction of the largest spectral distortion is quite high (>10).

6. Conclusions

The measurement of spectral distortions in the CMB poses hard experimental challenges, but represents a fundamental cosmology tool, able to test a variety of cosmological phenomena. In particular, this kind of measurement seems to be the best, among very few, to shed light on the pre-recombination evolution of the universe. COSMO represents a pioneering sub-orbital approach to investigate spectral distortions at mm wavelengths. It copes with atmospheric emission and its fluctuations using fast detectors and a fast atmospheric emission modulation technique, able to separate its spectral brightness from the isotropic cosmological component. The instrument is in an advanced stage of development, and promises to detect the largest spectral distortion (the y distortion due to ionized matter in the universe) in 2 years of integration from the French-Italian station of Concordia (Antarctica). A further implementation on a stratospheric balloon platform is under study, and promises significant advantages and a necessary validation step in view of the final space mission devoted to spectral distortions.

Acknowledgments

The COSMO activity is funded in Italy by PNRA (National Program for Antarctic Research) and PRIN (Programs with Relevant National Interest). The balloon-borne implementation is being studied within the COSMOS program of the Italian Space Agency.

Measuring the Hubble constant H_0 from gravitational lensing

Liliya L.R. Williams

E-mail: llrw@umn.edu

First proposed in 1964 by Sjur Refsdal, gravitational lensing provides a straightforward and elegant geometrical way of estimating the Hubble constant from cosmologically distant variable sources. The method relies on observationally determined time delays between light arriving through different multiple images, and the mass models of the lens, which are constrained by observed image properties and other information. While the time delays are obtained with increasing precision, the mass models, which are subject to lensing degeneracies, remain the main source of systematic uncertainty. Various modeling groups have adopted different strategies for dealing with degeneracies. In this talk I will describe the basics of extracting H_0 from lensing, the observational successes, modeling challenges, current results, and future prospects.

Keywords: Cosmological parameters – gravitational lensing

1. Introduction

The idea of measuring H_0 from multiple image (i.e., strong) gravitational lensing is due to the Norwegian astronomer, Sjur Refsdal.[1] Because H_0 is the property of global cosmology, with units of inverse time, and because light travel from lensed sources spans cosmological distances, light travel time will depend on H_0. Therefore there should be a way to extract H_0 from gravitational lensing.

Light travel time along null geodesics, from the source, passing the lens and arriving at the observer consists of two contributions: geometrical and gravitational, which are added linearly, since lensing almost always is in the weak field regime of General Relativity:

- **geometrical** – path length, related to the angular location of the image on the sky
- **gravitational** – integrated Newtonian potential along the line of sight, a.k.a. the Shapiro delay

Figure 1 illustrates the basic geometry. The observer on the left sees images at angular locations on the sky, $\vec{\theta}_i$, $\vec{\theta}_j$. The unlensed source position, $\vec{\beta}$, is also indicated. The light travel time, or the arrival time of the image seen at $\vec{\theta}$ is given by $t(\vec{\theta})$, and consists of the two aforementioned terms. The gravitational time delay is calculated as an integral over the observer sky of the sky-projected normalized (dimensionless) surface mass density in the lens, $\kappa(\vec{\theta})$, with a logarithmic kernel. The prefactor in

front of the square brackets is important because it involves cosmological angular diameter distances, each of which scales inversely with H_0. This is where the depence on the Hubble constant comes from in multple image gravitational lensing.

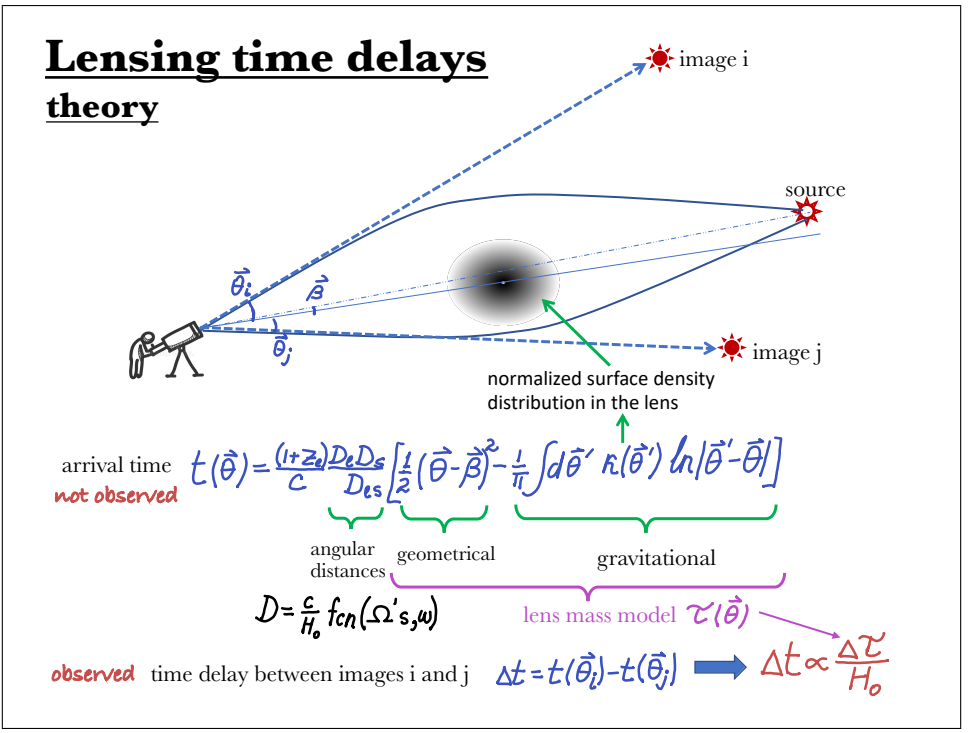

Fig. 1. A sketch of a multiple image (i.e., strong lensing) geometry. The light rays paths for two images are shown, $\vec{\theta}_{i,j}$, as well as the direction towards the unobservable source, $\vec{\beta}$. Hubble constant, H_0 enters through the angular diameter distance in the equation for the arrival time, $t(\vec{\theta})$. See § 1 for details.

The expression in the square brackets is the model arrival time, $\tau(\vec{\theta})$, because it is calculated from a lens model, which recovers the mass distribution in the lens, $\kappa(\vec{\theta})$, as well as the unobservable $\vec{\beta}$. The total light travel time, sometimes called the arrival time, $t(\vec{\theta})$ is not an observable. What we can observe is the difference between the arrival times of two images, Δt, related to $\Delta\tau$ through H_0:

$$\Delta t \propto \Delta\tau / H_0. \tag{1}$$

This is the essence of the method. Basically, to extract H_0 from lensing, one needs to measure time delays, and to construct a good model of the mass distribution in the lens. Thus, the basic principle of the method is simple, and very appealing because it is a one-step determination of H_0, and works on cosmological distances, bypassing all the rungs of the traditional astronomical distance ladder method,

which uses overlaping distance determination methods to reach the Hubble flow. The complications in the lensing measurement of H_0 come from uncertainties in the determination of observational values, as well as lens mass model building.

2. Overview of uncertainties

There are 4 main sources of uncertainties.

- *Line-of-sight (LoS) structures.* The Universe contains not just the source, the lens, and the observer, but also a wide range of other mass structures; in fact, a whole spectrum of mass density fluctuations. The main lens is usually by far the most massive object in the direction of the source, but other, smaller mass clumps also exist. Their influence on the lensing has been recently studied by a number of authors, including Ref. 2, who concluded that the corresponding uncertainty in the determination of H_0 for one lens contributes $\sim 0.6 - 2.4\%$ of scatter, with little bias. If a handful of lenses are used, which is usually the case, the scatter goes down to $\sim 0.5\%$, and at this level it is subdominant to other sources of uncertainty.
- Uncertainties in *cosmological parameters*, like energy densities Ω's, contribute very little to the uncertainties in H_0, typically $< 0.1\%$, if one uses cosmological parameter values that are broadly consistent with the concordance cosmological model ΛCDM.
- *Time delays between images;* see § 3.
- *Mass modeling of the lens;* see § 4.

3. Time delays between lensed images

To measure H_0 one generally uses lens systems that have quasars are sources. Fluxes of most quasars vary in time on scales from seconds to years. The variability is stochastic, its origin being the variations in the conditions of the inner accretion disk around supermassive black holes, residing at the centers of source galaxies. The upper left panel in Figure 2 shows an example of lightcurves (flux vs. time) of images of one particular lens system over about 14 years,[3] and the zoomed in portion below it concentrates on a much narrower time scale, and also resolves time variations of two close images, called A_1 and A_2 (see the sky-plot of the lens on the very left). Observing lightcurves require a lot of effort and dedication. The main group envolved in this is COSMOGRAIL, based at the EPFL in Switzerland.

The lightcurves show features that are common to all images, but displaced in the time direction. (There are also offsets in flux, since images are magnified by different amount by the lens.) These displacements can be measured and are the lensing-induced time delays. There are many algorithms that recover time delays from lightcurves: six examples are shown on the right, for one particular pair of images in this lens system. The two bottom values are two different ways of "averaging" over these individual determinations. In this case, the best estimate is about 36 days,

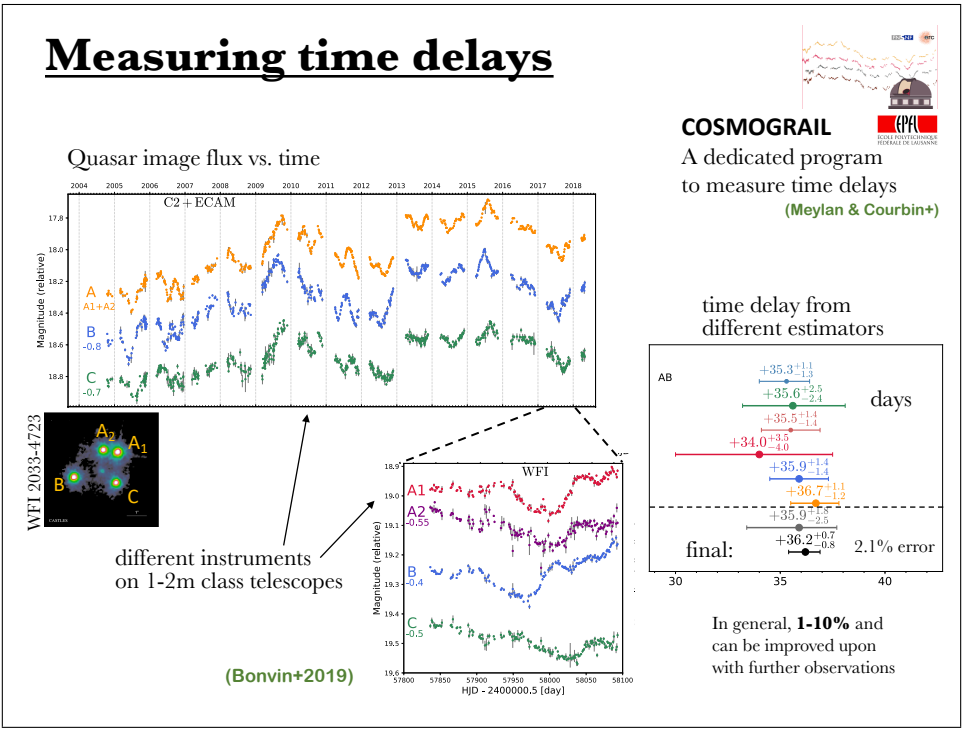

Fig. 2. An example of image lightcurves in one particular quad lens system (left). The results of time delay estimation using different methods are shown in the panel on the right. See § 3 for details.

with an error of 2.1%. In galaxy-scale lens systems, time delays of the order of few days to few weeks are common. Precision ranges from $1 - 10\%$, and can be improved upon with longer base-line, and possible improvements in the cadence of observations.

4. Mass modeling of lens systems

4.1. *Data constraints*

We start with assembling observational data that will help in constraining the mass distribution in the lensing galaxy. These are

- quasar image positions
- quasar time delays
- quasar image flux ratios
- Einstein ring, formed by the extended and usually merging multiple images of the host galaxy of the source quasar

While the first two are always used in deriving H_0, the last two have caveats.

Ratios of quasar image fluxes do constrain mass distribution in the lens, but not necessarily the aspects of the mass distribution that affect H_0. Specifically, image fluxes, and hence flux ratios can be affected by stars, or ΛCDM subhalos in the lensing galaxy that have relatively little mass, but happen to lie very close to the light path of the images. Interpreting these flux ratios as being due to the mass distribution on galaxy scales will lead to wrong conclusions. Because of this image flux ratios are usually not used.

The extended Einstein rings are spread over many pixels, so in principle can provide a lot of additional information. However, because the *Hubble Space Telescope*'s camera pixels are about a factor of 10 larger in linear dimension than the positional accuracy for quasar point images, the positional information from extended rings is not as constraining. Furthermore, the rings are often faint, with low signal-to-noise ratio. Finally, the shape of the (unlensed) source is unknown.

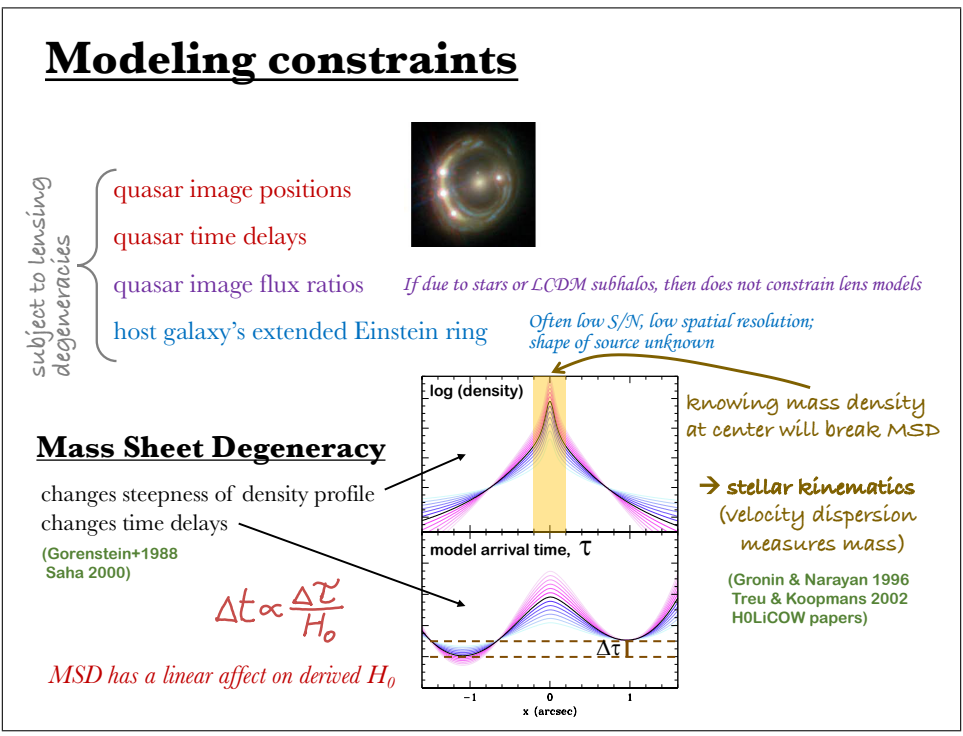

Fig. 3. Lens mass modeling constraints (top), and an illustration of models connected by Mass Sheet Degeneracy (MSD, bottom). See § 4.2 for details.

4.2. *Lensing degeneracies*

All the lensing observables are subject to lensing degeneracies. This means that a given set of observables can be reproduced by more than one lens mass distribution. The most famous degeneracy, the Mass Sheet Degeneracy (MSD) is an exact mathematical degeneracy, which was first recognized and described by Ref. 4. The bottom half of Figure 3 illustrates MSD. If the model arrival time surface τ is stretched or shrunk uniformly, i.e., $\tau \rightarrow \lambda\tau$, where λ is a constant, then the derived H_0 will be affected similarly, since observed Δt values have to stay the same (see eq. 1). In terms of the lens mass distribution this amounts to (approximately) changing the slope of the density profile, so MSD is sometimes referred to as the steepness degeneracy.[5] Steeper density profiles result in larger derived values of H_0.

The mathematically exact MSD is not the main problem; because of the limited precision of observations, it is actually the approximate version of MSD which we must try to limit in order to obtain good accuracy in derived H_0. This breaking of (approximate) MSD can be achieved if we use an independent method (not lensing) to measure the steepness of the lens density profile. The method usually used is the stellar kinematics: the motion of stars near the center of the lensing galaxy, as measured by the velocity dispersion, depends on the mass distribution.[6,7] The sense of the relation is as follows: If stellar kinematics indicate a lot of mass at the very center, that means the density profile is steep.

However, there are caveats which have been pointed out in the recent papers. Ref. 8 shows that the kinematic priors used in the analysis can have a significant effect on the results. Ref. 9 demonstrate that using kinematics can result in a bias in derived H_0 of a few percent or more. And Ref. 10 conclude that unresolved stellar kinematics—which is what being used today—have limited power to constrain the mass profile. Fortunately, spatially resolved kinematics—which will be possible with the *James Webb Space Telescope*—where stellar velocity dispersion is measured as a function of 2D projected position within the lensing galaxy, will be very helpful in breaking MSD.[11]

Other degeneracies exist as well, most of which affect the shape, or the morphology of the mass distribution in the lens. Known examples are the Source-Position Transformation (SPT), which is a generalization of the MSD,[15] monopole degeneracy,[5,16] and a whole range of other shape degeneracies,[17] which we are yet to classify and fully understand. An example is presented in Figure 4; it shows three different mass models of the same lens system, from Ref. 12 (left panel; parametric with one mass component), 13 (middle panel; parametric with two offset mass components), and 14 (right panel; free-form method). There are many common features in the three mass maps, but the differences in the shape of the mass distributions

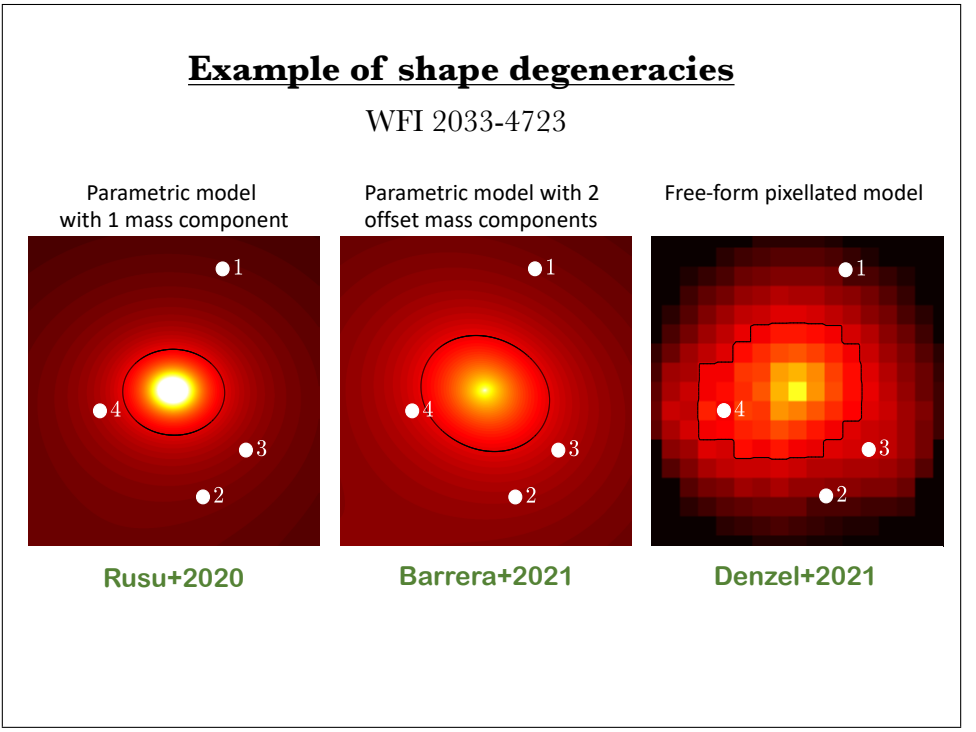

Fig. 4. Three different mass models of the same quad lens system: Ref. 12 (left panel; one mass component), 13 (middle panel; two offset mass components), and 14 (right panel; free-form). These illustrate shape degeneracies in lens mass modeling. See § 4.2 for details.

are also apparent. (Note that the H0LiCOW reconstruction [left panel; Ref. 12)] does not reproduce quasar image positions to even $\sim 5\sigma$, while the the other two [middle & right panels] reproduce these to $\sim 1\sigma$.)

Lensing degeneracies are the largest source of uncertainty in any lensing reconstruction, and hence in the determination of H_0.

4.3. *Constructing lens mass models*

Because lensing data is limited, and because of the existance of lensing degeneracies, lens mass models are not unique. Therefore, we need to appeal to data to constrain our models, based on our existing knowledge about galaxies. Different modeling groups have varying philosophies as to how much of the prior knowledge to incorporate into their models, and how exactly to parametrize this information.

One way to classify different modeling methods is by the number of models parameters they use. This is the horizontal axis in Figure 5. Please keep in mind that these numbers are approximate. The simplest models represent the lens mass distribution by one mass component, with some density profile slope, ellipticity, position

angle, and a tidal term (lensing external shear), which captures the contribution from the external mass. These add up to $\sim 5-6$ parameters. Somewhat more detailed lens mass models use two superimposed mass components, where the two are co-centered, and usually represent baryons (stars), and dark matter, respectively. These result in $\sim 9-15$ parameters. These two types of models are the ones used by the H0LiCOW Collaboration,[18] whose results for H_0 are reported in many papers.

However, there is evidence that these models are not sufficient to describe lenses accurately. For example, as already noted above, one and two co-centered mass component models struggle to reproduce quasar image positions to observational precision.[12] It appears that mass models need more freedom in order to reproduce lens systems more accurately. For example, Ref. 19–22 have shown that offsetting the 2 mass components, which results in deviations from purely elliptical mass distributions, allows better fits for many quad lens systems. The models with the most parameters are the free-form models, which allow each mass pixel in the lens to vary almost independently from others. These models—PixeLens and Glass—have also been used to estimate H_0.[14,17,23] I will present the results in § 5.

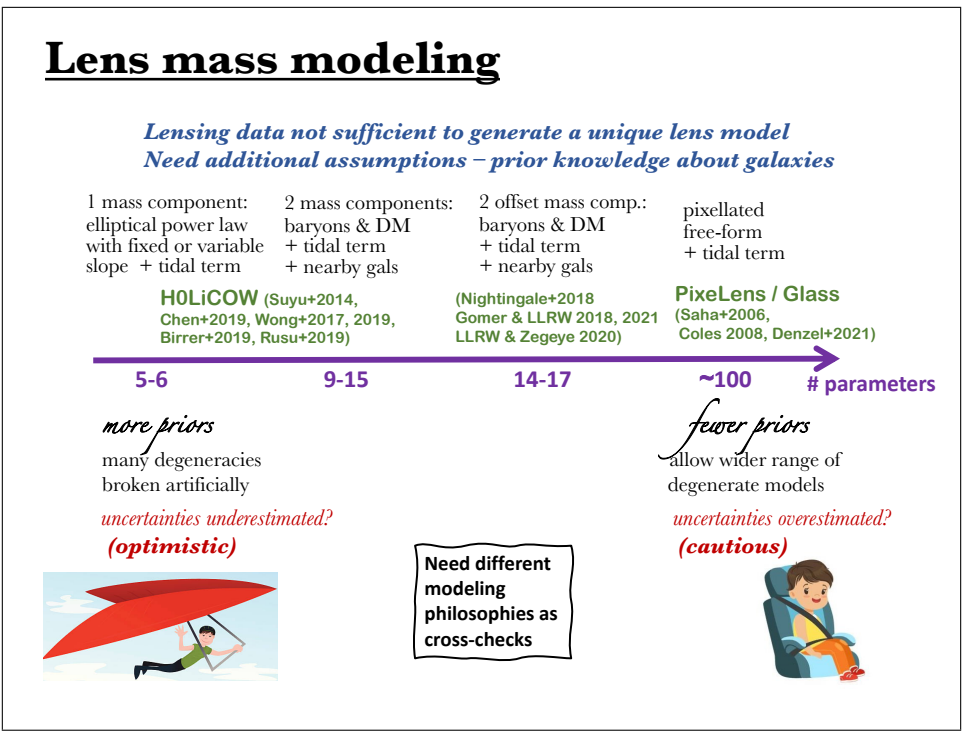

Fig. 5. A few lens mass modeling approaches exist in the literature. One way to classify them is by the number of models parameters they use, represented (approximately) on the horizontal axis. See § 4.3 for details.

Models with fewer parameters and restrictive priors represent a more optimistic view of our knowledge about the galaxies acting as lenses. They suppress lensing degeneracies through the strong assumptions they use, and as a result may underestimate uncertainties in H_0. On the other hand, models with many parameters have fewer priors, and are cautious about how much knowledge we can assume about galaxies. These allow a wider range of degenerate models to be present, and could overestimate the uncertainties. In the face of limited observational data, the best compromise is to have results from different modeling methods act as cross-checks.

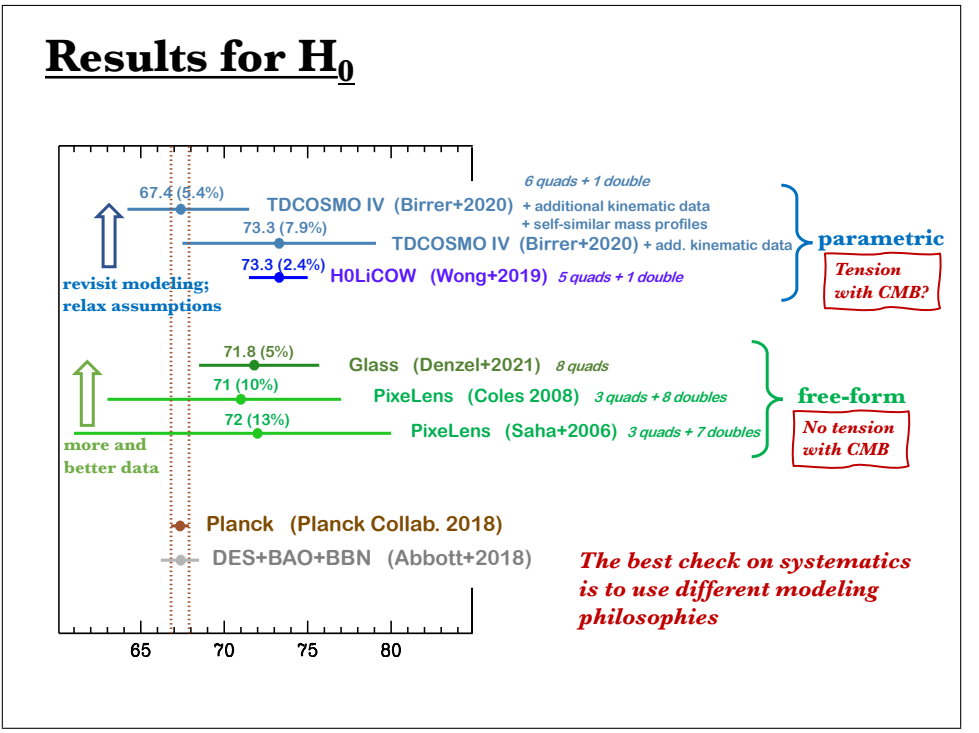

Fig. 6. Summary of the current results of H_0 estimation for strong lensing. See § 5 for details.

5. Results

Figure 6 summaries the results for H_0 determination from multiple image lensing from two groups with very different modeling approaches: parameteric models from the H0LiCOW Collaboration,[18,24] and free-form models.[14,25] (I am a part of the latter group.)

The top portion of Figure 6 presents the most recent H0LiCOW results, which used lens models with one and two co-centered mass components (TDCOSMO is

a continuation of that group's effort). The H0LiCOW's derived value of $H_0 = 73.3$ km/s/Mpc with 2.4% error[24] is probably the most widely quoted Hubble constant result from gravitational lensing. It is in tension with the Planck result,[26] and the other "early Universe" measurement.[27] About a year ago, the TDCOSMO Collaboration revisited the measurement, relaxing their earlier assumptions.[10] They dropped the assumption on the lens mass density profile, and instead added kinematic data from a larger sample galaxies that do not act as lenses. This recovers the same H_0 value as before, but increases the erorrs to about 7.9%. If one also assumes self-similarity in the galaxy mass distribution, then the central derived value becomes $H_0 = 67.4$, with uncertainty of 5.4%, which is now completely consistent with the early Universe Planck value. (Note that these 3 papers used nearly the same set of lens systems, namely, 5-6 quads and 1 double lens. Quads provide 3 times as many lensing data constrains compared to doubles.)

The middle portion of Figure 6 summarizes the results fro the free-form method. The two earlier papers,[17,23] used 3 quads and 7-8 doubles, and derived H_0 with rather large uncertainties, $10 - 13\%$, which easily encompassed the Planck result. In the past year, the number of quads in the sample was increased to 8, and the uncertainties shunk to 5%. (Most of these quads are in common with those in H0LiCOW and TDCOSMO samples.) The cenral value of H_0 remained nearly the same in all 3 papers. The latest value is $\sim 1.1\sigma$ away from that of the Planck Collaboration. There is no tension between the free-form model results and those from the early Universe probes.

In the estimation of H_0, systematics are the main source of concern. The best way to check on systematics is to use different modeling philosophies and compare their results. The parametric and the free-form methods discussed above have no common modeling assumptions, and yet their most recent results differ by at most $\sim 1\sigma$, and show no significant tension with the Planck early Universe value.

6. Future directions

Many exciting developments in the field of lensing determination of H_0 are just around the corner! In addition to multiply imaged quasars, we will use multiply imaged Supernova Type Ia, Gamma-Ray Bursts, and Fast Radio Bursts.[28–34] Measurements of image time delays from these will be much more precise. Furthermore, since the light from these sources will fade with time (in contrast to that of quasars), it will make it easier to characterize the light from the lensing galaxy, which will help with its mass modeling. Type Ia Superova, whose instrinsic flux is known, will also aide in breaking the mass sheet degeneracy.

In this talk I discussed lensing systems with galaxies as the main lens, but galaxy clusters can also be used,[35,36] especially if the number of lensed images is in the few hundreds. While the mass distribution in galaxy clusters is more complicated than in individual galaxies, clusters lense tens or even hundred(s) of background

sources, resulting in 1-few hundred of lensed images, which can constrain the mass distribution suffiently well to yield 1-few percent level accuracy on H_0.[37]

In the next several years, these improvements should be able to deliver $\sim 1\%$ accurary and precision determination of H_0 from gravitational lensing.

The standard ΛCDM cosmological model now seems to face some puzzles. One of the most serious problems is the so-called Hubble tension; the values of the Hubble constant H_0 obtained by local measurements look inconsistent with that inferred from Cosmic Microwave Background (CMB). Although introducing extra energy components such as the extra radiation or Early Dark Energy appears to be promising, such extra components could alter the abundance of light elements synthesized by Big Bang Nucleosynthesis (BBN). We perform a Monte Carlo simulation to evaluate the effect of those extra component scenarios to solve the Hubble tension on the BBN prediction.

Keywords: Cosmology; Big Bang Nucleosynthesis; Dark energy; Radiation; Hubble constant

1. Introduction

The ΛCDM model has been successful in explaining the evolution of our Universe. However, the tension of the Hubble constant is now apparent between the measurement of the local universe and the distant universe. Assuming ΛCDM model, Planck measurements of Cosmic Microwave Background (CMB) anisotropy infers the Hubble constant $H_0 = 67.4 \pm 0.5$ km/s/Mpc.[1] Other distant observations such as the Atacama Cosmology Telescope,[2] Baryon Acoustic Oscillation(BAO),[3] and the combined analysis of BAOand Big Bang Nucleosynthesis (BBN) (independent of CMB)[4] all infer $H_0 \sim 67$ km/s/Mpc. On the other hand, local measurements of H_0 by the SH0ES collaboration with Cepheids and type Ia supernovae (SNe Ia) in Ref.[5] and Ref.[6] and by the H0LiCOW collaboration with lensed quasars[7] have reported as $H_0 \sim 73$ km/s/Mpc. Another local measurement using the Tip of the Red Giant Branch (TRGB) as distance ladders has obtained a value between Planck and the SH0ES, $H_0 \sim 70$ km/s/Mpc.[8] It appears that the discrepancy is more than 3σ significance.

Several ideas have been proposed to extend ΛCDM model to resolve this tension. Among such ideas, we would like to consider the extra radiation and Early Dark Energy[9–18] solutions to the Hubble tension and the consistency with BBN. These extra components are promising solutions. However, the theoretical abundance of light elements synthesized by BBN should be different from the values of the standard scenario. Through the consideration, we confirm that extra radiation and Early Dark Energy are promising solutions. However, two scenarios are constrained by BBN measurements. Extra radiation is constrained by the helium abundance and Early Dark Energy is constrained by the deuterium abundance.[19]

2. H_0 from CMB

First, we explain how the Hubble constant is derived from the distant observation, especially the CMB anisotropy. The measured anisotropy includes the information of the angular size $\theta_* = r_*/D_{M*}$, where r_* is the comoving sound horizon at the recombination and D_{M*} is the comoving angular diameter distance. Planck team directly and strictly measured $\theta_* = 1.041 \times 10^{-2}$. A simple calculation according to the definition shows that $\theta_* \propto H_0/\sqrt{\rho_{\rm early}}$, where $\rho_{\rm early}$ is the energy density in the early universe. Therefore, in order for the Hubble constant from CMB to approach the local value, we need to increase ρ in the early universe. Then, we will consider two promising ways to increase ρ; Extra radiation and Early Dark Energy.

3. Modeling

3.1. *Extra radiation*

One simple "solution" to the Hubble tension is increasing the effective number of neutrinos $N_{\rm eff}$, which is expressed as

$$\Omega_r = \left(1 + \frac{7}{8}\left(\frac{4}{11}\right)^{4/3} N_{\rm eff}\right)\Omega_\gamma. \tag{1}$$

Here,

$$\Omega_i = \left.\frac{\rho_i}{3M_P^2 H^2}\right|_{t=t_0}, \tag{2}$$

with M_P being the reduced Planck mass, are the present values of density parameters for i spices. γ and r stand for CMB photon and total radiation, respectively.

3.2. *Early Dark Energy*

Another solution to the Hubble tension is introducing Early Dark Energy. In the Early Dark Energy scenario, the dark energy density in the early universe was much larger than today and after the critical point, the energy density decreases faster than the background energy densities do. In our analysis, we consider a model where

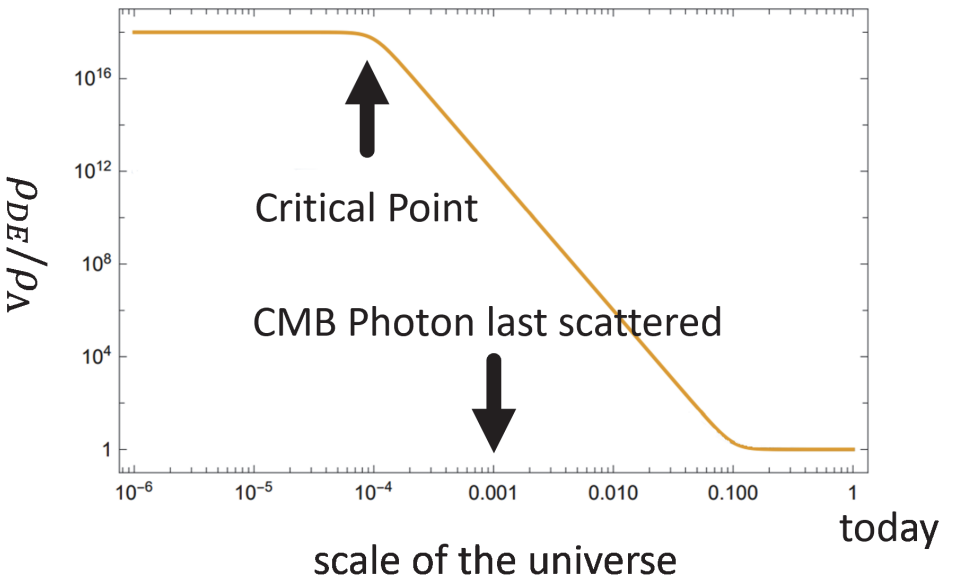

Fig. 1. Energy density evolution of Early Dark Energy

the energy density of Early Dark Energy ρ_{DE} decreases as the kination of scalar field after the critical point at $z = 3000$ around the matter-radiation equality. This setup is according to a preferred parameter set in Ref.[9]. The typical evolution of Dark Energy density $\rho_{DE}(a)$ normalized by ρ_{Λ} is shown in Fig. 1.

4. Data and Analysis

We perform a Markov-Chain Monte Carlo (MCMC) analysis on a $N_{\rm eff}$ model and the Early Dark Energy model described in the previous section. We use the public MCMC code `CosmoMC-planck2018`[20] with implementing the above Early Dark Energy scenarios by modifying its equation file in `camb`. For estimation of light elements, we have used `PArthENoPE_marcucci`.[21,22]

4.1. *Data sets*

We analyze models with referring to the following cosmological observation data sets. We include both temperature and polarization likelihoods for high l ($l = 30$ to 2508 in TT and $l = 30$ to 1997 in EE and TE) and low$l$ `Commander` and lowE `SimAll` ($l = 2$ to 29) of Planck (2018) measurement of the CMB temperature anisotropy.[1] We also include Planck lensing.[23] For constraints on low redshift cosmology, we include data of BAO from 6dF,[24] DR7[25] and DR12.[26] We also include Pantheon[27] of the local measurement of light curves and luminosity distance of supernovae as well as SH0ES (R19)[6] of the local measurement of the Hubble constant from the

Hubble Space Telescope observation of Supernovae and Cepheid variables. Finally, we include the data sets of helium mass fraction Y_P measurement[28] and deuterium abundance D/H measurement[29] to impose the constraints from BBN.

5. Result and Discussion

As is well known, an increase of $N_{\rm eff}$ affects the fit with the observation of light elements, because it contributes to the cosmic expansion at BBN epoch and alters the proton to neutron p/n ratio. This leads to increasing both the helium mass fraction Y_P and the deuterium abundance D/H. Thus, larger relativistic degrees are disfavored by the helium mass fraction measurement, while a little favored by deuterium measurement. This can be seen in Fig. 2.

On the other hand, in the Early Dark Energy scenarios, the Early Dark Energy increases the helium mass fraction little because the cosmic expansion rate in the BBN epoch increase little. Therefore, the Early Dark Energy scenario is consistent with the helium fraction measurement. However, increasing $\Omega_b h^2$ to adjust the CMB

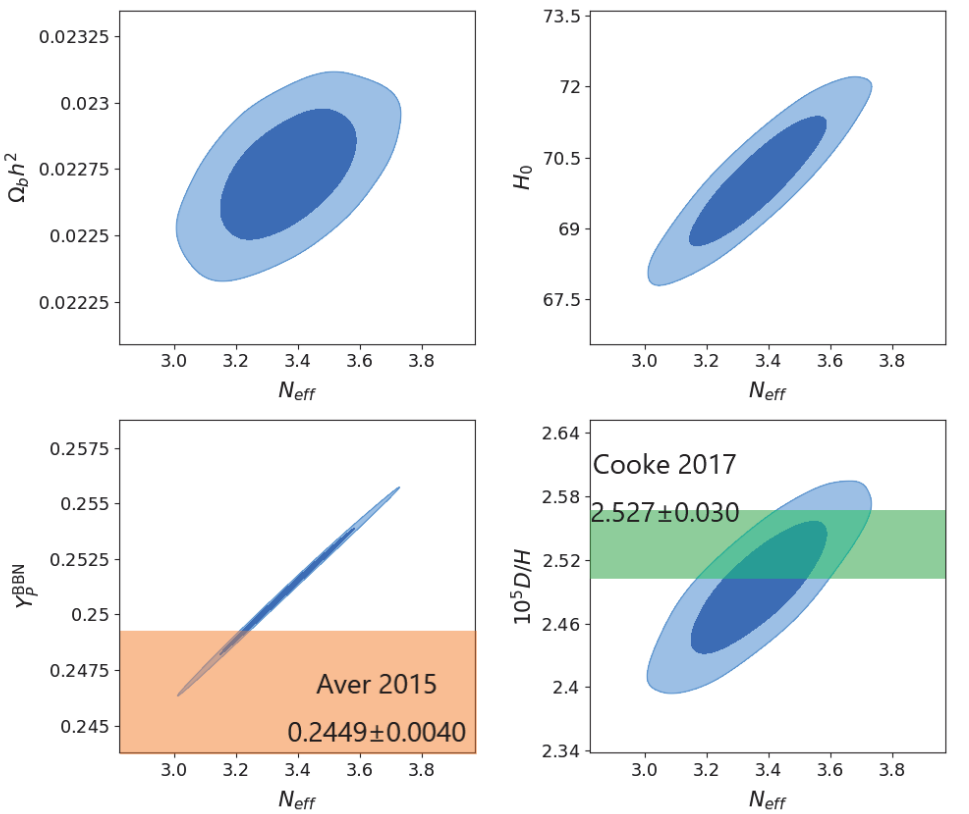

Fig. 2. The posterior and the constraints on the $N_{\rm eff}$ model

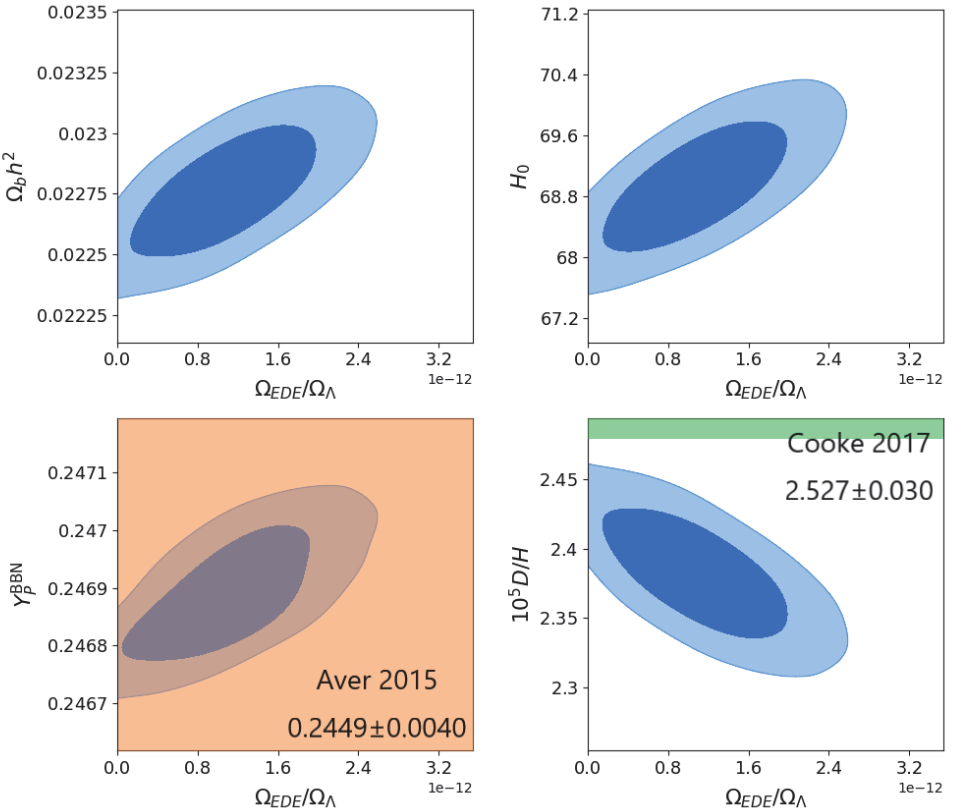

Fig. 3. The posterior and the constraints on the Early Dark Energy model

fit reduces the D/H abundance significantly. Thus, Early Dark Energy is disfavored from the deuterium measurement. This can be seen in Fig. 3.

6. Conclusion

The shorten sound horizon scale at the recombination epoch by introducing extra energy components such as the extra radiation or the Early Dark Energy is a promising solution to the Hubble tension. However, the compatibility with successful BBN would be another concern, because the extra radiation contribute the cosmic expansion or the inferred baryon asymmetry would differ from that in the ΛCDM.

We have performed analyses on the Early Dark Energy models and $N_{\rm eff}$ model with paying attention to the fit to BBN. Not only $N_{\rm eff}$ model but also the Early Dark Energy model is subject to the BBN constraints (as shown in Fig. 4.). Extra radiation is constrained by the helium abundance, while Early Dark Energy is constrained

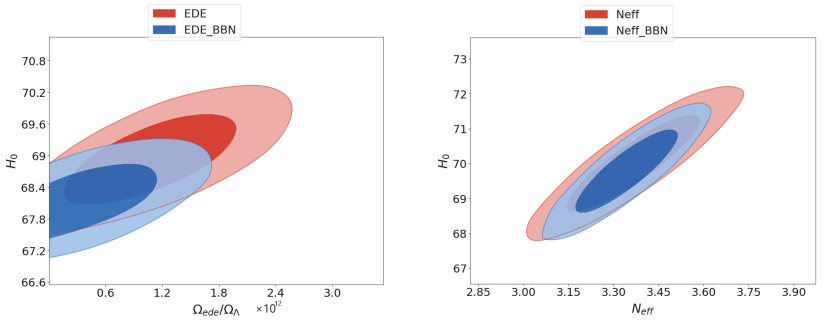

Fig. 4. Comparison of constraints based on data sets with and without BBN for the Early Dark Energy (left) model and the $N_{\rm eff}$ model (right)

by the deuterium abundance. Therefore, when we introduce extra components for the Hubble tension resolution, we should pay attention to the BBN as well.

I review a string-inspired cosmological model with gravitational anomalies in its early epochs, which is based on fields from the (bosonic) massless gravitational multiplet of strings, in particular gravitons and Kalb Ramond (KR), string-model independent, axions (the dilaton is assumed constant). I show how condensation of primordial gravitational waves, which are generared at the very early eras immediately after the big bang, can lead to inflation of the so called running vacuum model (RVM) type, without external inflatons. The role of the slow-roll field is played by the KR axion, but it does not drive inflation. The non-linearities in the anomaly terms do. Chiral fermionic matter excitations appear at the end of this RVM inflation, as a result of the decay of the RVM vacuum, and are held responsible for the cancellation of the primordial gravitational anomalies. Chiral anomalies, however, survive in the post-inflationary epochs, and can lead to the generation of a non perturbative mass for the KR axion, which could thus play the role of dark matter in this Universe. As a result of the condensed gravitational anomaly, there is a Lorentz-invariance violating KR axion background, which remains undiluted during the RVM inflation, and can lead to baryogenesis through leptogenesis in the radiation era, in models with sterile right-handed neutrinos. I also discuss the phenomenology of the model in the modern era, paying particular attention to linking it with a version of RVM, called type II RVM, which arguably can alleviate observed tensions in the current-epoch cosmological data.

Keywords: String Cosmology; Running Vacuum; Inflation, Axions; Dark Matter.

1. Introduction

Although the plethora of the available cosmological data today[1] agree very well with the standard concordance model of Cosmology,[2] also known as ΛCDM, nonetheless there are compelling reasons for seeking alternative models, that go beyond it. Theoretically, given that the ΛCDM model is a global (de Sitter) solution of Einstein's general relativity (GR) theory, with a positive cosmological constant $\Lambda > 0$ added without explanation, one needs to seek microscopic frameworks of quantum gravity, which the GR can be embedded to, that could provide a detailed origin of the

observed dark energy component in the current-Universe energy budget.[a] Moreover, one of the most important drawbacks of GR *per se* is that it is a non-renormalizable theory, and as such, it cannot provide by itself a framework for quantising gravity along with the rest of the fundamental interactions in nature (assuming of course that gravity can admit conventional quantization; for alternative views, treating gravity as an entropic force, associated with changes of information pertaining to the positions of material bodies, see Ref. 4). On the observational side, there appear to exist discrepancies ("tensions"[5,6]) between the results of data analyses from Planck Collaboration, based on ΛCDM,[1] and local direct measurements of the Hubble parameter today, the so called H_0 tension,[7–9] but also tensions in the growth-of-galaxies data, the so-called σ_8 tension.[10] Thus, although such tensions could admit more mundane astrophysical explanations,[11–14] or even disappear in future data, being due to statistical uncertainties, nonetheless, several theoretical attempts are currently on the way in order to provide an explanation for them or alleviate them.

One phenomenological framework, which deals successfully with such an alleviation of both the H_0 and the σ_8 tensions, is a mildly modified version of the running vacuum model of cosmology (RVM),[15–20] the so-called type II RVM.[21] In this talk, I will review a microscopic framework for obtaining the RVM, actually a version of RVM somewhat analogous to the aforementioned type II RVM, which pertains to a string-inspired[22] cosmological model with *gravitational anomalies* in the early Universe.[23–28]

The structure of the talk is as follows: in the next section 2, I describe briefly the RVM framework, and then the string-inspired gravitational theory, with gravitational anomalies coupled to *massless* string-model independent (Kalb-Ramond (KR)) axions fields, which can give rise to an RVM inflation, without external inflatons. Only bosonic fields from the massless gravitational string multiplet enter the early-Universe era string-effective action as external fields. Primordial gravitational waves can lead to condensation of the gravitational anomalies, which in turn induces the RVM inflation. In section 3, I describe briefly the post inflationary epochs, placing the emphasis on how a gravitational-anomaly-induced Lorentz-violating (LV) KR axion background, which remans undiluted at the end of the RVM inflationary era, can lead to leptogenesis in models with right-handed sterile neutrinos (RHN) in their spectra. I also explain how the stringy KR axion field can play the rôle of Dark matter, by acquiring a non-perturbative mass during the Quantum Chromo-Dynamics (QCD) epoch of the Universe. In section 4, I speculate on potential links of this stringy RVM effective theory to a modified version of RVM, somewhat analogous (but with crucial differences) to the aforementioned type-II RVM. The crucial

[a]See, however, the arguments of Ref. 3 claiming that the "observed" dark energy might be an artefact of supernova data interpretation based on the assumption of homogeneity and isotropy of the universe at large (cosmological) scales, in the context of the Friedman-Lemaitre-Robertson-Walker (FLRW) framework. In our approach here, the large-scale isotropy and homogeneity of the Universe is assumed.

modifications are due to quantum-graviton-mode integration in the respective path integral of the string-inspired theory, and could lead to observable departures from ΛCDM and potential alleviation of tensions in the current-era data. Finally, section 5 contains our conclusions and outlook.

2. Running Vacuum Model (RVM) Framework, its String-Theory Embedding and Inflation from Gravitational Anomalies

I commence the discussion by first summarising briefly the basic features of the RVM framework. This is a phenomenologically successful effective cosmological framework, which leads to observable, in principle, deviations from ΛCDM,[19,20] and alleviation of the current cosmological tensions.[21] It describes a smooth evolution of the Universe from a dynamical inflationary phase till the present era.[18]

2.1. *Features of RVM cosmology*

The basic feature of the RVM cosmology is that the vacuum energy density is a function of even powers of the Hubble parameter at a given era of the Universe, $H(t)$ (with t the cosmic time), due to general covariance. To describe the entire evolution of the Universe from inflation till the present epoch, it is sufficient to truncate this series to quartic powers of $H(t)$, thus writing::[15–18]

$$\rho^{\Lambda}_{\rm RVM}(H) = \frac{\Lambda(H)}{\kappa^2} = \frac{3}{\kappa^2}\left(c_0 + \nu H^2 + \alpha\frac{H^4}{H_I^2} + \dots\right) > 0\,, \tag{1}$$

with κ the four-dimensional gravitational constant $\kappa = \sqrt{8\pi\,\mathrm{G}} = M_{\rm Pl}^{-1}$, with $M_{\rm Pl} = 2.43 \times 10^{18}$ GeV (we work in natural units $\hbar = c = 1$ throughout this work), $H_I \sim 10^{-5} M_{\rm Pl}$, the inflationary scale, as inferred from the latest Planck-Collaboration data,[1] and $c_0 \geq 0$, ν and α constants, throughout the Universe evolution. In the conventional RVM, $\nu > 0$ and $\alpha > 0$, while $c_0 > 0$ is the current-epoch cosmological constant.[1,2] The $\dots$ in (1) denote terms of higher orders in $H^2(t)$. In general there is also dependence on $\dot{H}$ (with the overdot denoting cosmic-time-t derivative), but for a given era of the Universe, one can express $\dot{H}$ in terms of the cosmic deceleration of that era (assumed approximately constant) and of H^2, hence the expression (1) suffices for our purposes here. The defining feature of the RVM is its de-Sitter type equation of state,[15]

$$p^{\rm vac}_{\rm RVM}(H(t)) = -\rho^{\rm vac}_{\rm RVM}(H(t)) < 0, \tag{2}$$

despite the fact that the pressure $p^{\rm vac}_{\rm RVM}$ and energy $\rho^{\rm vac}_{\rm RVM}$ densities are time-dependent functions of $H(t)$. We note for completeness that a similar feature characterises the super-critical (Liouville) string cosmologies, where the cosmic time is identified with (the zero mode of) a world-sheet renormalization-group scale.[29]

From the conservation of the total stress tensor of the vacuum plus radiation and matter excitations, the latter being characterised by an equation of state w_m, one

can easily arrive at the following evolution equation for the Hubble parameter:[18]

$$\dot{H} + \frac{3}{2}\,(1+\omega_m)\,H^2\left(1-\nu-\frac{c_0}{H^2}-\alpha\,\frac{H^2}{H_I^2}\right)=0\ . \tag{3}$$

At early stages of the Universe, one may ignore the c_0 term, thus arriving at a solution for $H(a)$ as a function of the scale factor a (in units of the present-era scale factor):[18,19]

$$H(a)=\left(\frac{1-\nu}{\alpha}\right)^{1/2}\ \frac{H_I}{\sqrt{D\,a^{3(1-\nu)(1+\omega_m)}+1}}\,, \tag{4}$$

where $D>0$ is an integration constant. For the early Universe, one may assume without loss of generality that $D\,a^{3(1-\nu)(1+\omega_m)}\ll 1$, which from (4) leads to an (unstable) dynamical early de Sitter phase, characterised by an approximately constant $H_{\rm de\ Sitter}\simeq\left(\frac{1-\nu}{\alpha}\right)^{1/2}\ H_I$. This inflationary era is due to the non-linear terms H^4 in (1), and is not characterised by external inflaton fields.

After inflation, the RVM evolution (3) is characterised by radiation-dominance ($w_m=1/3$) and, subsequently, by a matter-dominated ($w_m=0$) era, both occurring for considerably larger values of the scale factor than the RVM inflation. In such cases, the corresponding quantities $D\,a^{3(1-\nu)(1+\omega_m)}\gg 1$. One can therefore determine the RVM vacuum energy density (1) during radiation as[18,30] $\rho^{\rm vac\ radiation\ era}_{\rm RVM}\simeq\frac{3H_I^2}{\kappa^2\,\alpha}\frac{1}{(1+Da^4)^2}$, and the radiation energy density $\rho_{\rm rad}(a)\simeq\frac{3H_I^2}{\kappa^2\,\alpha}\frac{Da^4}{(1+Da^4)^2}$, thus recovering the familiar a^{-4} scaling for $Da^4\gg 1$. As the evolution continues, matter starts to dominate ($\omega_m=0$), and at that point the cosmological constant term c_0 can no longer be ingored, leading eventually to a modern-era scaling of the Hubble parameter $H\ll H_I$ (obtained as the solution of the evolution equation (3) at this era):[18,30] $H^2_{\rm modern}(a)\simeq\frac{H_0^2}{1-\nu}\Big[(1-\Omega^0_\Lambda)\,a^{-3(1-\nu)}+\Omega^0_\Lambda-\nu\Big]$, with H_0 the present-day Hubble parameter, and $\Omega^0_\Lambda=\frac{c_0+H_0^2\nu}{H_0^2}$. Notice that the presence of the parameter $\nu>0$ implies observable deviations from the ΛCDM concordance model of cosmology[19,20] (which is recovered in the limit $\nu=0$, in which case Ω^0_Λ coincides with the present-era cosmological constant (in units of the current-era critical density)).

We remark at this stage that the non-linearities-induced inflation (4) is different[19,26,30] from Starobinsky's model of inflation,[31] which is also due to conformal-("trace")-anomaly-induced non-linear curvature corrections to Einstein's GR theory. Starobinsky's model does not have in its energy density the crucial H^4 term of the RVM (*cf.* (1)). As discussed in Refs. 19, 26, it is an inflation characterised mainly by $\dot{H}\simeq$ constant rather than $H\simeq$ constant, which is the case of RVM. The crucial for inflation H^4 term of the RVM energy density (1) is also missing in the case of a quantum field theory of a scalar field non-minimally coupled to a gravity background.[32] As we shall discuss below, a direct (geometric in origin) induction of an RVM H^4 term in the corresponding energy density can be achieved through *condensates* of *gravitational anomalies*, induced by primordial gravity waves,[33] in the string-inspired model for cosmology discussed in Refs. 23, 24, 25, 26, 27, 28, which we now come to describe briefly.

2.2. *String-inspired RVM, gravitational anomalies and inflation*

The basic assumption[24] towards the construction of the string-inspired cosmology model that will lead to RVM, is that at early stages of the Universe, only fields from the bosonic massless gravitational multiplet of strings[22] appear as external fields. Assuming constant dilatons, this assumption implies that the effective action in the four dimensional space time, after string compactification, will consist only of gravitons and antisymmetric tensor fields $B_{\mu\nu} = -B_{\nu\mu}$, $\mu, \nu = 0, \dots 3$. As a result of an appropriate U(1) gauge symmetry in the closed string sector:[22] $B_{\mu\nu} \to B_{\mu\nu} + \partial_\mu \theta_\nu(X) - \partial_\nu \theta_\mu(X)$, where $\theta_\mu(X)$ are gauge parameters, the field $B_{\mu\nu}$ appears in the effective four space-time dimensional action only through its field strength. Due to the Green-Schwarz anomaly cancellation mechanism,[22] the latter is modified by appropriate gauge and gravitational Chern-Simons terms. In our model, only the latter are present in the early Universe,[24] and as such the modified field strength $\mathcal{H}_{\mu\nu\rho}$ of the field $B_{\mu\nu}$ reads (in differential form language):[22] $\mathcal{H} = \mathbf{dB} + \frac{\alpha'}{8\,\kappa}\,\Omega_{3\mathrm{L}}$, with $\alpha' = M_s^{-2}$ the Regge slope, M_s the string mass scale, and the gravitational Chern Simons term is defined as $\Omega_{3\mathrm{L}} = \omega^a{}_c \wedge \mathbf{d}\,\omega^c{}_a + \frac{2}{3}\omega^a{}_c \wedge \omega^c{}_d \wedge \omega^d{}_a$, where $\wedge$ denotes the exterior product among forms, $\mathbf{d}$ is the exterior derivative one form. and $\omega^a_{\mu\ b}$ is the spin connection, with Latin indices $a, b = 0, \dots 3$ denoting tangent space indices. The field strength satisfies a Bianchi identity:

$$\varepsilon_{abc}{}^{\mu}\,\mathcal{H}^{abc}{}_{;\mu} = \frac{\alpha'}{32\,\kappa}\,\sqrt{-g}\,R_{\mu\nu\rho\sigma}\,\widetilde{R}^{\mu\nu\rho\sigma} \tag{5}$$

where the semicolon denotes covariant derivative with respect to the standard Christoffel connection, $\varepsilon_{\mu\nu\rho\sigma}$ is the gravitationally covariant Levi-Civita tensor density, totally antisymmetric in its indices, and $\widetilde{R}_{\mu\nu\rho\sigma} = \frac{1}{2}\varepsilon_{\mu\nu\lambda\pi}R^{\lambda\pi}{}_{\rho\sigma}$ is the dual Riemann curvature tensor (we follow the conventions of Ref. 24). To lowest (quadratic) order in derivatives, the target-space effective action (for constant dilatons) reads:

$$S_B = \int d^4x\sqrt{-g}\Big(\frac{1}{2\kappa^2}[-R - \frac{1}{6}\,\mathcal{H}_{\lambda\mu\nu}\mathcal{H}^{\lambda\mu\nu} + \dots\Big), \tag{6}$$

with the $\dots$ representing higher-derivative terms. We mention at this stage the rôle of $\mathcal{H}_{\mu\nu\rho}$ as a totally antisymmetric component of torsion in string-inspired effective gravitational theories,[22,34] in the sense that the action (6) can be expressed in terms of a generalised curvature scalar with respect to such a torsion. As we shall describe below, the torsion is associated with an axion field.[34]

Indeed, on implementing (5) as a constraint in the respective path-integral of the action (7) by means of a pseudoscalar Lagrange mutl[plier field $b(x)$, and integrating out $\mathcal{H}$, one obtains the effective action[34,35]

$$\begin{aligned} S_B^{\mathrm{eff}} &= \int d^4x\sqrt{-g}\Big[-\frac{1}{2\kappa^2}\,R + \frac{1}{2}\,\partial_\mu b\,\partial^\mu b + \sqrt{\frac{2}{3}}\,\frac{\alpha'}{96\,\kappa}\,b(x)\,R_{\mu\nu\rho\sigma}\,\widetilde{R}^{\mu\nu\rho\sigma} + \dots\Big] \\ &= \int d^4x\,\sqrt{-g}\Big[-\frac{1}{2\kappa^2}\,R + \frac{1}{2}\,\partial_\mu b\,\partial^\mu b - \sqrt{\frac{2}{3}}\,\frac{\alpha'}{96\,\kappa}\,\mathcal{K}^\mu(\omega)\,\partial_\mu b(x) + \dots\Big], \end{aligned} \tag{7}$$

where we took into account that the gravitational anomaly is a total derivative $\sqrt{-g}\,R_{\mu\nu\rho\sigma}\,\widetilde{R}^{\mu\nu\rho\sigma} = \sqrt{-g}\,\mathcal{K}^{\mu}(\omega)_{;\mu} = \partial_\mu\Big(\sqrt{-g}\,\mathcal{K}^{\mu}(\omega)\Big) = -2\,\partial_\mu\Big[\sqrt{-g}\,\varepsilon^{\mu\nu\alpha\beta}\,\omega^{ab}_{\nu}\,\Big(\partial_\alpha\,\omega_{\beta ab} + \frac{2}{3}\,\omega_{\alpha a}{}^{c}\,\omega_{\beta cb}\Big)\Big]$. One observes from (7) that the Lagrange multiplier field $b(x)$ became a fully dynamical axion-like field, the so called Kalb-Ramond (KR) or string-model-independent axion.[34,35] Classically, as follows from the saddle-point of the path integral over $\mathcal{H}$, one has the relation:[34] $3\sqrt{2}\,\partial_\sigma\bar{b} = -\sqrt{-g}\,\epsilon_{\mu\nu\rho\sigma}\,\overline{\mathcal{H}}^{\mu\nu\rho}$, where the bar denotes classical fields. Hence the association of the torsion with the axion field $b(x)$.

The effective action (7) forms the basis of our cosmological model.[24] In a FLRW space-time background the gravitational anomaly terms vanish.[36] This is not true, however, in the presence of primordial gravity waves (GW) perturbations, which violate CP symmetry:

$$ds^2 = dt^2 - a^2(t)\Big[(1 - h_+(t,z))\,dx^2 + (1 + h_+(t,z))\,dy^2 + 2h_\times(t,z)\,dx\,dy + dz^2\Big], \tag{8}$$

using standard notation for the graviton polarizations of the GW. In the metric (8), the gravitational anomaly term is *non zero*.[33] In fact, on assuming an inflationary space time with constant Hubble parameter $H \simeq$ constant, one can compute the anomaly condensate in the presence of GW CP-violating perturbations:[33]

$$\begin{aligned}\langle R_{\mu\nu\rho\sigma}\,\widetilde{R}^{\mu\nu\rho\sigma}\rangle &\simeq \frac{16}{a^4}\,\kappa^2\int^{\mu}\frac{d^3k}{(2\pi)^3}\,\frac{H^2}{2\,k^3}\,k^4\,\Theta = \frac{1}{\pi^2}\Big(\frac{H}{M_{\rm Pl}}\Big)^2\,\mu^4\,\Theta \\ &= \frac{2}{3\pi^2}\,\frac{1}{96\times 12}\,\Big(\frac{H}{M_{\rm Pl}}\Big)^3\,\Big(\frac{\mu}{M_{\rm Pl}}\Big)^4\,M_{\rm Pl}\,\times\,\mathcal{K}^0(t)\,,\end{aligned} \tag{9}$$

to leading order in the slow-roll parameter

$$\Theta = \sqrt{\frac{2}{3}}\,\frac{\alpha'\,\kappa}{12}\,H\,\dot{\bar{b}} \ll 1\,, \tag{10}$$

with the overdot denoting derivative with respect to the cosmic time t. The quantity μ is an UltraViolet (UV) cutoff in the momenta of the graviton modes.

Assuming isotropy and homogeneity in the Universe, the condensate (9) implies the following solution of the Euler-Lagrange equation of the KR axion $b(t)$:[24]

$$\dot{\bar{b}} = \sqrt{\frac{2}{3}}\,\frac{\alpha'}{96\,\kappa}\,\mathcal{K}^0 \simeq \text{constant}, \tag{11}$$

provided $\mu/M_s \simeq 15\,\Big(M_{\rm Pl}/H\Big)^{1/2}$. Combining the slow-roll condition (10), with the transplanckian conjecture, *i.e.* the absence of transplanckian graviton modes ($\mu \leq M_{\rm Pl}$), one can show that for the inflationary Hubble parameter $H = H_I = 10^{-5}\,M_{\rm Pl}$, as dictated by data,[1] the string mass scale is restricted to the range:[27,28]

$$2.6\times 10^{-5}\,M_{\rm Pl} \lesssim M_s \lesssim 10^{-4}\,M_{\rm Pl}. \tag{12}$$

Eq. (11) admits a spontaneous-Lorentz-violating (LV) KR axion background solution, parametrised as:[24,26]

$$b(t) = \overline{b}(0) + \sqrt{2\epsilon} H M_{\rm Pl}\, t, \quad H \simeq \text{constant}, \tag{13}$$

with $\overline{b}(0)$ a boundary condition for the field $b(x)$ at the onset of inflation at $t = 0$. For phenomenological reasons[1] we may take[24] $\epsilon = \mathcal{O}(10^{-2})$. Thus, the KR axion is a slow-roll field, but, as we shall discuss next, it does not drive inflation.

To this end, we remark that the condensate (9) implies a condensate of the quantity:[24] $\langle b(t) R_{\mu\nu\rho\sigma} \widetilde{R}^{\mu\nu\rho\sigma} \rangle$, which remains approximately constant during the entire duration of inflation, thus corresponding to a de-Sitter-type (cosmological-constant) contribution to the effective target-space action (7), provided that

$$\frac{|\overline{b}(0)|}{M_{\rm Pl}} \gg \sqrt{2\,\epsilon}\,\mathcal{N} = \mathcal{O}(10), \quad \overline{b}(0) < 0, \tag{14}$$

where the end of inflation[37] has been set to $t_{\rm inf} H \simeq \mathcal{N}$, with $\mathcal{N}$ the number of e-foldings of the inflationary era, which phenomenologically[1] lies in the range $\mathcal{N} = 60 - 70$.

Expanding the effective action (7) about such de-Sitter background configurations, one can show that the equation of state of the total energy $\rho_{\rm total} = \rho^b + \rho^{\rm gCS} + \rho^{\rm condensate}$ and pressure $p_{\rm total} = p^b + p^{\rm gCS} + p^{\rm condensate}$ densities of this fluid, consisting of contributions from the KR axion (superscript b), fluctuations of the gravitational anomaly (Chern-Simons) term (superscript gCS) and the condensate term (superscript "condensate"), assumes an RVM form:[27]

$$p_{\rm total} = -\rho_{\rm total} < 0, \tag{15}$$

with the total energy density being dominated by the H^4 term during the inflationary era

$$0 < \rho_{\rm total} \simeq 3\kappa^{-4} \Big[-1.65 \times 10^{-3} \Big(\kappa\, H\Big)^2 + \frac{\sqrt{2}}{3} |\overline{b}(0)|\, \kappa \times 5.86 \times 10^6 \, (\kappa\, H)^4 \Big] \tag{16}$$

under the condition (14). The reader should notice that the coefficient of the H^2 term is negative, due to the contribution of the anomalous gravitational Chern-Simons terms, and this is a difference from the conventional RVM form (1). We stress that it is the dominance of the condensate term that makes the total energy density (16) positive, and thus leads to a proper RVM fluid. Without the formation of this condensate, the equation of state of the remaining terms curiously acquire the form of an RVM-like (i.e. de Sitter-type) "phantom-matter":[27,38,39]

$$p^b + p^{\rm gCS} = -(\rho^b + \rho^{\rm gCS}) > 0\ , \tag{17}$$

violating the weak energy conditions.[b] Such exotic matter can be used for the stabilisation of traversable wormholes,[40] so in this respect our anomalous gravitational theory, in conditions in which the condensate $\langle b(x)\, R_{\mu\nu\rho\sigma}\, \widetilde{R}^{\mu\nu\rho\sigma}\rangle$ is not formed, might find applications to this problem as well.

The dominance of the non-linear H^4 term in (16) at early eras of this string-inspired Universe, will lead to an RVM type inflation (4), as we discussed in the previous subsection 2.1. It is in this sense that an inflationary phase arises dynamically in a self consistent way in our approach, so our assumption of a constant H in the computation of (9) is justified *a posteriori*.

2.3. *Potential origin of GW: the dynamically-broken supergravity example*

So far, we have assumed the existence of primordial GW perturbations (8), without examining in detail their microscopic origin. In Refs. 26, 27, we have discussed several scenarios which lead to the creation of GW in a pre-RVM-inflationary era of our string-inspired cosmology. One of the most relevant ones to our model, consistent with the basic assumption that only fields from the massless gravitational string multiplet appear as external fields at the very early stages of the Universe, is the scenario considering an underlying superstring theory, whose low energy limit will result in a supergravity model. Although the precise supergravity model depends crucially on the microscopic higher-dimensional string theory considered, for our qualitative purposes here, we may consider a simplified but highly non-trivial example for our (3+1)-dimensional gravitational theory at the very early stages of our cosmology, that of $N = 1$ (3+1)-dimensional supergravity.[41]

The model contains massless spin-2 gravitons, $g_{\mu\nu}(x)$, $\mu, \nu = 0, \ldots 3$, and their spin-3/2 supersymmetric partners, the gravitinos, $\psi_\mu(x)$. The supergravity can be broken dynamically in this model as a consequence of gravitino condensation.[42,43] The corresponding effective potential $\widetilde{V}(\sigma)$ of the gravitino-condensate scalar field

[b]The computation leading to (17) is based on the fact that the graviton variations of the anomalous gravitational Chern-Simons terms in (7) yield the Cotton tensor $C_{\mu\nu}$:[36]

$$\delta\Big[\int d^4x\sqrt{-g}\, b\, R_{\mu\nu\rho\sigma}\, \widetilde{R}^{\mu\nu\rho\sigma}\Big] = 4\int d^4x\sqrt{-g}\, \mathcal{C}^{\mu\nu}\, \delta g_{\mu\nu} = -4\int d^4x\sqrt{-g}\, \mathcal{C}_{\mu\nu}\, \delta g^{\mu\nu},$$

where

$$\mathcal{C}^{\mu\nu} \equiv -\frac{1}{2}\Big[v_\sigma\left(\varepsilon^{\sigma\mu\alpha\beta}R^{\nu}{}_{\beta;\alpha} + \varepsilon^{\sigma\nu\alpha\beta}R^{\mu}{}_{\beta;\alpha}\right) + v_{\sigma\tau}\left(\widetilde{R}^{\tau\mu\sigma\nu} + \widetilde{R}^{\tau\nu\sigma\mu}\right)\Big],$$

with $v_\sigma \equiv \partial_\sigma b = b_{;\sigma}$, $v_{\sigma\tau} \equiv v_{\tau;\sigma} = b_{;\tau;\sigma}$. This implies that the Einstein's equations stemming from (7) read: $R^{\mu\nu} - \frac{1}{2}\, g^{\mu\nu}\, R - \mathcal{C}^{\mu\nu} = \kappa^2\, T_b^{\mu\nu}$, where $T_b^{\mu\nu}$ is the KR axion stress tensor. Taking into account conservation properties of the Cotton tensor,[36] $\mathcal{C}^{\mu\nu}{}_{;\mu} = \frac{1}{8}\, v^\nu\, R^{\alpha\beta\gamma\delta}\, \widetilde{R}_{\alpha\beta\gamma\delta}$, we observe that there is an exchange of energy between the KR axion and the gravitational anomaly, when $\mathcal{C}_{\mu\nu}$ is non trivial, as is the case of GW perturbations of the metric (*cf.* (8)). We note that classically the Cotton tensor is traceless $g^{\mu\nu}\mathcal{C}_{\mu\nu} = 0$. However, the formation of the condensate $\langle b(t) R_{\mu\nu\rho\sigma}\, \widetilde{R}^{\mu\nu\rho\sigma}\rangle$, as a result of (9), introduces in a sense a quantum-gravity-induced trace of $\langle \mathcal{C}^\mu_\mu\rangle$, which leads to the addition of a de Sitter type cosmological-constant term in the effective action (7).[24]

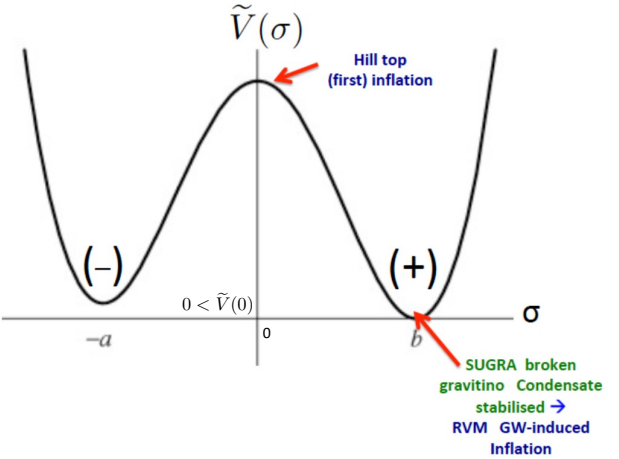

Fig. 1. The biased double-well gravitino potential $\widetilde{V}(\sigma)$ for dynamical supergravity breaking that could characgterise the early epochs of the string-inspired RTVM Cosmology.[26] The bias between the two ($\pm$) vacua is assumed to be due to percolation effects in the early Universe,[45,46] and leads to the formation of unstable domain walls, whose collapse or collisions lead to GW. There is also a first hill-top inflation near the origin $\sigma = 0$.

$\sigma = \langle \overline{\psi}_\mu \psi^\mu \rangle$, evaluated at one loop in a local de Sitter space-time background,[44] after graviton and gravitino Euclidean path-integration, assumes a double-well shape (see fig. 1), defining two local minima, at each of which the potential takes on non-negative values, compatible with the breaking of global and local supersymmetry. There could be a statistical bias, in the sense of unequal occupation numbers of these two local minima/"vacua", as a result of percolation effects.[45,46] Such a situation leads to the formation of "biased" domain walls in the theory, whose non-spherical collapse or collision, leads to GW. The $N = 1$ supergravity model is also characterised by a very early hill-top inflationary phase,[47] which is not necessarily slow roll, and has no observable consequences.

This first inflationary phase is consistent with the study of the theory in a local de Sitter (LDS) background, in the absence of a mass parameter,[44] given the existence of an appropriate general coordinate transformation[48] that maps the LDS space-time without a mass parameter to a cosmological (global) de Sitter one (GDS), and leaves the effective action invariant.[c]

[c]The local de Sitter-Schwarzschild metric with a mass parameter M is described by the following invariant element

$$ds^2 = \left(1 - 2\frac{M}{\bar{r}} - \frac{\Lambda}{3}\bar{r}^2\right) c^2 dT^2 - \left(1 - 2\frac{M}{\bar{r}} - \frac{\Lambda}{3}\bar{r}^2\right)^{-1} d\bar{r}^2 - \bar{r}^2(d\bar{\theta}^2 + \sin^2\bar{\theta}\mathrm{d}\bar{\phi}^2) \qquad (18)$$

in de Sitter-Schwarzschild coordinates. In the case $M = 0$, as required by the isotropy and homogeneity of space, the following transformation[48]

$$x^\mu \equiv \{cT, \bar{r}, \bar{\theta}, \bar{\phi}\} \to x'^\mu \equiv \{ct, r, \bar{\theta}, \bar{\phi}\} \text{ (comoving frame) :}$$
$$t = T + \frac{1}{2H}\ln\left(1 - H^2\bar{r}^2\right), \quad r = \frac{\bar{r}}{\sqrt{1 - H^2\bar{r}^2}} e^{-HT} = \bar{r}\, e^{-Ht}, \quad H^2 \equiv \frac{\Lambda}{3} > 0\,. \qquad (19)$$

This hill-top inflation is a different phase from our RVM inflation. In fact, it ensures that any spatial inhomogeneities or isotropies are washed out well before entrance into the RVM inflationary phase, so the assumptions and calculations of Refs. 24, 26 are formally justified. The RVM inflation occurs[26] at the phase where the gravitino has settled in its lowest minimum (see fig. 1), is massive and the supergravity is dynamically broken. This phase coincides with the exit phase from the hill-top inflation.[47] This exit phase is characterised by the creation of the biased domain walls and GW, as a consequence of wall collisions. The massive gravitino can be integrated out of the path integral.

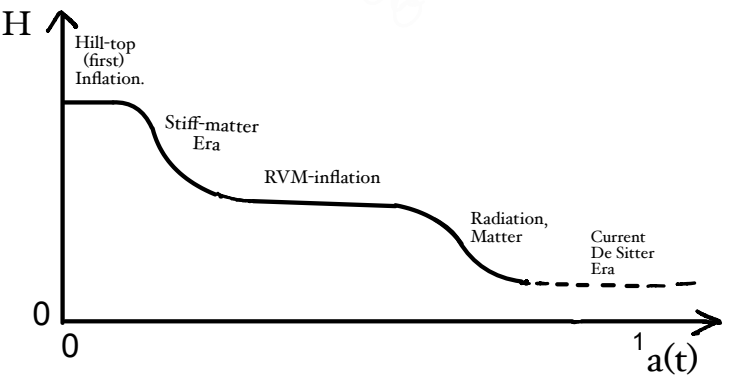

Fig. 2. Schematic evolution of the Hubblle parameter (H) as a function of the scale factor a(t) in the string-inspired RVM universe,[27] from the Big-Bang (a=0) till the current epoch (a=1, in units of today's scale factor).

Embedding this simple supergravity model into our string framework implies[26,28] that the exit from the hill-top inflation may be succeeded by dominance of the KR axion matter,[26] which, due to the lack of a potential, constitutes a stiff matter fluid (with equation of state $w = +1$).[49,50] This era interpolates between the first-hill-top inflation and the GW-induced RVM inflation (see fig. 2). Indeed, the presence of GW as a consequence of domain-wall collapse or collisions, implies the appearance of CP-violating anomalous gravitational Chern Simons terms coupled

where t and r denote co-moving frame time and radial space coordinates, respectively, maps the metric (18) to a standard cosmological de Sitter space-time:

$$ds^2 = c^2\,dt^2 - a(t)^2\left[dr^2 + r^2 d\Omega^2\right], \quad d\Omega^2 = d\bar{\theta}^2 + \sin^2\bar{\theta}\mathrm{d}\bar{\phi}^2\ , \tag{20}$$

where $a(t) = e^{\sqrt{\frac{\Lambda}{3}}\,t} \equiv e^{H\,t}$ (H = constant), is the exponentially expanding scale factor of the de-Sitter/FLRW (inflationary) Universe. The above result is exact, valid for every non-negative value of the cosmological constant $\Lambda \geq 0$. Notice that in this form of the metric there is no preferred origin of space, as appropriate for a space-time generated by a uniform homogeneous and isotropic fluid. The apparent existence of an origin at zero for the radial coordinate in the local form of the pure de-Sitter metric (18) with $M = 0$ is thus an artefact of an inappropriate choice of coordinates, much like the internal observer de Sitter horizon at $\sqrt{\Lambda/3}$.

to the KR axions in the effective action (7). As the cosmic time elapses, conditions for the condensation of GW can develop, leading to the anomaly condensate (9), and the eventual RVM inflationary era, driven by the H^4 term in (16).

Before closing this subsection, we would like to discuss some formal properties of the one-loop corrected effective action of supergravity in the de-Sitter background, which we shall make use of in section 4. As discussed in Ref. 43 (see also Ref. 30), the Euclidean (E) one-loop effective action of the dynamically-broken $N = 1$ supergravity model, in a given gauge, evaluated in a de Sitter background, with (one-loop corrected) cosmological constant $1 \gg \Lambda > 0$ reads:

$$\Gamma^{(\mathrm{E})} \simeq S_{\mathrm{cl}} - \frac{24\pi^2}{\Lambda^2}\big(\alpha_0^F + \alpha_0^B + \big(\alpha_1^F + \alpha_1^B\big)\,\Lambda + \big(\alpha_2^F + \alpha_2^B\big)\,\Lambda^2 + \dots\big)\ , \tag{21}$$

where the superscripts $B(F)$ denote terms arising from integration of massless (quantum) gravitons (B) (and gravitinos (F)), f is the scale of supergravity (and global suprsymmetry) breaking, $\sigma_c < f$,[43] is the value of the gravitino condensate field at the minimum of its effective potential (see fig. 1) and S_{cl} denotes the classical supergravity action with tree-level (bare) cosmological constant $\Lambda_0 < 0$

$$\frac{\Lambda_0}{\kappa^2} \equiv \sigma_c^2 - f^2\ , \tag{22}$$

which is necessarily *negative* for reasons of incompatibility of (unbroken) supergravity with de Sitter vacua.[41–43] The one-loop renormalised cosmological constant Λ, though, is *positive*, due to quantum corrections (*cf.* (25)), compatible with dynamically broken supergravity. Taking into account that the Euclidean de Sitter volume is[44] $24\pi^2/\Lambda^2 \to \int d^4x\sqrt{\widehat{g}_{\mathrm{E}}}$, we may express the effective action (21) in a generally covariant form (using the notation $\widehat{\dots}$ for quantities evaluated in the background de Sitter space-time):

$$\Gamma^{(\mathrm{E})} \simeq -\frac{1}{2\kappa^2}\int d^4x\sqrt{\widehat{g}_{\mathrm{E}}}\left[\left(\widehat{R} - 2\Lambda_1\right) + \alpha_1\,\widehat{R} + \alpha_2\,\widehat{R}^2\right]\ , \tag{23}$$

where we have replaced Λ by the curvature scalar,

$$\widehat{R} = 4\Lambda. \tag{24}$$

The various quantities entering (23) are given by[30,43]

$$\Lambda_1 = -\,\kappa^2\,\left(-\frac{\Lambda_0}{\kappa^2} + \alpha_0^F + \alpha_0^B\right)\ , \tag{25}$$

where

$$\begin{aligned}
\alpha_0^F &= \kappa^4\,\sigma_c^4\left(0.100\,\ln\left(\frac{\kappa^2\,\sigma_c^2}{3\mu^2}\right) + 0.126\right)\ ,\\
\alpha_0^B &= \kappa^4\,\left(f^2 - \sigma_c^2\right)^2\left(0.027 - 0.018\ln\left(\frac{3\kappa^2\left(f^2 - \sigma_c^2\right)}{2\mu^2}\right)\right)\ ,
\end{aligned} \tag{26}$$

and

$$\alpha_1 = \frac{\kappa^2}{2}\left(\alpha_1^F + \alpha_1^B\right)\ ,\quad \alpha_2 = \frac{\kappa^2}{8}\left(\alpha_2^F + \alpha_2^B\right)\ , \tag{27}$$

with

$$\alpha_1^F = 0.067\,\kappa^2\sigma_c^2 - 0.021\,\tilde{\kappa}^2\sigma_c^2 \ln\left(\frac{\Lambda}{\mu^2}\right) + 0.073\,\kappa^2\sigma_c^2 \ln\left(\frac{\kappa^2\sigma_c^2}{\mu^2}\right) \ ,$$
$$\alpha_2^F = 0.029 + 0.014 \ln\left(\frac{\kappa^2\sigma_c^2}{\mu^2}\right) - 0.029 \ln\left(\frac{\Lambda}{\mu^2}\right) \ ,$$
$$\alpha_1^B = -0.083\Lambda_0 + 0.018\,\Lambda_0 \ln\left(\frac{\Lambda}{3\mu^2}\right) + 0.049\,\Lambda_0 \ln\left(-\frac{3\Lambda_0}{\mu^2}\right) \ ,$$
$$\alpha_2^B = 0.020 + 0.021 \ln\left(\frac{\Lambda}{3\mu^2}\right) - 0.014 \ln\left(-\frac{6\Lambda_0}{\mu^2}\right) \ , \tag{28}$$

with the replacement (24) understood in all the above expressions.

The scale μ^2 is a proper-time ultraviolet cutoff, used to regularise UV divergences.[42–44] Supergravity breaks dynamically for μ^2 close to Planck scale.[42] We then set from now on

$$\mu^2 \sim M_{\rm Pl}^2 = \kappa^{-2}. \tag{29}$$

It can be arranged that the masses of the gravitino condensate and the gravitino become very large compared to the low-energy mass scales. They can be taken to be above the grand-unification scale, even close to Planck scale, for our purposes,[26–28] provided the scale f is chosen appropriately. Since the effective action (23) is evaluated after one-loop integration of (weak) graviton perturbations about the de Sitter background, it is actually a quantum-gravity effective action.

In the broken supergravity RVM phase, where the hypermassive gravitino and gravitino-condensate fields, with masses of order of the Planck mass, are integrated out from the low-energy effective action, leading to Planck-mass suppressed terms, the only leading quantum corrections are those due to massless graviton integration. As can be seen from the expressions (25),(26),(27),(28), such corrections involve $\widehat{R}^n \ln(\kappa^2\widehat{R})$, $n = 1, 2$ terms (*cf.* coefficients with superscript B). Passing onto a slowly-varying global de Sitter background (via the coordinate transformations[48] (19)), we may approximately replace $\widehat{R} \to 12H^2$, where H is the approximately constant inflationary Hubble parameter.

In the framework of our cosmology, this RVM phase will also involve the KR axion and gravitational anomaly terms, in addition to the aforementioned quantum-gravity corrections of the effective action (23) contributing terms of the form $H^{2n'}\ln(\kappa^2 H^2)$, $n' = 1, 2$. From the pertinent expressions (25),(26),(27),(28), it becomes clear that, on assuming $\kappa^2|\Lambda_0| < 1$, for the scale of the bare cosmological constant (22), and taking into account (14), these quantum-gravity-induced corrections are subdominant compared to the gravitational-anomaly-condensate-induced H^4 term in (16). Thus, our discussion and conclusions on the rôle of anomalies in inducing an RVM inflation are not affected.[27,28]

As we speculated though in Refs. 27, 28, quantum-gravity corrections of the form $H^2\ln(\kappa^2 H^2)$ could lead to observable deviations from the ΛCDM in the modern era (which again is characterised by an approximately de Sitter cosmological space-time

background, with $H \simeq H_0$). In particular, they could lead to a modified version of RVM, somewhat analogous to the type-II RVM considered in Ref. 21 for the simultaneous alleviation of the H_0 and σ_8 tensions. We shall briefly discuss these issues in section 4.

3. After RVM Inflation: KR-Axion Dark Matter and Leptogenesis

In this section we review briefly the situation charactrerising the exit from the RVM inflation and post inflationary eras of the model. For details we refer the reader to Refs. 25, 24, 27, 26.

At the exit from RVM inflation, gauge fields and chiral fermionic matter, including massive sterile right-handed neutrinos (RHN) of interest to us here, are assumed to be generated from the decay of the RVM vacuum.[25] Chiral fermions have their own gravitational and chiral anomalies. The former are assumed[24,26] to cancel the primordial gravitational anomalies due to the Green-Schwarz counterterms. The chiral anomalies, however, remain in the radiation and matter eras:[25]

$$\begin{aligned}&\partial_\mu\Big[\sqrt{-g}\,\Big(\sqrt{\frac{3}{8}}\frac{\alpha'}{\kappa}\,J^{5\mu} - \frac{\alpha'}{\kappa}\,\sqrt{\frac{2}{3}}\,\frac{1}{96}\,\mathcal{K}^\mu\Big)\Big]\\ &= \sqrt{\frac{3}{8}}\,\frac{\alpha'}{\kappa}\,\Big(\frac{\alpha_{\rm EM}}{2\pi}\,\sqrt{-g}\,F^{\mu\nu}\,\widetilde{F}_{\mu\nu} + \frac{\alpha_s}{8\pi}\,\sqrt{-g}\,G^a_{\mu\nu}\,\widetilde{G}^{a\mu\nu}\Big)\,,\end{aligned} \tag{30}$$

where $J^{5\mu} = \sum_{i=\text{chiral fermions}} \overline{\psi}_i\gamma^5\gamma^\mu\psi_i$, $F_{\mu\nu}$ denotes the electromagnetic (EM) Maxwell tensor, $G^a_{\mu\nu}$ is the gluon field strength, with $a = 1,\dots 8$ an adjoint SU(3) colour index, $\alpha_{\rm EM}$ the electromagnetic fine structure constant, and α_s the strong-interactions fine structure constant. The gluon terms in (30) may lead, through non-perturbative instanton effects in the post-inflationary QCD era, to the generation of a potential and a mass m_b term, for the KR axion, which, due to (12), is within phenomenologically acceptable ranges,[24,28]

$$1.17\times 10^{-8} \lesssim m_b/(\text{eV}) \lesssim 1.17\times 10^{-5}. \tag{31}$$

In this way, the KR axion field can play the rôle of a dominant component of dark matter.[25] In view of the association of the KR axion with torsion, then, one obtains a geometric origin of the dark matter sector of this Universe.

Moreover, the spontaneous-LV KR axion background (13), which remains undiluted at the exit phase from RVM inflation, can trigger the generation of Leptogenesis in models involving RHN, according to the mechanism discussed in Refs. 51, 52. The pertinent lagrangian of the RHN and their interactions with the standard model (SM) sector is:

$$\mathcal{L} = \mathcal{L}_{\rm SM} + i\overline{N}\,\gamma^\mu\,\partial_\mu\,N - \frac{m_N}{2}(\overline{N^c}N + \overline{N}N^c) - \overline{N}\gamma^\mu\,B_\mu\,\gamma^5 N - \sum_f\, y_f\overline{L}_f\tilde{\phi}^d N + \text{h.c.} \tag{32}$$

where h.c. denotes hermitian conjugate, $\mathcal{L}_{\rm SM}$ denotes the SM Lagrangian, N is the RHN field, of (Majorana) mass m_N, $\tilde{\phi}$ is the SU(2) adjoint of the Higgs field

ϕ ($\tilde{\phi}_i^d \equiv \varepsilon_{ij}\phi_j$, $i,j = 1,2$, SU(2) indices), L_f is a SM lepton doublet, with f a generation index, $f = e,\mu,\tau$, y_f is a Yukawa coupling of the "Higgs portal" interactions between the SM sector and RHN, which can lead to the generation of SM light neutrino masses, via, *e.g.*, the seesaw mechanism. The quantity B_μ is associated with the KR axion background (13) induced by the anomaly condensates during the RVM inflation:

$$B_\mu = M_{\rm Pl}^{-1}\,\dot{\bar{b}}\,\delta_{\mu 0}\,. \tag{33}$$

As discussed in Ref. 24, during the radiation era, B_μ is slowly varying with the cosmic temperature T ($B_0 \propto T^3$), so the Lagrangian (32) resembles that of a Standard Model Extension (SME) Lagrangian in a LV and CPT Violating (CPTV) (approximately constant) background.[53,54] A lepton asymmetry is then generated due to asymmetric tree-level decays of the RHN N into SM leptons and anti-leptons in the background (33) between the channels I and II:[51,52] Channel $I: N \to l^- h^+$, $\nu\, h^0$, and Channel II : $N \to l^+ h^-$, $\overline{\nu}\, h^0$, where $\ell^\pm$ are charged leptons, $h^\pm$ are the charged Higgs fields, which, at the high temperatures, above the electroweak symmetry breaking, at which this leptogenesis takes place,[51,52] do not decouple from the physical spectrum, ν ($\overline{\nu}$) are the light SM neutrinos (antineutrinos), and h^0 is the neutral Higgs field. The lepton asymmetry reads (assuming that the dominant lepton asymmetry is generated by one sterile neitrino, although extension to more RHN species, as required by the seesaw mechanism, is straightforward):[52]

$$\frac{\Delta L^{TOT}(T=T_D)}{s} \sim q\,\frac{B_0(T_D)\,m_N^2}{T_D^3} \sim q\,3.5\times 10^{11}\left(\frac{m_N}{M_{\rm Pl}}\right)^2, \quad q>0, \tag{34}$$

where $s \propto T^3$ is the entropy density of the Universe, $T_D \simeq m_N$ denotes the freeze-out temperature, and $0 < q = \mathcal{O}(10)$ is a numerical factor expressing theoretical uncertainties in the approximate analytic (Padé) methods used.[52] The lepton asymmetry (34) can then be communicated to the baryon sector via Baryon-minus-Lepton-number ($B-L$) conserving sphaleron processes in the SM sector.

4. Modern Era Phenomenology: Links of the Stringy RVM to a Modified Type-II RVM and Potential Data Tension Alleviation

In the modern era, the energy density of this stringy Universe also assumes an RVM form,

$$\rho_0 = \frac{3}{\kappa^2}\left(c_0 + \nu_0\, H_0^2\right)\,, \tag{35}$$

where now $\nu_0 > 0$, due to contributions from cosmic electromagnetic background fields[24] (we ignore terms of order H_0^4, as they are negligible in the current era). Comparison with the data[19,20] indicates $\nu_0 = \mathcal{O}(10^{-3})$. The present-day cosmological constant $c_0 > 0$ cannot be uniquely determined in our string-inspired cosmology, given that there might be various contributions to it,[28] some associated with details

of the extra dimensional geometry of the underlying microscopic string/brane theory. For comparison with data, we therefore should treat c_0 as a phenomenological parameter at this stage.

What is important to realise is that, as discussed in subsection 2.3, integrating out massless quantum graviton fluctuations in the path integral of the current-era gravitational theory, which is also characterised by a de Sitter background, generates terms in the one-loop effective action of the form (taking into account (29)):

$$\delta\mathcal{L}^{1-\text{loop}}_{\text{quant. grav.}} = \sqrt{-\widehat{g}}\left[\widetilde{\alpha}_0 + \widehat{R}\Big(c_1 + c_2\ln(\frac{1}{12}\kappa^2\widehat{R})\Big)\right] + \dots \tag{36}$$

From the supergravity example[30,42,43] we have that the constant coefficients $c_i \propto \kappa^2\mathcal{E}_0$, or $c_i \propto \kappa^2\mathcal{E}_0\ln(\kappa^4|\mathcal{E}_0|)$, $i = 1, 2$, (*cf.* (28)) with $\mathcal{E}_0$ a bare (constant) vacuum energy density scale (the ellipses $\dots$ denote terms of quadratic and higher order in $\widehat{R} = 12H^2$, which are subdominant in the current epoch ($H = H_0$)). The structures (36) appear generic for weak quantum gravity corrections about de Sitter backgrounds,[44] and we may therefore conjecture that they can play a rôle in the current era phenomenology.

From the graviton equations of the one-loop corrected effective Lagrangian, it can be readily seen that the terms (36) will imply corrections to the effective stress-energy tensor in the current era of the form,[28]

$$\delta\rho_0^{\text{vac}} = \frac{1}{2}\widetilde{\alpha}_0 + 3(c_1 - c_2)H_0^2 + 3c_2H_0^2\ln(\kappa^2H_0^2)\ , \tag{37}$$

which should be added to (35). Moreover, the supergravity prototype[30,42,43] indicates that the one-loop correction (dark-energy-type) term $\frac{1}{2}\widetilde{\alpha}_0$ is constant, independent of $\ln H^2$ terms. This will lead to some crucial differences from the standard type II RVM used in Ref. 21 to alleviate the H_0 and σ_8 tensions, which is characterised only by a mild cosmic-time t dependence of an effective gravitational constant, $\kappa^2_{\text{eff}}(t) = \kappa^2/\varphi(t)$, with $\varphi(t)$ a phenomenological non-dynamical function.

Another issue to be clarified is the sign of the bare cosmological constant $\Lambda_0 \propto \mathcal{E}_0\,\kappa^2$ which, as in the supergravity example of subsection 2.3, enters the computation of the effective action about de Sitter backgrounds in generic quantum gravity (QG) models that could describe the current-era. Such a sign depends on the details of the underlying QG theory. In the supergravity example this is negative (22) (Anti de Sitter type (AdS)), due to fundamental reasons of compatibility with supersymmetry.[42,43] One may also use such negative bare cosmological constant scales as formal regulators in the quantization procedure, as, *e.g.*, has been considered in the context of black hole physics[55] motivated by the AdS/conformal-field-theory correspondence.[56] We stress though that the one-loop corrected cosmological constant is always positive in such constructions, compatible with the current phenomenology (and also with the broken supergravity scenario[30,42,43]). We plan to study such issues, and their modern-era phenomenology, in future works.

Before closing the section, we mention that in string theory there might be a mixing of the KR axion with the other, string-model dependent, axions that exist

as a result of the compactification procedure.[35] In Ref. 24, we have argued that, depending on details of this mixing, one might obtain KR axion backgrounds that may be characterised by an approximately constant $\dot{b}$ even in the current era of the string Universe. Such backgrounds can therefore be parametrised by

$$\dot{b}_0 \sim \sqrt{2\,\epsilon'}\, H_0\, M_{\rm Pl}. \tag{38}$$

Phenomenological considerations, associated with the rôle of the KR axion background as dark matter, imply then that $\epsilon' \sim 10^{-2}$, in order to reproduce a dark matter energy density due to the KR axion in the phenomenologically right ballpark.[1,2] This, in turn, leads to a curious coincidence in the order of magnitude of the slow-roll parameters entering the expressions for $\dot{b}$ in the RVM-inflationary (13) (ϵ) and modern (38) eras (ϵ'),

$$\epsilon' \sim \epsilon \simeq 10^{-2}\ , \tag{39}$$

which needs to be understood further, in the context of the underlying microscopic string theory models. We do note though[25,28] that the background (38), under the assumption (39), is compatible with the stringent current experimental bounds of LV and CPTV discussed in ref. 54.

5. Conclusions and Outlook

In this talk, I reviewed a string-inspired model of a running vacuum (RVM) cosmology, which seems consistent with the current phenomenology, but also provides a geometrical origin of both, RVM inflation and dark matter. Crucial rôles are played by the gravitational anomalies that characterise the model at early eras, and the KR axion fields from the fundamental massless multiplet of the underlying string theory. The KR axion field is associated with a totally antisymmetric torsion in the underlying string theory. The RVM inflation arises from the non-linear H^4 term in the vacuum energy density (16), which is exclusively due to primordial GW that induce non trivial condensates of the gravitational Chern-Simons terms that are present in the very early stages of this string-inspired cosmology. Such terms do not arise in the context of anomaly-free quantum field theories, or Starobinsky inflation, and, as such, are rather exclusive to our string-inspired RVM. The anomaly condensates also imply LV KR axion backgrounds that induce baryogenesis through leptogenesis. In this sense, we may dare state that our very existence, that is the dominance of matter over antimatter in the Cosmos, is due to cosmic anomalies. *We are anomalously made of star stuff*, to paraphrase the famous quote by Carl Sagan.[23,24]

There are several open issues that we need to understand, and explore further, such as: (i) potential hints in the cosmic-microwave-background data[1] about the LV KR axion backgrounds, (ii) prospects of getting some phenomenological indications in early-Universe data about the negative, anomaly-induced, coefficient of the H^2 term in the RVM-like cosmic energy density (16) during the RVM inflation.

This, however, is a difficult task, in view of the phase transition occurring in our model at the exit from the RVM inflation, (iii) the rich phenomenology of both, the string-model-independent KR axion and the other, string-model dependent, axions, that exist in string theory,[35,57] (iv) the precise rôle of quantum-gravity-induced $H^2\ln(\kappa^2 H^2)$ corrections in the vacuum energy density of the current era, comparing the model with the type-II RVM,[21] in an attempt to discuss potential alleviation of the observed tensions in the cosmological data, and (v) last but not least: in view of the association of the KR axion with (totally antisymmetric) torsion, the phenomenological comparison of the stringy RVM with other cosmologies with torsion[58,59] (in which the torsion has more components than the totally antisymmetric one characterising our model) or other teleparallel-gravity models[60] (where torsion mimics gravity, in contrast to our case, which contains also graviton fields). We hope to be able to report on these important issues in the near future.

Early and not so early dark energy. What do cosmological observations tell us about them?

Adrià Gómez-Valent[1,*], Ziyang Zheng[1], Luca Amendola[1], Valeria Pettorino[2] and Christof Wetterich[1]

Cosmological data still allow for the presence of a non-negligible amount of dark energy at very high redshifts, namely during the matter- and radiation-dominated epochs. This is the so-called early dark energy (EDE), which could help to mitigate the tensions that affect the standard model of cosmology since (i) it reduces the sound horizon at the baryon-drag epoch, hence giving room to higher values of H_0 than those found in the ΛCDM; and (ii) it could potentially decrease the number of large-scale structures in the Universe due its negative pressure and its inability to cluster efficiently for large enough values of its sound speed. Here we put constraints on the fraction of EDE using two methods: first, we use a perfect fluid parameterization that produces plateaux in $\Omega_{ede}(z)$ during the relativistic and non-relativistic matter-dominated eras. Second, we apply a tomographic approach to constrain the EDE density in redshift bins, which allows us to reconstruct the evolution of the EDE fraction before and after the decoupling of the Cosmic Microwave Background (CMB) photons. We have employed *Planck* data 2018, the Pantheon compilation of supernovae of Type Ia (SNIa), data on galaxy clustering, the prior on the absolute magnitude of SNIa by SH0ES, and weak lensing data from KiDS+VIKING-450 and DES-Y1. Using our minimal parameterization we find that EDE is not able to loosen the cosmological tensions, and show that the constraints on the EDE fraction weaken considerably when its sound speed takes lower values. Thanks to our binned analysis we are able to put tight constraints on the EDE fraction around the CMB decoupling time, $\lesssim 0.4\%$ at 2σ c.l. We confirm previous results that a significant EDE fraction in the radiation-dominated epoch loosens the H_0 tension, but tends to worsen the tension for σ_8. A subsequent presence of EDE in the matter-dominated era helps to alleviate this problem. When both the SH0ES prior and weak lensing data are considered in the fitting analysis in combination with data from CMB, SNIa and baryon acoustic oscillations, the EDE fractions are constrained to be $\lesssim 2.6\%$ in the radiation-dominated epoch and $\lesssim 1.5\%$ in the redshift range $z \in (100, 1000)$ at 2σ c.l. The two tensions remain with a statistical significance of $\sim 2-3\sigma$ c.l. This contribution to the proceedings of the CM3 parallel session of the MG16 Marcel Grossmann virtual Conference: "Status of the H_0 and σ_8 tensions: theoretical models and model-independent constraints" is based on the paper arXiv:2107.11065,[1] which appeared in the arXiv shortly after my talk of July 6th 2021.

Keywords: Cosmology: observations – Cosmology: theory – cosmological parameters – dark energy – dark matter.

1. Introduction

The cosmological constant, Λ, is (together with other assumptions as the Cosmological Principle, the existence of cold dark matter (CDM) and an inflationary period prior to the radiation-dominated era) a key building block of the standard model of Cosmology. By adding this very simple term in Einstein's field equations it is possible to produce the late-time acceleration of the Universe[2,3] and help to explain a large variety of cosmological observations[4–6] without increasing excessively the mathematical complexity of the equations. However, the model is not free from extremely intricate theoretical conundrums, as the famous old cosmological constant[7–9] and coincidence problems, see e.g.[10] The former might be strongly intertwined with the latter, which should not be considered as a "why now" problem,[11] but as a matter of why the energy density associated to Λ, i.e. $\rho_\Lambda = \Lambda/8\pi G$, takes the value $\rho_\Lambda \sim \mathcal{O}(10^{-47})$ GeV^4 in natural units, hence being of the same order of magnitude of the non-relativistic matter energy density $\rho_m(z)$ when $z \lesssim 1$. This is pivotal for the model to exhibit an excellent phenomenological performance. We can soften the coincidence problem if we depart from the ΛCDM by allowing some sort of dynamical dark energy (DE) density instead of considering a rigid ρ_Λ.[12–14] This is a more appealing framework, since it is actually hard to believe in an immutable entity like the cosmological constant. Why should the component in charge of the current acceleration of the Cosmos be insensitive e.g. to the Universe's evolution and energy content? Such dynamics could lead to the presence of a non-negligible fraction of early dark energy (EDE) in the Universe during the radiation-dominated epoch (RDE) and/or the matter-dominated era (MDE). Of particular relevance concerning the coincidence problem are the quintessence models with scaling solutions, as the one with an exponential potential originally proposed by C. Wetterich in the late 80's,[14] in which the EDE fraction follows the dominant component in the Universe in both, the RDE and MDE,[15] making more natural the scenario with $\rho_{de} \sim \mathcal{O}(\rho_m)$ at low redshifts.

Apart from the aforementioned theoretical problems there are also some observational tensions affecting the ΛCDM, making the concordance model less concordant than it was thought to be ten years ago. At least, if these tensions are not induced by systematic errors in the data. The cosmic microwave background (CMB) temperature, polarization and lensing data from *Planck* 2018 leads to a value of the Hubble parameter $H_0 = (67.36 \pm 0.54)$ km/s/Mpc when analyzed under the assumption of the ΛCDM,[4] and a similar result is obtained from measurements of the baryon acoustic oscillations (BAO) and the deuterium abundance, again in the standard model.[16] These values are at odds with the one measured by the SH0ES team, $H_0 = (73.2 \pm 1.3)$ km/s/Mpc,[17] which is obtained with the cosmic distance ladder method and does not rely on the assumption of any cosmological model. There exists a $\sim 4.1\sigma$ tension between them, which has been persistently and consistently increasing in the last years,[18,19] see also the reviews.[20,21] On the other hand, galaxy clustering (through redshift-space distortions, RSD), direct peculiar velocity and

weak lensing (WL) measurements suggest that the Universe is less clumpy than preferred by the CMB data under the ΛCDM, see e.g.[22–25] The tension is usually formulated in terms of the root-mean-square (*rms*) of mass fluctuations at scales of $8h^{-1}$ Mpc, σ_8, and related composite quantities like $S_8 = \sigma_8(\Omega_m^{(0)}/0.3)^{0.5}$, with $\Omega_m^{(0)}$ the current matter energy fraction in the Universe. The first indication of its existence appeared already almost a decade ago[26] and it is still there.[27–29] The tension is in this case less significant from a statistical point of view than the aforesaid one of H_0, of about $2-3\sigma$ depending on the data source and the large-scale structure (LSS) estimator employed to quantify the tension. For instance, by combining the KiDS-1000 WL results with BOSS and 2dFLenS data the authors of[25] have shown that it is possible to reduce by a factor ~ 2 the uncertainty on S_8, and also to write the tension only in terms of σ_8, since BOSS puts tight constraints on $\Omega_m^{(0)}$ and the degeneracy in the $\sigma_8 - \Omega_m^{(0)}$ plane can be broken. They find $S_8 = 0.766^{+0.020}_{-0.014}$ and $\sigma_8 = 0.760^{+0.021}_{-0.023}$, which are in 3.1σ and 2.2σ tension with *Planck*, respectively.

Whether the H_0 and S_8/σ_8 tensions are to some degree physical or not is still unclear and under intense debate.[30–32] Hopefully this question will be resolved in the near future. In the meanwhile, theoreticians have worked very hard to find ways of loosening the tensions, taking for granted that they are real, see the reviews[21,33,34] and the complete lists of references therein. It is important to remark, though, that it is very difficult to find models in the literature capable of relieving both tensions at a time in a significant way. There are only some few exceptions that offer better perspectives, as e.g. the running vacuum model of type-II studied in[29] or the Brans-Dicke ΛCDM model explored in.[35,36] The latter, though, might encounter some problems when trying to match the cosmological and local values of the gravitational coupling through an appropriate screening mechanism,[37] and the effect of the *Planck* 2018 CMB polarization data might also hinder its overall fitting performance. Other models are only able to loosen one of the tensions, while worsening the other. This is the case e.g. of the class of new EDE models based on early phase transitions,[38–40] ultra-light axions[41,42] or alike.[43] In practice, all these models fight against the H_0 tension in a very similar way. There is a new component in the energy budget of the Universe that acts as a cosmological constant deep in the RDE and has an associated (constant) density which is of about $5-10\%$ the radiation energy density around the matter-radiation equality time, when the EDE fraction reaches its maximum. This excess of energy with respect to the standard model decreases the sound horizon at the baryon-drag epoch, and this forces the Hubble parameter to be larger in order to decrease the angular diameter distance to the last-scattering surface and keep in this way intact the location of the first peak of the temperature CMB anisotropies. The latter is very well constrained by *Planck*. After that moment, the energy density dilutes typically faster than radiation, leaving no imprint in the late-time universe, where a cosmological constant is still assumed to produce the current positive acceleration, as in the standard ΛCDM. Although it is possible to obtain posterior values of the Hubble parameter

much closer to the SH0ES measurement[17] in the context of these new EDE models, they require larger values of the current matter energy density in order to compensate the early Sachs-Wolfe effect introduced by EDE in the pre-recombination epoch, and this enhances the LSS formation processes in the late-time Universe, which in turn exacerbates the S_8/σ_8 tension.[44–46]

Here we first explore EDE models with scaling solutions in the MDE and RDE, or just in the MDE. As already discussed above, they can alleviate in some sense the coincidence problem. They could in principle have an impact on the cosmological tensions as well, depending on how strong are the constraints on the EDE fraction imposed by the the cosmological data. In these models, EDE might not be negligible after the recombination era, and this could lead to a softening of the S_8/σ_8 tension. Moreover, the shape of $\Omega_{ede}(z) = \rho_{ede}(z)/\rho_c(z)$, with $\rho_c(z) = 3H^2(z)/8\pi G$ the critical energy density in the Universe, is very different from the one encountered in the new EDE models mentioned in the previous paragraph, since in this case the EDE fraction is constant during the epochs at which the scaling behavior comes into play. Hence, it is clearly worth to study these EDE models and to determine to what extent they can alleviate the tensions, if they do at all. In view of the existing tensions, there is a clear interest of revisiting these models, whose seeds where already present more than thirty years ago.[14] In addition, we also perform a more model-independent analysis, applying a tomographic method to reconstruct the shape of $\Omega_{ede}(z)$ that is preferred by different combinations of cosmological data sets. We will see that this is very useful to extract more general information about how is EDE constrained in the various epochs of the cosmic expansion.

2. Early dark energy

EDE affects observables in several ways. The presence of EDE at decoupling can change the position and height of the peaks in the CMB[47–49] and can also impact it through the early integrated Sachs-Wolfe effect. Furthermore, EDE suppresses the growth of structure:[50–52] a smaller number of clusters can form with respect to the ΛCDM[53] because of the negative pressure of EDE and also because of its large sound speed, which does not allow it to cluster; the lensing potential is also weaker, with an impact on weak lensing and the CMB peaks at large multipoles. Thus, EDE can potentially have a direct impact on the cosmological tensions. In the following we first design a general parameterization able to mimic the background dominant component, and then proceed with a tomographic analysis in different redshift bins.

2.1. *Parametric EDE*

We build now a simple parameterization of the DE density that allows us to reproduce the behavior of uncoupled quintessence models with scaling solutions. For this reason, we want our parameterization to be able to generate two plateaux in $\Omega_{de}(z)$. The first plateau occurs in the RDE, and the second one in the MDE,

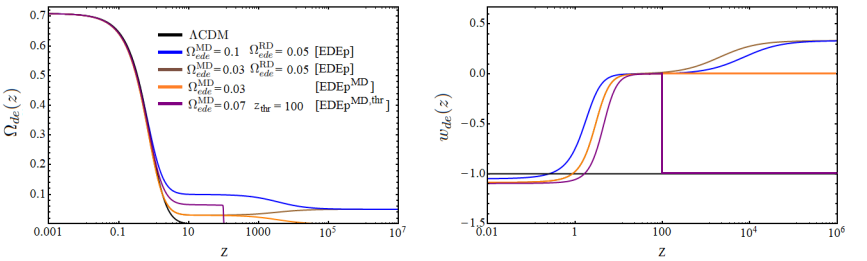

Fig. 1. Functions $\Omega_{de}(z)$ (left plot) and $w_{de}(z) = p_{de}(z)/\rho_{de}(z)$ (right plot) obtained using the parametrizations described in Sec. 2.1, for some illustrative values of the parameters.

and can have different heights in principle. This is what happens for instance in quintessence models with a single exponential potential $V(\phi) = V_0 e^{-\sqrt{8\pi G}\lambda\phi}$, where the fractions of EDE in the RDE and MDE depend only on one parameter, λ.[14,15] By introducing a second exponential potential it is possible to control the height of the two plateaux independently.[54]

With this aim in mind, we generalize the parameterizations proposed earlier in[48,49] and we consider here a DE density with the following form,

$$\rho_{de}(z) = \rho_1(1+z)^4 + \rho_2(1+z)^3 + \rho_3(1+z)^{3(1+w)}\,, \tag{1}$$

parameterized by the constant energy densities ρ_1, ρ_2 and ρ_3 and by a constant equation of state parameter (EoS) w. We call this parameterization EDEp, where the "p" reminds us of the 'plateaux' that characterise it. The last term of (1) is able to mimic the behavior of a late-time dynamical DE with the wCDM form,[55] whereas the first two terms produce the plateaux in the RDE and MDE. It is useful to write the constants ρ_1 and ρ_2 in terms of dimensionless parameters, as follows

$$\rho_1 = \chi_1 \Omega_{r,*}^{(0)} \rho_c^{(0)}\,; \qquad \rho_2 = \chi_2 \Omega_{m,*}^{(0)} \rho_c^{(0)}\,, \tag{2}$$

where $\Omega_{r,*}^{(0)}$ and $\Omega_{m,*}^{(0)}$ are the current density parameters of radiation and matter, respectively, computed considering three massless neutrinos, and $\rho_c^{(0)} = \rho_c(z=0)$. We consider standard General Relativity and a flat Friedmann-Lemaître-Robertson-Walker universe. $\chi_1, \chi_2, \rho_3 > 0$ in order the DE density to be positive during the expansion. Deep in the RDE and MDE the EDE fractions are constant,

$$\Omega_{ede}^{\rm RD} = \frac{\chi_1}{1+\chi_1}\,; \qquad \Omega_{ede}^{\rm MD} = \frac{\chi_2}{1+\chi_2}\,. \tag{3}$$

The present dark energy density, $\rho_{de}^{(0)}$, can be directly computed from the Hubble parameter, $H_0 = 100h$ km/s/Mpc, and the reduced CDM and baryon density parameters, $\omega_{cdm} = \Omega_{cdm}^{(0)} h^2$ and $\omega_b = \Omega_b^{(0)} h^2$. Thus, one of the three ρ_i's appearing in (1) can be expressed in terms of the other two, e.g. $\rho_3 = \rho_{de}^{(0)} - \rho_1 - \rho_2$, so in this EDE parametrization we deal with three additional parameters with respect to the ΛCDM. We have nine cosmological parameters in total, namely the spectral

index n_s and amplitude A_s of the primordial power spectrum, H_0, ω_b, ω_{cdm}, the optical depth to reionization, τ, together with w, χ_1 and χ_2 (or, equivalently, $\Omega_{ede}^{\rm RD}$ and $\Omega_{ede}^{\rm MD}$). We consider a massive neutrino of 0.06 eV and two massless neutrinos.

The DE fluid is covariantly conserved so its associated pressure reads,

$$\dot{\rho}_{de}+3H(\rho_{de}+p_{de})=0 \longrightarrow p_{de}(z)=\frac{\rho_1}{3}(1+z)^4+w\rho_3(1+z)^{3(1+w)}\,, \qquad (4)$$

where the dot refers to a derivative with respect to the cosmic time. The corresponding equation of state parameter can be obtained from the ratio of (4) and (1), i.e. $w_{de}(z)=p_{de}(z)/\rho_{de}(z)$. It is clear that $w_{de}=1/3$ and $w_{de}=0$ in the RDE and MDE, respectively, and $w_{de}\approx w$ at present for low values of χ_2. For the perturbations, in our main analyses we take the sound speed of the DE fluid to be equal to the speed of light in the DE rest frame,[56] i.e. $\hat{c}_s=1$, so in our model the DE does not cluster efficiently. We will study also what happens when $\hat{c}_s<1$.

If we set $\rho_1=0$ ($\Omega_{ede}^{\rm RD}=0$) in (1) EDE is completely negligible during the RDE,

$$\rho_{de}(z)=\rho_2(1+z)^3+\rho_3(1+z)^{3(1+w)}\,. \qquad (5)$$

We denote this particular case of EDEp as EDEp$^{\rm MD}$, to remind us that the plateau is in this case following the matter component. If we turn the first term on in (5) at a particular 'threshold' redshift $z_{\rm thr}$, in the MDE we obtain,

$$\rho_{de}(z)=\rho_2(1+z)^3\theta(z_{\rm thr}-z)+\rho_3(1+z)^{3(1+w)}\,, \qquad (6)$$

with θ the Heaviside step function. This is what we call EDEp$^{{\rm MD},thr}$. For $z_{\rm thr}\to\infty$ we recover the pure EDEp$^{\rm MD}$ parametrization (5). We show typical shapes of the functions $\Omega_{de}(z)$ and $w_{de}(z)$ obtained with EDEp, EDEp$^{\rm MD}$ and EDEp$^{{\rm MD},thr}$ in Fig. 1.

2.2. *Tomographic EDE*

We further consider the possibility of binning the amount of $\Omega_{de}(z)$ in 11 bins to perform a tomographic analysis using the data sets described in Sec. 3. Here, again, $\rho_{de}^{(0)}$ can be directly determined from H_0, ω_b and ω_{cdm}; the other constant densities ρ_i, with $i=A,...,J$ (see Table 1 in[1] for details), are left free in our Monte Carlo (MC) runs, together with w and the six usual ΛCDM parameters. We keep $\hat{c}_s=1$. Our main aim is to see how much EDE we can have in each bin, and therefore which shape of $\Omega_{de}(z)$ is preferred by the data, regardless of its complexity. The corresponding fitting results and reconstructed shapes of $\Omega_{de}(z)$ are shown and discussed in Sec. 4.2.

3. Methodology and data

We have implemented the various parametrizations of Sec. 2.1 and also the binned $\rho_{de}(z)$ described in Sec. 2.2 in our own modified version of the Einstein-Boltzmann code `CLASS`.[57] We have constrained the parameters of our models through a Bayesian

exploration of the parameter space, employing the MC sampler `MontePython`.[58] We have used flat priors for the cosmological parameters in common with the ΛCDM model, with widths that fully respect the *Planck* 2018 uncertainties.[4] Regarding the priors on the EDE fractions, previous studies in the literature showed that they are always lower than $\sim 10\%$,[48,49] so we have used $0 < \chi_i < 0.12$ in the MC analyses of the parametrizations of Sec. 2.1, and similar priors for each bin of the tomographic study of Sec. 2.2.

Now we list the various data sets used in this study:

- CMB: We consider the full *Planck* 2018 TTTEEE+lowE and TTTEEE+lowE+lensing likelihoods.[4] We denote these data sets as CMBpol and CMBpolens, respectively.
- Supernovae of Type Ia (SNIa): We use the observed SNIa apparent magnitude and redshifts of the Pantheon compilation.[5] The absolute magnitude of these SNIa, M, is left free in the fitting analysis, and we impose a prior on it. See the next item of the list for details.
- Prior on M: We use in some of our fitting analyses the SH0ES effective calibration prior on the absolute magnitude of the SNIa as provided in,[59] $M_{\rm SH0ES} = -19.2191 \pm 0.0405$. It is obtained from the calibration of nearby SNIa (at $z \lesssim 0.01$) with Cepheids.[60] It is better to use this prior rather than the one on H_0,[17,61] especially when it is combined with data from SNIa compilations that include the same SNIa in the Hubble flow considered by the SH0ES team (as in the Pantheon compilation[5]) because in this way we avoid double-counting issues. In some of our Tables we also provide the best-fit values of M. This allows us to quantity the 'M tension', i.e. the tension between the latter and $M_{\rm SH0ES}$. We show in Sec. 4.2 that the statistical level of the SH0ES-*Planck* tension can be in some cases quite different when formulated in terms of H_0 and M.
- BAO: We have employed the data reported in.[6,22,62–65]
- WL: In some of our fitting analyses we employ the KiDS +VIKING-450+DESY1 prior $S_8 = 0.762^{+0.025}_{-0.024}$.[66] The author of[67] has raised some concerns about the use of σ_8 and derived quantities as S_8. He suggests the use of σ_{12}, defined as the *rms* linear theory variance at the fixed scale of 12 Mpc, and $S_{12} = \sigma_{12}(\omega_m/0.14)^{0.4}$. We provide the values of these parameters in some of our Tables, together with the usual σ_8 and S_8.
- RSD: Data on anisotropic clustering of galaxies in redshift space, and from the direct measurement of peculiar velocities.[6,22,68–75] We call this data set RSD in short because most of these points are obtained from the analysis of redshift-space distortions.

The corresponding fitting results are presented and discussed in Sec. 4. In order to quantify the impact of the SH0ES prior on the fitting results and on the ability of the models to loosen the H_0/M tension we study and compare the constraints on our

Table 1. The mean fit values and 68.3% confidence limits for the ΛCDM, the wCDM, EDEp (1) and EDEp$^{\rm MD}$ (5), using the CMBpol+SNIa and CMBpolens+SNIa+M data sets (cf. Sec. 3). For $\Omega_{ede}^{\rm RD}$ and $\Omega_{ede}^{\rm MD}$ we also show the 2σ limits inside the parentheses. Constraints on τ are provided in.[1] See the comments in Sec. 4.1.

EDE models obtained: (i) with a minimal data set composed by CMBpol+SNIa; and (ii) adding on top of the latter the SH0ES prior on M, i.e. using CMBpol+SNIa+M. The SNIa data help to break the strong degeneracies found in the w-H_0 plane when only CMB data are used in the analysis.[76]

The properties and limitations of the EDEp and EDEp$^{\rm MD}$ parametrizations are already grasped with the aforementioned minimal data sets (cf. Table 1). For EDEp$^{{\rm MD},thr}$ we study also the effect of the CMB lensing and BAO+RSD data when combined with CMBpol+SNIa. We provide the corresponding constraints in figures 2 and 3. For the analyses of the binned $\rho_{de}(z)$ described in Sec. 2.2 we report our results in Table 2, where we explicitly test the impact of BAO and the weak lensing data, by considering not only the minimal data sets described in the previous paragraph, but also adding the information on BAO and BAO+WL. In addition, we redo the fitting analyses considering also the CMB lensing in order to quantify

its impact. For further explanations on the data we refer the reader to our work[1] and the original data sources.

4. Results and discussion

We present and discuss now the results obtained from the fitting analyses of the EDE parametrizations and the tomographic EDE described in Secs. 2.1 and 2.2, respectively, using the methodology and data sets of the previous section.

4.1. *Results for the parametric analysis*

The mean fit values and corresponding uncertainties for the various cosmological parameters in the EDEp and EDEp$^{\rm MD}$ parametrizations obtained with the baseline CMBpol+SNIa dataset are reported in Table 1. The constraints on the fraction of early dark energy in the EDEp parametrization in the radiation- and matter-dominated epochs, $\Omega_{ede}^{\rm RD}$ and $\Omega_{ede}^{\rm MD}$, are very strong. They lie below $\sim 2\%$ and $\sim 0.7\%$, respectively, at the 2σ c.l. It is interesting to observe that the upper limit of $\Omega_{ede}^{\rm MD}$ in the EDEp$^{\rm MD}$ parametrization coincides with the one obtained in the more general EDEp. The constraints on $\Omega_{ede}^{\rm MD}$ and $\Omega_{ede}^{\rm RD}$ in EDEp are quite independent. Actually, we have checked that the correlation coefficient between these two parameters is pretty small, $\sim 5.6\%$. As already noticed in,[48] the low upper limits on $\Omega_{ede}^{\rm RD}$ and $\Omega_{ede}^{\rm MD}$ are due to the very tight constraint on the fraction of EDE around the CMB decoupling time. The latter acts as an anchor for $\Omega_{ede}^{\rm RD}$ and even more for $\Omega_{ede}^{\rm MD}$, since in the last scattering surface the matter energy density is already ~ 3 times larger than the radiation one.

Another result from Table 1 to remark is that EDEp cannot alleviate significantly the H_0 and σ_8 tensions. The shape of the early dark energy density seems to be too restricted in these parametrization. There is a slight increase of H_0 in EDEp and EDEp$^{\rm MD}$ with respect to the ΛCDM, but it is mainly due to the dynamics of the late-time DE, and this is why the major part of the effect is already found with the wCDM parametrization.[55]

When we include the SH0ES prior in our fitting analysis we increase, of course, the value of the Hubble parameter, see Table 1. The tension with the distance ladder determination is now only of $\sim 1.7\sigma$, but this is again mainly thanks to the lowering of w, which now lies more in the phantom region (3σ away below $w = -1$). The values of w and H_0 are almost identical to those found in the wCDM parametrization, and EDE does not have any important impact on the H_0 tension in the context of the EDEp parametrization. The loosening of the H_0 tension is accompanied by a slight worsening of the σ_8 one due to the positive correlation between H_0 and σ_8. Phantom dark energy leads to lower values of the DE density in the past and this produces, in turn, an increase of the structure formation processes in the Universe. It seems that the EDE density has a too restricted form in the parameterizations under study here. They allow for plateaux and generalize previous

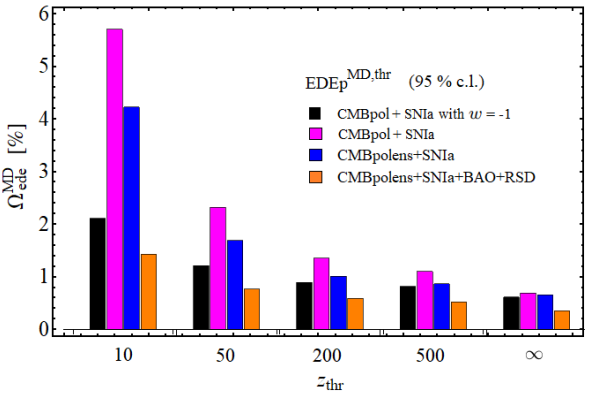

Fig. 2. Constraints on $\Omega_{ede}^{\rm MD}$ at 95% c.l. obtained from the fitting analyses of the EDEp$^{\rm MD,thr}$ parametrization (6), and under the data sets shown in the legend.

studies, but still seem to be quite constrained and unable to resolve the tensions. In the next section we then investigate the binned tomographic approach described in Sec. 2.2. Before moving on, however, we discuss briefly two options to weaken the constraints on the fraction of EDE.

Much weaker constraints on the fraction of EDE can be obtained by allowing for values of $\hat{c}_s^2 \ll 1$. The only difference between our EDE and cold dark matter during the MDE is found at the perturbations level. Both are pressureless fluids at the background level, but have different $\hat{c}_s$. The latter is equal to 1 for EDE and 0 for the dark matter. Hence, we expect the constraints on $\Omega_{ede}^{\rm MD}$ to loosen if we decrease the value of $\hat{c}_s$ of EDE, and even obtain a full degeneracy between the fraction of EDE and CDM during the MDE in the limit $\hat{c}_s \to 0$. This is actually what happens, as we explicitly show in Fig. 2 of.[1] We have to say, though, that the change in the sound speed does not help to alleviate the cosmological tensions, neither. For instance, under the CMBPol+SNIa data set the Hubble parameter remains close to ~ 67.5 km/s/Mpc, and the 1σ uncertainty is lower than ~ 0.8 km/s/Mpc regardless of the value of $\hat{c}_s$ under consideration when the late-time DE dynamics is switched off.

One can also get weaker constraints on EDE in the MDE by activating EDE at lower redshifts. In order to study this effect we explore the EDEp$^{{\rm MD},thr}$ parametrization (6). In Fig. 2 we provide the 2σ c.l. bounds on $\Omega_{ede}^{\rm MD}$ obtained with the baseline data set CMBpol+SNIa with and without late-time dark energy dynamics, and also adding the CMB lensing and the BAO+RSD data sets. When $z_{\rm thr} \to \infty$ we recover the constraints obtained in the EDEp$^{\rm MD}$ model, of course, but when we allow for lower values of the threshold redshift (below the CMB decoupling one) we get larger upper bounds on $\Omega_{ede}^{\rm MD}$, which depend on the concrete data set under consideration and also on $z_{\rm thr}$. We report the results obtained with $z_{\rm thr} = 10, 50, 200, 500, \infty$. The addition of the *Planck* 2018 CMB lensing to the CMBpol+SNIa baseline data set leads to stronger constraints on $\Omega_{ede}^{\rm MD}$. Its value decreases by a $\sim 25\%$ $\forall z_{\rm thr}$. When

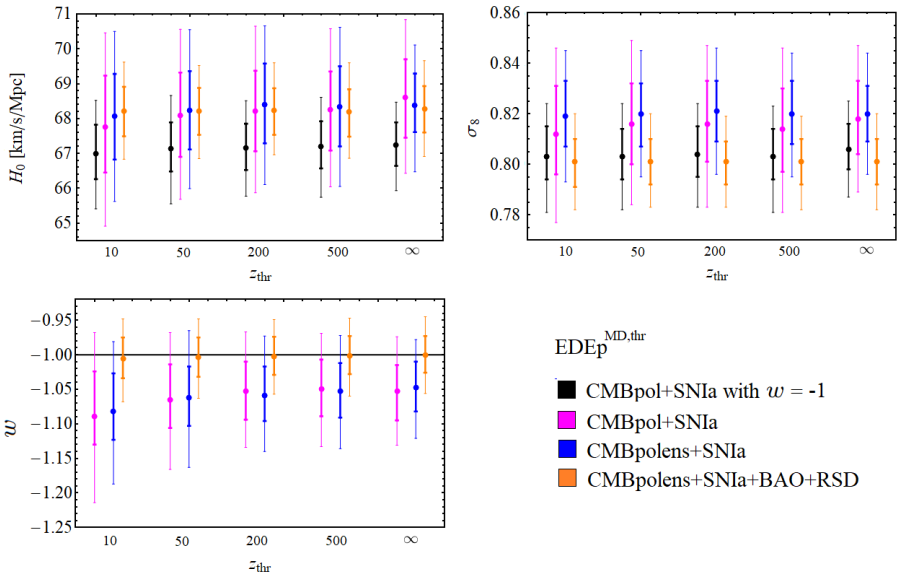

Fig. 3. Constraints for H_0, σ_8 and w at 1σ and 2σ c.l. obtained with the EDEp$^{\mathrm{MD},thr}$ parametrization (6) for different values of the threshold redshift z_{thr} and using the same combined data sets as in Fig. 2.

we also include the BAO+RSD data the decrease is even bigger, $\sim 75\%$. If we turn off the late-time dynamics of DE we also obtain tighter bounds on $\Omega_{ede}^{\mathrm{MD}}$, just because in this case we remove the degeneracy between this parameter and w. Our Fig. 2 can be compared with Figs. 6-7 of[48] and Fig. 11 of,[49] which were obviously obtained with older data sets. In[48] the authors employed CMB data from WMAP9 combined with small scale measurements from the South Pole Telescope (SPT), whereas in[49] the authors employed the *Planck* 2015 CMB likelihood and studied the impact of some other background and weak lensing data sets, as described in Sec. 4 in that reference. The results presented in this section constitute a significant update obtained with the *Planck* 2018 likelihood and also other more recent background and LSS data (cf. Sec. 3 for details).

In Fig. 3 we provide the corresponding constraints on H_0, σ_8 and w at 1σ and 2σ c.l. in the EDEp$^{\mathrm{MD,thr}}$ parameterization for the same scenarios explored in Fig. 2. They support some of the comments made in the previous paragraphs of this section, e.g. (i) the values of σ_8 and H_0 remain close to those found in the ΛCDM model. In other words, the tensions are not significantly alleviated in this class of scaling early dark energy models; (ii) phantom values of $w < -1$ allow us to decrease the H_0 tension very slightly; and (iii) larger values of w lead to lower values of σ_8 due to the presence of a larger fraction of dark energy at low redshifts. This is why we get $w \sim -1$ when we include the BAO+RSD data set.

The dedicated analysis presented in this section updated and generalized previous constraints on this class of early dark energy models, and motivated the study of

Table 2. The mean fit values and 68.3% confidence limits for the most important cosmological (main+derived) parameters, obtained under different data sets (with and without CMB lensing) for the binned $\rho_{de}(z)$ described in Sec. 2.2. See Fig. 4 for the constraints on $\Omega_{de}(z)$, and Sec. 4.2 for a thorough discussion on these results. Here we have employed the following notation: Base≡CMBpol+SNIa and BaseL≡CMBpolens+SNIa.

the next section, in which we will reconstruct the shape of $\Omega_{de}(z)$ without sticking to a restricted family of parametrizations.

4.2. *Results for tomographic dark energy*

Now we provide the results obtained in the tomographic model described in Sec. 2.2 in order to see whether more general shapes of $\Omega_{de}(z)$ can loosen the cosmological tensions. This is in fact suggested by previous analyses in the literature, see e.g.[38–43, 77]

Our results are presented in Table 2 and Fig. 4. They confirm that a significant (and non-constant) fraction of EDE in the RDE can alleviate the H_0 tension if it can be kept below $\sim 0.6\%$ at 2σ c.l. around the CMB decoupling time, i.e. at $z \sim 1000 - 2000$. For instance, from the analysis of the CMBpolens+SNIa and CMBpolens+SNIa+M+BAO data sets we obtain $H_0 = (68.25^{+1.27}_{-1.26})$ km/s/Mpc

and $H_0 = (70.21^{+0.80}_{-0.84})$ km/s/Mpc, respectively. They are 2.77σ and 1.95σ below the SH0ES measurement, and the central value is significantly lower when the SH0ES prior is not considered. The authors of[44] reported similar results in the context of the ultra-light axion model. Nevertheless, if we compare the values of M obtained from these data sets with $M_{\rm SH0ES}$ we still obtain a tension of 3.80σ and 3.07σ, respectively. This means that in terms of M, the tension is bigger than when it is formulated in terms of H_0, and the capability of EDE of alleviating the tension is much lower, at least in the EDE framework we are considering here.

We also see that the large fraction of $\Omega_{de}(z)$ required in the RDE to loosen the H_0 tension, which can be of about $\sim 4-5\%$ at 2σ c.l. according to some data sets that include the SH0ES prior on M but no LSS information, leads to higher values of ω_{cdm} and, to a lesser extent, also of n_s, which in turn exacerbates the σ_8/S_8 tension. The former is needed to reduce the early integrated Sachs-Wolfe effect introduced by the EDE. This is aligned with previous works that also consider EDE in the pre-recombination epoch, see e.g.[44–46,78,79] Table 2 shows that the tension decreases $\sim 1\sigma$ when it is analyzed through the LSS estimators σ_{12} and S_{12}.[67] Nevertheless, it does not disappear. Under the CMBpolens+SNIa+M data set the σ_8 tension is of 3.63σ, whereas for the σ_{12} parameter it is of 2.64σ, and a similar decrease is observed when other data combinations are employed in the fitting analysis.

When the SH0ES prior on M is taken into account in absence of LSS data, we get a $\sim 2\sigma$ evidence for the presence of a non-null EDE fraction during the RDE, similar to.[41] Nevertheless, the inclusion of the weak lensing data from KiDS+VIKING-450 and DES-Y1 (cf. Sec. 3) forces the EDE fraction in the RDE to be again compatible at 1σ with 0 in order to allow ω_{cdm} to take values closer to the ΛCDM ones and not to worsen the σ_8/S_8 tension. Notice that, as expected, the upper bound on the fraction of EDE in the MDE that we obtain in our binned analysis is larger than the one found with EDEp and its variants, even when the prior on S_8 is not included (see Table 1 and Fig. 4). Indeed, higher fractions of EDE in the MDE (see again Fig. 4) also allow to keep the amount of LSS more under control. With the CMBpolens+SNIa+M+BAO+WL we obtain $H_0 = (70.00^{+0.76}_{-0.73})$ km/s/Mpc and $M = -19.362 \pm 0.016$. They are in 2.13σ and 3.28σ tension with the SH0ES values, respectively. Again, the tension in M is larger than in H_0 by $\sim 1\sigma$. Regarding the LSS estimators, we obtain $S_8 = 0.824^{+0.012}_{-0.013}$ and $\sigma_{12} = 0.810^{+0.010}_{-0.011}$. The former is in 2.25σ tension with the KiDS+VIKING-450+DESY1 value, whereas the latter is compatible at 1σ with the value obtained in the ΛCDM. The tensions in H_0 and S_8 can be kept at $\sim 2\sigma$ c.l. under this concrete data set, as advocated in.[78]

The effect of the CMB lensing from *Planck* 2018 on the EDE fraction can be appreciated by direct comparison of the plots in the left and right columns of Fig. 4. When the CMB lensing is included, the upper bound on $\Omega_{de}(z)$ is reduced by $\sim 1\%$ for $z \gtrsim 5000$, by a $\sim 0.5\%$ for $3000 \lesssim z \lesssim 5000$ and by a smaller fraction at lower redshifts. Some differences are found, though, depending on the other data sets employed in the fitting analyses. The preferred matter densities decrease, although

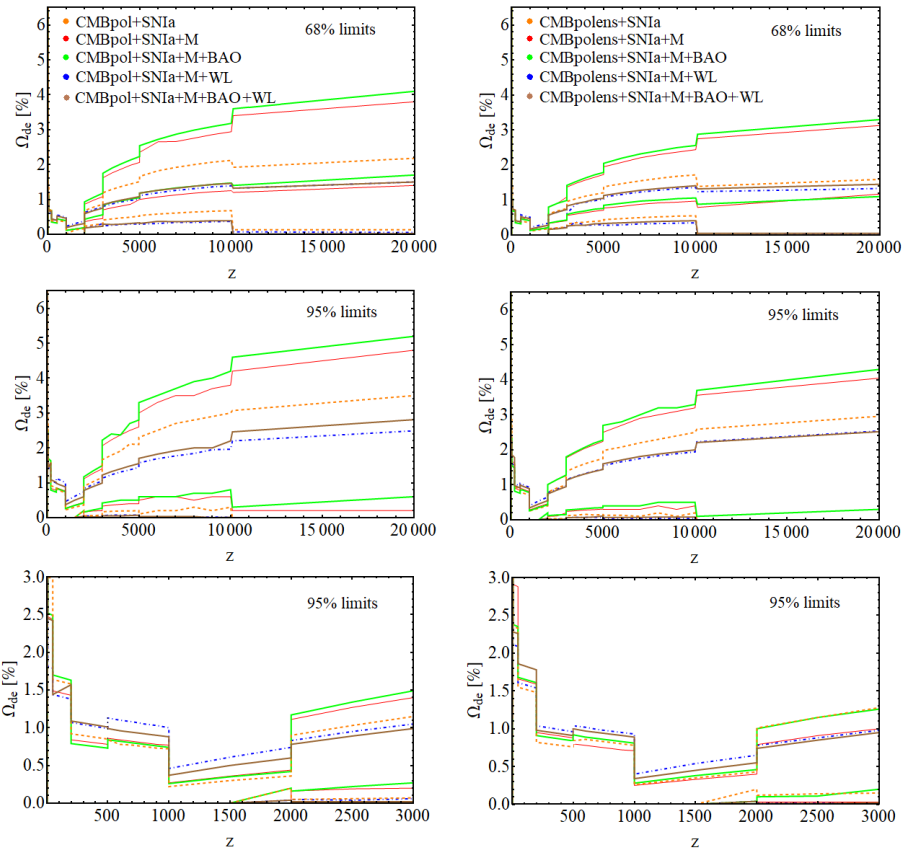

Fig. 4. *Left plots:* Reconstructed shapes of $\Omega_{de}(z)$ obtained from the fitting analyses without the Planck 2018 CMB lensing data (cf. Sec. 3). In the first and second rows we show the constraints in the region $z \in [0, 2 \cdot 10^4]$ at 1σ and 2σ c.l., respectively. In the last row we zoom in the redshift range $z \in [0, 3000]$ to better appreciate the details in the MDE. The tightest upper bound on $\Omega_{de}(z)$ is obtained around the CMB decoupling time, i.e. at $z \sim 1000 - 2000$, where the data force $\Omega_{de}(z) \lesssim 0.6\%$ at 2σ c.l.; *Right plots:* The same, but including the CMB lensing data. See the comments in Sec. 4.2.

they are still compatible at 1σ with the ones inferred without including the CMB lensing. This leads also to a slight decrease on the LSS estimators when the weak lensing prior is not considered. When the latter is included, the values of σ_{12} and S_{12} (and also σ_8 and S_8) remain stable under the addition of the CMB lensing likelihood.

We would like to remark the very low upper bounds that we obtain for the EDE fraction in the redshift range $z \in (1000, 2000)$, cf. Fig. 4. The exact value for these upper bounds depend on the specific data set, e.g. the constraints are a little bit weaker when the WL prior is used in the fitting analysis, but the EDE fraction when $\hat{c}_s = 1$ is, in any case, very strongly constrained in that epoch and lies always below $\sim 0.6\%$ regardless of the data set under consideration. Under the full data set, the

EDE fractions are constrained to be below 2.6% in the RDE and $\lesssim 1-1.5\%$ in the redshift range $z \in (100, 1000)$ at 2σ c.l. This limits strongly the possible impact of EDE on the value of the Hubble parameter or the present amount of structure.

5. Conclusions

In this work we have studied the phenomenological performance of a family of flexible parametrizations for the dark energy density that are able to mimic the scaling behavior that is encountered in a wide variety of quintessence models. DE has been treated as a perfect fluid with two plateaus in $\Omega_{de}(z)$, one in the matter-dominated epoch and another one in the radiation-dominated era. We have put very tight constraints on the fraction of EDE in the radiation- and matter-dominated epochs in the context of these models. The CMBpol+SNIa data set already forces these two quantities to lie below 2.44% and 0.52% at 2σ c.l., respectively. These strong constraints are necessary to respect the upper bound on the amount of EDE at the last scattering surface, as we have explicitly checked in our tomographic analysis. We have found that this class of scaling EDE models does not lead to a significant alleviation of the H_0 and σ_8 tensions. Larger EDE fractions are allowed by the data if: (i) the sound speed for DE is fixed at values $\hat{c}_s^2 \ll 1$, since in this limit dark energy behaves as dark matter during the matter-dominated epoch at the background and perturbations levels and, hence, there is a huge degeneracy between these two components. If we would assume a vanishing sound speed for dark energy there would be no way to distinguish it from dark matter. We find indeed no bounds on the dark energy fraction in this case. This changes drastically already for a rather small sound speed of EDE of the order 10^{-4}; and (ii) if EDE is switched on at later times, already in the matter-dominated era. Nevertheless, the cosmological tensions remain also in these cases.

EDE can only have a larger impact on the cosmological tensions if $\Omega_{de}(z)$ takes more flexible shapes that allow to respect the very strict constraints found around the CMB decoupling time ($\Omega_{de}(z_{dec}) \lesssim 0.4\%$ at 2σ c.l.), while still leading to a significant EDE fraction in other epochs of the cosmic expansion. The strong bound on EDE for redshift $200 < z < 1000$ ($\Omega_{de}(z) \lesssim 1\%$ at 2σ c.l.) is rather impressive since it is entirely based on the different clustering properties of dark energy and dark matter.

In general, when the SH0ES prior is not included in the fitting analysis there is no significant shift in the value of the Hubble parameter when compared to the ΛCDM, although the uncertainties clearly grow by a factor $2-3$. This allows to decrease the H_0 tension to the 2.66σ c.l. under the minimal CMBpol+SNIa data set. The addition of the CMB lensing has a very mild effect, increasing the tension up to the 2.73σ level.

When the BAO data and the SH0ES prior are also considered, the H_0 tension is reduced to the $\sim 2\sigma$ level by increasing the EDE fraction at the radiation-dominated epoch. A 2σ preference for a non-null EDE density in that epoch is obtained,

$\Omega_{de}(z) \lesssim 4\%$ at 95% c.l. Our reconstructed $\Omega_{de}(z)$ allows for non-peaked shapes, in contrast to what one finds e.g. in models based on ultra-light axions.[41,80] The model needs, though, values of the current dark matter density much larger than the ones typically encountered in the concordance model. This is to lower the early integrated Sachs-Wolfe effect down, which is enhanced by the presence of EDE in the pre-recombination epoch. This automatically leads to an increase of σ_8 and S_8 that worsens the LSS tension, which lies now at the $3 - 3.5\sigma$ c.l. In terms of σ_{12}, the tension is somewhat lower, but still remains at the $\sim 2.7\sigma$ level, as when the M prior is not used in the analysis. It is also to be noted that the H_0 tension still stays at the 3σ level when formulated in terms of the absolute magnitude of SNIa M.

Finally, when we use the most complete data set, taking also the weak lensing data into account, we find that the model can keep the H_0 and S_8 tensions at the $\sim 2\sigma$ c.l., thanks also to a slight increase of the EDE fraction in the matter-dominated epoch, although, again, the M tension remains at $\gtrsim 3\sigma$.

In view of our results, it seems unlikely that EDE alone can provide a satisfactory resolution of the cosmological tensions. Whether the latter have or not a physical origin, or whether their statistical significance is as high as claimed by some sectors of the cosmological community, is still a matter of discussion and is certainly not a closed subject. Here we conclude that, in any case, if the data sets employed in this study do not suffer from any important systematic errors, uncoupled EDE is not able to relieve completely the tensions. Under our full data set CMBpolens+SNIa+M+BAO+WL they remain at $2 - 3\sigma$ c.l.

Nothing prevents, though, the solution to the cosmological tensions to be multi-sided, rather than due to a single new physics component. EDE could still play a significant role in this story. Some interesting directions to explore in the future are: (i) a possible coupling of EDE to dark matter, (ii) the impact of more complicated behavior of the EDE sound speed, parameterizing its time dependence, or performing a tomographic analysis similar to the one we have carried out in this work for the EDE density; and (iii) the potential degeneracy between EDE and other cosmological parameters, as the neutrino masses, which could in principle help to soften the S_8 tension while keeping the needed amount of non-relativistic matter at the CMB decoupling time. The latter would be needed, together with a higher EDE fraction in the radiation-dominated epoch, in order to increase the value of the Hubble parameter. We leave these investigations for a future work.

Acknowledgments

The author is very grateful to Prof. Joan Solà Peracaula for his kind invitation to give this talk and co-chair the CM3 session with him. He was funded by the Deutsche Forschungsgemeinschaft (DFG) - Project number 415335479 - during the time at which the MG16 meeting was held and the research of this project carried out.

The cosmological constant (CC) term, Λ, in Einstein's equations has been for about three decades a fundamental building block of the concordance or standard ΛCDM model of cosmology. Although the latter is not free of fundamental problems, it provides a good phenomenological description of the overall cosmological observations. However, an interesting improvement in such a phenomenological description and also a change in the theoretical status of the Λ-term occurs upon realizing that the vacuum energy is actually a "running quantity" in quantum field theory in curved spacetime. Several works have shown that this option can compete with the ΛCDM with a rigid Λ term. The so-called, "running vacuum models" (RVM) are characterized indeed by a vacuum energy density, $\rho_{\rm vac}$, which is evolving with time as a series of even powers of the Hubble parameter and its time derivatives. This form has been motivated by semi-qualitative renormalization group arguments in previous works. Here we review a recent detailed computation by the authors of the renormalized energy-momentum tensor of a non-minimally coupled scalar field with the help of adiabatic regularization procedure. The final result is noteworthy: $\rho_{\rm vac}(H)$ takes the precise structure of the RVM, namely a constant term plus a dynamical component $\sim H^2$ (which should be detectable in the present universe) including also higher order effects $\mathcal{O}(H^4)$ which can be of interest during the early stages of the cosmological evolution. Besides, it is most remarkable that such renormalized form of the vacuum energy density does not carry dangerous terms proportional to m^4, the quartic powers of the masses of the fields, which are a well-known source of exceedingly large contributions to the vacuum energy density and are directly responsible for extreme fine tuning in the context of the cosmological constant problem.

Keywords: Cosmology, Dark Energy, Quantum Field Theory.

1. Introduction

Since the mid nineties, the cosmological constant (CC) term, Λ, in Einstein's equations has been a crucial ingredient of the 'concordance' or standard ΛCDM model of cosmology.[1] From the phenomenological point of view it was favored only as of the time Λ became a physically measured quantity some twenty years ago.[2] Nowadays, precision cosmology[3] is able to do better measurements of Λ, or more precisely of the associated parameter $\Omega^0_{\rm vac} = \rho^0_{\rm vac}/\rho^0_c$, established by observations to be $\Omega^0_{\rm vac} \sim 0.7$. Here, the vacuum energy density (VED) is associated to Λ and defined as $\rho^0_{\rm vac} = \Lambda/(8\pi G_N)$, where G_N is Newton's constant and $\rho^0_c = 3H_0^2/(8\pi G_N)$ is the critical density in our times. However, there is a lot of uncertainty with the CC with respect its nature and origin at a fundamental level. For instance it is commonly

*Speaker

assumed that Λ may be related with the Zero-Point Energy (ZPE) of the quantum matter fields and with the Higgs potential of the Standard Model (SM). However, if ones compares the observational value $\rho_{\rm vac}$ with the ZPE of a typical SM particle such as the electron we are left with a tiny value of $\rho_{\rm vac}^{\rm obs}/\rho_{\rm ZPE} \sim 10^{-34}$. If compared with the ground state energy of the effective Higgs potential, $V_{\rm eff}$, we find $\rho_{\rm vac}^{\rm obs}/\langle V_{\rm eff}\rangle \sim 10^{-56}$. This issue is generically called the cosmological constant problem[4,5] and affects all forms of dark energy (DE).[6–10] Another aspect of this intriguing topic is the fact that, at the present time, $\rho_{\rm vac}^{\rm obs}$ and $\rho_{\rm CDM}$, the energy density associated to Cold Dark Matter (CDM), are observed to be of the same order of magnitude, despite the fact that $\rho_{\rm CDM}$ is assumed to decrease with the expansion as a^{-3}, being a the scale factor, whereas $\rho_{\rm vac}$ maintains constant.

The astonishing theoretical problems, though, are not the only ones concerning the concordance model. Currently, some important measurements seems to be in tension with the ΛCDM, emphasizing the discrepant values of the Hubble parameter at the present time, H_0, obtained from independent measurements of the early and the local universe.[11] It is still unknown if these tensions are the result of systematic errors, but the chance that a deviation from the ΛCDM model could provide an explanation for such discrepancies[12] is totally open.

As it has been shown in the literature, models mimicking a time-evolving $\rho_{\rm vac}$, which are allowed by the cosmological principle, could help in alleviating the mentioned problems, see e.g.[13–18] and.[19–25] In this work, we review recent work[26] on the possibility of having dynamical vacuum energy density (VED), $\rho_{\rm vac}$, in the context of quantum field theory (QFT) in curved spacetime with a spatially flat Friedmann-Lemaître-Robertson-Walker (FLRW) metric. We want to focus on the dynamics associated to the running vacuum model (RVM);[27–29] for a review, see[30–32] and references therein. Related studies are e.g.[33,34] and,[35,36] but also others extending the subject to the context of supersymmetric theories[37,38] and to supergravity.[39] Recently, some works in the framework of the effective action of string theories[40–45] have been dealed with the topic.

In the calculations reviewed here, the renormalization of the energy-momentum tensor is done using the adiabatic regularization procedure (ARP).[46–49] The renormalization process is a WKB approximation of the field modes in an expanding FLRW background. Once the VED is renormalized, obtained upon inclusion of the renormalized value of ρ_Λ (associated to Λ) at a given scale, it does not include the dangerous contributions depending on the fourth power of the particle masses ($\sim m^4$) and therefore it is free from huge induced corrections to the VED.[26] Additionally, we find a RVM-like form for the VED in the current times, $c_0 + \nu H^2$, with c_0 related to the usual constant term and $|\nu| \ll 1$. This last parameter represents only a small (dynamical) correction to the constant term and, depending on the sign of ν, it can mimic quintessence or phantom DE.

First, in Sec. 2 our framework is defined, consisting of a real scalar field non-minimally coupled to gravity, and we present the classical energy-momentum tensor (EMT). Later on, in Sections 3 and 4, we present the quantum fluctuations in the

adiabatic vacuum by means of a WKB expansion of the field modes in the FLRW background and we discuss the adiabatic regularization of the EMT. In Sec. 5 we start with the renormalization of the EMT in the FLRW context through the ARP, which is then needed in Sec. 6 to derive the precise result of $\rho_{\rm vac}$ from the renormalized ZPE up to terms of adiabatic order 4. In our case that means up to $\mathcal{O}(H^4)$. We also demonstrate that the values of the VED at different scales are related by an expression which does not contain quartic powers of the masses. To continue, in Sec. 7, we connect the computed VED in this work with the well-known running vacuum model (RVM), which originally was justified from renormalization group arguments in curved spacetime in previous works. A summary of the conclusions and discussion appear in Sec. 8. At the end, we define our conventions and collect some useful formulas in Appendix.

2. Energy-Momentum Tensor for non-minimally coupled scalar field

Einstein's equations read[a]

$$R_{\mu\nu} - \frac{1}{2}Rg_{\mu\nu} + \Lambda g_{\mu\nu} = 8\pi G_N T_{\mu\nu}^{\rm matter}\,, \tag{1}$$

where $T_{\mu\nu}^{\rm matter}$ is the EMT of matter. They can also be written as

$$\frac{1}{8\pi G_N}G_{\mu\nu} + \rho_\Lambda g_{\mu\nu} = T_{\mu\nu}^{\rm matter}\,, \tag{2}$$

where $G_{\mu\nu} \equiv R_{\mu\nu} - \frac{1}{2}Rg_{\mu\nu}$ and $\rho_\Lambda \equiv \Lambda/(8\pi G_N)$ is the VED associated to Λ. The associated contribution of Λ to $T_{\mu\nu}^{\Lambda} \equiv -\rho_\Lambda g_{\mu\nu}$. But, in general, there are more contributions to the total VED, associated to the quantum fluctuations of the fields, and also to their classical ground state energy. In this work, for practical reasons, we will assume that there is only one (matter) field in the form of a real scalar field, ϕ, and we will denote by $T_{\mu\nu}^{\phi}$ the piece of the EMT associated to it. Thus $T_{\mu\nu}^{\rm tot} = T_{\mu\nu}^{\Lambda} + T_{\mu\nu}^{\phi}$. We neglect other incoherent matter contributions such as dust and radiation because they can be added without altering the QFT considerations developed here.

A non-minimal coupling between the scalar field and gravity is assumed, without any classical potential for ϕ . The part of the action associated to ϕ is

$$S[\phi] = -\int d^4x\sqrt{-g}\left(\frac{1}{2}g^{\mu\nu}\partial_\nu\phi\partial_\mu\phi + \frac{1}{2}(m^2+\xi R)\phi^2\right)\,, \tag{3}$$

where ξ is the non-minimal coupling between ϕ and gravity. In the special case $\xi = 1/6$, the massless ($m = 0$) action has conformal symmetry, i.e. symmetric under simultaneous rescalings of the $g_{\mu\nu}$ and ϕ with a local function $\alpha(x)$: $g_{\mu\nu} \to e^{2\alpha(x)}g_{\mu\nu}$ and $\phi \to e^{-\alpha(x)}\phi$. However, we will keep ξ general as it enables a richer phenomenology.

[a]Some useful geometrical quantities can be seen in the Appendix.

The Klein-Gordon (KG) equation is satisfied by the field ϕ,

$$(\Box - m^2 - \xi R)\phi = 0. \tag{4}$$

Here $\Box\phi = g^{\mu\nu}\nabla_\mu\nabla_\nu\phi = (-g)^{-1/2}\partial_\mu\left(\sqrt{-g}\, g^{\mu\nu}\partial_\nu\phi\right)$. On the other hand, the EMT takes this form :

$$T_{\mu\nu}(\phi) = -\frac{2}{\sqrt{-g}}\frac{\delta S_\phi}{\delta g^{\mu\nu}} = (1-2\xi)\partial_\mu\phi\partial_\nu\phi + \left(2\xi - \frac{1}{2}\right) g_{\mu\nu}\partial^\sigma\phi\partial_\sigma\phi$$
$$- 2\xi\phi\nabla_\mu\nabla_\nu\phi + 2\xi g_{\mu\nu}\phi\Box\phi + \xi G_{\mu\nu}\phi^2 - \frac{1}{2}m^2 g_{\mu\nu}\phi^2. \tag{5}$$

In this work we consider a spatially flat FLRW metric in the conformal frame. Being η the conformal time we have $ds^2 = a^2(\eta)\eta_{\mu\nu}dx^\mu dx^\nu$, with $\eta_{\mu\nu} = \mathrm{diag}(-1,+1,+1,+1)$ the Minkowski metric. Differentiation with respect the conformal time is denoted by $()' \equiv d\,()\,/d\eta$. It is convinient to define $\mathcal{H}(\eta) \equiv a'/a$ and, since $dt = ad\eta$, it is related with the usual Hubble rate $H(t) = \dot{a}/a$ as $\mathcal{H}(\eta) = aH(t)$. Despite the fact we will do intermediate calculations in conformal time, at the end it will be useful to express the VED in terms of the usual Hubble rate $H(t)$, because it is the easiest way to compare with other RVM results in the literature.

3. Quantum fluctuations and WKB ansatz

Now, we can take into account the quantum fluctuations of the field ϕ as an expansion around the background field (or classical mean field), ϕ_b:

$$\phi(\eta, x) = \phi_b(\eta) + \delta\phi(\eta, x). \tag{6}$$

The vacuum expectation value (VEV) of the field is $\langle 0|\phi(\eta,x)|0\rangle = \phi_b(\eta)$, whereas we assume that the VEV of the fluctuations vanishes: $\langle 0|\delta\phi|0\rangle = 0$. The vacuum state to which we are referring to is the so-called adiabatic vacuum, we will make some comments about this below.

The corresponding EMT decomposes itself as $\langle T^\phi_{\mu\nu}\rangle = \langle T^{\phi_b}_{\mu\nu}\rangle + \langle T^{\delta_\phi}_{\mu\nu}\rangle$, where $\langle T^{\phi_b}_{\mu\nu}\rangle = T^{\phi_b}_{\mu\nu}$ is the contribution from the background part and $\langle T^{\delta\phi}_{\mu\nu}\rangle$ is related with the quantum fluctuations. In particular, the $\langle T^{\delta\phi}_{00}\rangle$ is associated to the ZPE density of the scalar field in the FLRW background. Thus, the total vacuum contribution to the EMT reads

$$\langle T^{\rm vac}_{\mu\nu}\rangle = T^\Lambda_{\mu\nu} + \langle T^{\delta\phi}_{\mu\nu}\rangle = -\rho_\Lambda g_{\mu\nu} + \langle T^{\delta\phi}_{\mu\nu}\rangle\,. \tag{7}$$

This means that the total vacuum EMT receives contributions from the cosmological constant term and from the quantum fluctuations. A renormalized version of this equation will lead us to a renormalized VED, as we will see later.

The KG equation (4) is satisfied independently by the classical field and the quantum part (6). Let us concentrate on the fluctuation $\delta\phi$. Its Fourier decomposition in frequency modes $h_k(\eta)$ is

$$\delta\phi(\eta,\mathbf{x}) = \frac{1}{(2\pi)^{3/2}a}\int d^3k\left[A_{\mathbf{k}}e^{i\mathbf{k}\cdot\mathbf{x}}h_k(\eta) + A^\dagger_{\mathbf{k}}e^{-i\mathbf{k}\cdot\mathbf{x}}h^*_k(\eta)\right]. \tag{8}$$

$A_{\mathbf{k}}$ and $A^{\dagger}_{\mathbf{k}}$ are the (time-independent) annihilation and creation operators, with commutation relations

$$[A_{\mathbf{k}}, {A_{\mathbf{k}'}}^{\dagger}] = \delta(\mathbf{k}-\mathbf{k}'), \qquad [A_{\mathbf{k}}, A_{\mathbf{k}'}] = 0. \tag{9}$$

Introducing the Fourier expansion (8) in $\left(\Box - m^2 - \xi R\right)\delta\phi = 0$ we find that the frequency modes of the fluctuations satisfy

$$h_k'' + \Omega_k^2 h_k = 0\,, \qquad \Omega_k^2(\eta) \equiv \omega_k^2(m) + a^2\,(\xi - 1/6)R\,, \tag{10}$$

with $\omega_k^2(m) \equiv k^2 + a^2 m^2$. As we can see, h_k depends uniquely on the modulus $k \equiv |\mathbf{k}|$ of the momentum. Since $\Omega_k(\eta)$ is a nontrivial function of the conformal time, there is no closed form of the solution of (10). Instead of looking to an analytical solution, we will generate an approximate solution from a recursive method based on the phase integral ansatz

$$h_k(\eta) \sim \frac{1}{\sqrt{W_k(\eta)}} \exp\left(i\int^{\eta} W_k(\tilde{\eta})d\tilde{\eta}\right). \tag{11}$$

Therefore, the function $W_k(\eta)$ satisfies the following differential equation:

$$W_k^2 = \Omega_k^2 - \frac{1}{2}\frac{W_k''}{W_k} + \frac{3}{4}\left(\frac{W_k'}{W_k}\right)^2. \tag{12}$$

This non-linear differential equation can be solved using the WKB approximation. The solution is valid for large k (i.e. for short wave lengths) and the function Ω_k is slowly varying for weak fields. The notion of vacuum we work with it is called the adiabatic vacuum,[50–52] and can be defined as the quantum state annihilated by all the operators A_k of the Fourier expansion of the scalar field, see[46–49] for details. The physical interpretation of the modes (10) with frequencies dependending on time, must be understood in terms of field observables rather than in particle language. Therefore, for a more physical interpretation of the vacuum effects of the expanding background, we must compute the renormalized EMT in the FLRW spacetime, but first we need to regularize it.

4. Adiabatic regularization of the EMT

The adiabatic (slowly varying) Ω_k, is susceptible to be computed using Eq. (12) to generate an (asymptotic) series solution. In this context, the series is obtained through the adiabatic regularization procedure (ARP)[b] and it is organized in what we call adiabatic orders. First, the quantites considered of adiabatic order 0 are: k^2 and a. Of adiabatic order 1 are: a' and $\mathcal{H}$. Then $a'', a'^2, \mathcal{H}'$ and $\mathcal{H}^2$ are quantities

[b]This method was introduced for minimally coupled massive scalar fields in.[51,52] In,[50] it is generalized for other couplings. A review can be found in the classic books.[46,47] The ARP has been used in the context of QFT in curved backgrounds[35,36] and also it has been extended to other fields, such as the spin one-half fields in.[53,54]

of adiabatic order 2. We can sum up by saying that each extra derivative in conformal time increases the adiabatic order one unit. As a consequence, the "effective frequency" W_k can be written as an asymptotic expansion:

$$W_k = \omega_k^{(0)} + \omega_k^{(2)} + \omega_k^{(4)} + \dots, \tag{13}$$

where each $\omega_k^{(j)}$ is an adiabatic correction of order j. This leads to an expansion of the mode function h_k in even order adiabatic terms. This is justified by arguments of general covariance, since only terms of even adiabatic order (an even number of time derivatives) are allowed in the field equations.

4.1. *Introducing the renormalization parameter*

We start by defining the $0th$ order terms

$$\omega_k^{(0)} \equiv \omega_k = \sqrt{k^2 + a^2 M^2}. \tag{14}$$

In this approach the WKB expansion is performed off-shell, at an arbitrary mass scale M replacing the scalar field mass m in (14). In consequence, ARP can be formulated in such a way that we can relate the adiabatically renormalized theory at two different scales.[36] If $M = m$ we obtain the renormalized theory on-shell. In the computation of the EMT, the parameter $\Delta^2 \equiv m^2 - M^2$ will appear in the correction terms and it has to be considered of adiabatic order 2 since it appears in the WKB expansion together with other terms of the same adiabatic order.[36] If $\Delta = 0$, then $M = m$ and corresponds to the usual on-shell ARP, see.[46,47] With the help of this formalism one can explore the evolution of the VED throughout the cosmological history as it has been done for the first time in.[26] As we shall see, it will be convenient to consider m to be of the order of magnitude as the masses of Grand Unified Theory (GUT) fields in order to explore the dynamics of the VED in the low energy domain $M^2 \ll m^2$ (corresponding to the late universe). For simplicity, we model here all particles in terms of real scalar fields as in.[26] For a generalization to fermion fields, see.[55]

4.2. *Regularized ZPE*

Our starting point is the initial solution $W_k \approx \omega_k^{(0)}$ indicated in Eq. (14). For $a = 1$, it corresponds to the standard Minkowski space modes. Since $a = a(\eta)$ we have to find a better approximation. We use the initial solution $\omega_k^{(0)}$ in (12) and expand the RHS in powers of ω_k^{-1}, then collect the new terms up to adiabatic order 2 to find $\omega_k^{(2)}$. Now, we repeat the process with $W_k \approx \omega_k^{(0)} + \omega_k^{(2)}$ on the RHS of the same equation, expand again in ω_k^{-1}, collect contributions of adiabatic order 4... After some steps, the expansion seems to be organized in powers of $\omega_k^{-1} \sim 1/k$ (i.e. a short wavelength expansion). The UV divergent terms of the ARP are precisely the first lowest powers of ω_k^{-1}, which are present in the first adiabatic orders of the expansion. Higher adiabatic orders come later in the iteration, and represent finite

contributions[50–52] since they decay quickly at large k and the associated integrals are manifestly convergent. In our case, the divergent terms of the EMT are present up to $4th$ adiabatic order so that, at least, we have to compute all the terms up to this order (more detail below in Eq. (16)). After renormalization, we will obtain a finite expression for the EMT and then compute the vacuum energy density. But first, we need to consider the EMT associated to the fluctuations, using Eq. (5) and (6). For the 00-component,

$$\langle T_{00}^{\delta\phi}\rangle = \Big\langle \frac{1}{2}\left(\delta\phi'\right)^2 + \left(\frac{1}{2}-2\xi\right)\sum_i \partial_i\delta\phi\partial_i\delta\phi + 6\xi\mathcal{H}\delta\phi\delta\phi' - 2\xi\delta\phi\nabla^2\delta\phi + 3\xi\mathcal{H}^2\delta\phi^2 + \frac{a^2m^2}{2}\left(\delta\phi\right)^2\Big\rangle, \tag{15}$$

where $\nabla^2 \equiv \sum_{i=1}^3 \partial_i^2$ and $\left(\delta\phi'\right)^2 \equiv \left(\delta\partial_0\phi\right)^2 = \left(\partial_0\delta\phi\right)^2$. We may now substitute the Fourier expansion of $\delta\phi$, as given in (8), into Eq. (15) and apply the commutation relations (9). After symmetrizing the operator field product $\delta\phi\delta\phi'$ with respect to the annihilation and creation operators, we end up with

$$\begin{aligned}\langle T_{00}^{\delta\phi}\rangle = \frac{1}{8\pi^2a^2}\int dkk^2\Bigg[&2\omega_k + \frac{a^4M^4\mathcal{H}^2}{4\omega_k^5} - \frac{a^4M^4}{16\omega_k^7}(2\mathcal{H}''\mathcal{H} - \mathcal{H}'^2 + 8\mathcal{H}'\mathcal{H}^2 + 4\mathcal{H}^4)\\ &+ \frac{7a^6M^6}{8\omega_k^9}(\mathcal{H}'\mathcal{H}^2 + 2\mathcal{H}^4) - \frac{105a^8M^8\mathcal{H}^4}{64\omega_k^{11}}\\ &+ \bar{\xi}\left(-\frac{6\mathcal{H}^2}{\omega_k} - \frac{6a^2M^2\mathcal{H}^2}{\omega_k^3} + \frac{a^2M^2}{2\omega_k^5}(6\mathcal{H}''\mathcal{H} - 3\mathcal{H}'^2 + 12\mathcal{H}'\mathcal{H}^2)\right.\\ &\left.- \frac{a^4M^4}{8\omega_k^7}(120\mathcal{H}'\mathcal{H}^2 + 210\mathcal{H}^4) + \frac{105a^6M^6\mathcal{H}^4}{4\omega_k^9}\right)\\ &+ \bar{\xi}^2\left(-\frac{1}{4\omega_k^3}(72\mathcal{H}''\mathcal{H} - 36\mathcal{H}'^2 - 108\mathcal{H}^4) + \frac{54a^2M^2}{\omega_k^5}(\mathcal{H}'\mathcal{H}^2 + \mathcal{H}^4)\right)\Bigg]\\ &+ \frac{1}{8\pi^2a^2}\int dkk^2\Bigg[\frac{a^2\Delta^2}{\omega_k} - \frac{a^4\Delta^4}{4\omega_k^3} + \frac{a^4\mathcal{H}^2M^2\Delta^2}{2\omega_k^5} - \frac{5}{8}\frac{a^6\mathcal{H}^2M^4\Delta^2}{\omega_k^7}\\ &+ \bar{\xi}\left(-\frac{3a^2\Delta^2\mathcal{H}^2}{\omega_k^3} + \frac{9a^4M^2\Delta^2\mathcal{H}^2}{\omega_k^5}\right)\Bigg] + \ldots,\end{aligned} \tag{16}$$

where we have defined $\bar{\xi} \equiv \xi - 1/6$ and we have integrated $\int \frac{d^3k}{(2\pi)^3}(...)$ over solid angles and expressed the final integration in terms of $k = |\mathbf{k}|$. Let us note the presence of the Δ-dependent terms in the last two rows, which contribute at $2th$ (Δ^2) and $4th$ (Δ^4) adiabatic order.

5. Renormalization of the ZPE in curved spacetime

The ZPE part of the EMT, as given by Eq. (16) can be split into two parts as follows:

$$\langle T_{00}^{\delta\phi}\rangle(M) = \langle T_{00}^{\delta\phi}\rangle_{Div}(M) + \langle T_{00}^{\delta\phi}\rangle_{Non-Div}(M), \tag{17}$$

where

$$\langle T_{00}^{\delta\phi}\rangle_{Div}(M) = \frac{1}{8\pi^2 a^2}\int dk k^2 \Bigg[2\omega_k + \frac{a^2\Delta^2}{\omega_k} - \frac{a^4\Delta^4}{4\omega_k^3} - 6\bar{\xi}\mathcal{H}^2\left(\frac{1}{\omega_k} + \frac{a^2M^2}{\omega_k^3} + \frac{a^2\Delta^2}{2\omega_k^3}\right) - 9\frac{\bar{\xi}^2}{\omega_k^3}(2\mathcal{H}''\mathcal{H} - \mathcal{H}'^2 - 3\mathcal{H}^4)\Bigg], \tag{18}$$

which containts the powers $1/\omega_k^n$ up to $n = 3$, manifestly UV-divergent.

On the other hand, the non-divergent part of (17) involves the integrals with powers of $1/\omega_k$ higher than 3 which are perfectly finite. Computing these convergent integrals (see Eq. (45) in Appendix), the result reads

$$\langle T_{00}^{\delta\phi}\rangle_{Non-Div}(M) = \frac{m^2\mathcal{H}^2}{96\pi^2} - \frac{1}{960\pi^2 a^2}\left(2\mathcal{H}''\mathcal{H} - \mathcal{H}'^2 - 2\mathcal{H}^4\right) + \bar{\xi}\frac{3\Delta^2\mathcal{H}^2}{8\pi^2} + \frac{1}{16\pi^2 a^2}\bar{\xi}\left(2\mathcal{H}''\mathcal{H} - \mathcal{H}'^2 - 3\mathcal{H}^4\right) + \frac{9}{4\pi^2 a^2}\bar{\xi}^2(\mathcal{H}'\mathcal{H}^2 + \mathcal{H}^4) + \ldots \tag{19}$$

where the dots in the last expression correspond to higher adiabatic orders. Let us now focus on the divergent part of the ZPE, Eq. (18). The adiabatic series is an asymptotic series representation of Eq. (15). Thefore, such series is not convergent but it provides an approximation, which is obtained once the series is cut at a particular order.[36] As a consequence there is some arbitrariness in the way of choosing the leading adiabatic order, which we can use in our favour. There is, nonetheless, some previous steps to do before obtaining a meaningful result. First, we are going to set the arbitrary scale at the mass of the scalar field. That is, $M = m$ and hence $\Delta = 0$ (cf. Sec. 4.1). The divergent part (18) is reduced in this case to

$$\langle T_{00}^{\delta\phi}\rangle_{Div}(m) = \frac{1}{8\pi^2 a^2}\int dk k^2 \Bigg[2\omega_k(m) - \bar{\xi}6\mathcal{H}^2\left(\frac{1}{\omega_k(m)} + \frac{a^2m^2}{\omega_k^3(m)}\right) - \bar{\xi}^2\frac{9}{\omega_k^3(m)}(2\mathcal{H}''\mathcal{H} - \mathcal{H}'^2 - 3\mathcal{H}^4)\Bigg]. \tag{20}$$

What we are going to do next, in order to renormalize the ZPE and the EMT, is to subtract the terms that appear up to $4th$ adiabatic order at the arbitrary mass scale M. This procedure is enough to cancel the divergent terms through the ARP, as it is discussed in the literature.[46–48]

5.1. *Renormalized ZPE for generic M*

As said before, our proposal for the renormalized ZPE in curved spacetime at the scale M is[26]:

$$\begin{aligned}\langle T_{00}^{\delta\phi}\rangle_{\rm Ren}(M) &= \langle T_{00}^{\delta\phi}\rangle(m) - \langle T_{00}^{\delta\phi}\rangle^{(0-4)}(M)\\ &= \langle T_{00}^{\delta\phi}\rangle_{Div}(m) - \langle T_{00}^{\delta\phi}\rangle_{Div}(M) - \bar{\xi}\frac{3\Delta^2\mathcal{H}^2}{8\pi^2} + \ldots,\end{aligned} \tag{21}$$

here $(0-4)$ means that the expansion is up to fourth adiabatic order and the dots in (21) denote perfectly finite terms of higher adiabatic order. Using now Eq. (20), we arrive to

$$\langle T_{00}^{\delta\phi}\rangle_{\rm Ren}(M) = \frac{1}{8\pi^2 a^2}\int dk k^2\left[2\omega_k(m) - \frac{a^2\Delta^2}{\omega_k(M)} + \frac{a^4\Delta^4}{4\omega_k^3(M)} - 2\omega_k(M)\right]$$
$$+\bar{\xi}\frac{6\mathcal{H}^2}{8\pi^2 a^2}\left\{\int dk k^2\left[\frac{1}{\omega_k(M)} + \frac{a^2M^2}{\omega_k^3(M)} + \frac{a^2\Delta^2}{2\omega_k^3(M)} - \frac{1}{\omega_k(m)} - \frac{a^2m^2}{\omega_k^3(m)}\right] - \frac{a^2\Delta^2}{2}\right\}$$
$$-\bar{\xi}^2\frac{9\left(2\mathcal{H}''\mathcal{H} - \mathcal{H}'^2 - 3\mathcal{H}^4\right)}{8\pi^2 a^2}\int dk k^2\left[\frac{1}{\omega_k^3(m)} - \frac{1}{\omega_k^3(M)}\right] + \ldots \tag{22}$$

In this equation we have introduced new notation in order to distinguish between the off-shell energy mode $\omega_k(M) \equiv \sqrt{k^2 + a^2M^2}$ (formerly denoted just as ω_k) and the on-shell one $\omega_k(m) \equiv \sqrt{k^2 + a^2m^2}$. The involved computations of these convergent integrals are not so straightforward but, after some algebra and the help of Mathematica,[56] we find

$$\langle T_{00}^{\delta\phi}\rangle_{\rm Ren}(M) = \frac{a^2}{128\pi^2}\left(-M^4 + 4m^2M^2 - 3m^4 + 2m^4\ln\frac{m^2}{M^2}\right)$$
$$-\bar{\xi}\frac{3\mathcal{H}^2}{16\pi^2}\left(m^2 - M^2 - m^2\ln\frac{m^2}{M^2}\right) + \bar{\xi}^2\frac{9\left(2\mathcal{H}''\mathcal{H} - \mathcal{H}'^2 - 3\mathcal{H}^4\right)}{16\pi^2 a^2}\ln\frac{m^2}{M^2} + \ldots \tag{23}$$

The obtained expression vanishes for $M = m$ as expected from Eq. (21). However, let us remind the reader that this only happens because we have computed the on-shell value $\langle T_{\mu\nu}^{\delta\phi}\rangle_{\rm Ren}(m)$ up to adiabatic order 4 in Eq. (23). Nevertheless, $\langle T_{\mu\nu}^{\delta\phi}\rangle_{\rm Ren}(m)$ can be computed up to an arbitrary, but finite, adiabatic order. Beyond $4th$ order one always obtains subleading and perfectly finite corrections. We expect that these effects become suppressed when the physical mass m of the quantum field is large, so that they satisfy the Appelquist-Carazzone decoupling theorem.[57]

So far, we have obtained a renormalized ZPE in curved spacetime (23) which, despite the fact it is finite, it includes the quartic powers of the masses corresponding to undesired contributions to the vacuum energy.

6. Renormalized vacuum energy density

The renormalization in the context of QFT in curved spacetime implies the consideration of the higher derivative (HD) terms in the classical effective action,[46] beyond the usual Einstein-Hilbert (EH) term with a cosmological constant, Λ. In particular, in the FLRW background in four dimensions, the only surviving HD term is $H_{\mu\nu}^{(1)}$, as suggested by the geometric structure of (23). $H_{\mu\nu}^{(1)}$ is obtained by functionally differentiating R^2 with respect the metric (see Appendix). So, the full action contains the EH+HD terms and also the matter part which, in our simplified case, only consists of a scalar field ϕ non-minimally coupled to gravity, Eq. (3).

As usual, the modified Einstein's equations are obtained through the variation of the new action with respect to $g_{\mu\nu}$, extending (2) as follows:

$$\frac{1}{8\pi G_N(M)}G_{\mu\nu}+\rho_\Lambda(M)g_{\mu\nu}+a_1(M)H^{(1)}_{\mu\nu}=T^{\phi_b}_{\mu\nu}+\langle T^{\delta\phi}_{\mu\nu}\rangle_{\rm Ren}(M)\,, \tag{24}$$

where the dependence in M indicates we are considering renormalized quantities. In particular, the classical part of the matter EMT does not depend on it. Our goal is to relate the theory at different renormalization points[c], and with this purpose in mind let us subtract Einstein's equations as written in (24) at two different scales, M and M_0. We find

$$\langle T^{\delta\phi}_{\mu\nu}\rangle_{\rm Ren}(M)-\langle T^{\delta\phi}_{\mu\nu}\rangle_{\rm Ren}(M_0)=f_{G_N^{-1}}G_{\mu\nu}+f_{\rho_\Lambda}g_{\mu\nu}+f_{a_1}H^{(1)}_{\mu\nu}, \tag{25}$$

here $f_X(m,M,M_0)\equiv X(M)-X(M_0)$ for the various couplings involved $X=G_N^{-1},\rho_\Lambda,a_1$. Since we know the expression of the renormalized EMT within the ARP, namely Eq (23), we can obtain the renormalization shift of the couplings G_N^{-1}, ρ_Λ and a_1 in (25) between the two scales M and M_0. This is possible by taking the value of the components G_{00} and $H^{(1)}_{00}$ (from Appendix) and comparing with (23). Notice that the first term of (23), in the *r.h.s*, is of $0th$ adiabatic order and is associated to $f_{\rho_\Lambda}(m,M,M_0)$ and, therefore, to the running of ρ_Λ. By doing this comparision we find that the functions are

$$\begin{aligned}
f_{G_N^{-1}}(m,M,M_0)&=\frac{\overline{\xi}}{16\pi^2}\left[M^2-M_0^2-m^2\ln\frac{M^2}{M_0^2}\right],\\
f_{\rho_\Lambda}(m,M,M_0)&=\frac{1}{128\pi^2}\left(M^4-M_0^4-4m^2(M^2-M_0^2)+2m^4\ln\frac{M^2}{M_0^2}\right),\\
f_{a_1}(M,M_0)&=-\frac{\overline{\xi}^2}{32\pi^2}\ln\frac{M^2}{M_0^2}.
\end{aligned} \tag{26}$$

6.1. *Running Vacuum Energy Density. Absence of $\sim m^4$ terms*

At this point we can come back to the definition of vacuum energy (7) which was used in this work. Considering $\langle T^{\rm vac}_{\mu\nu}\rangle=p_{\rm vac}g_{\mu\nu}+(p_{\rm vac}+\rho_{\rm vac})\,u_\mu u_\nu$, with $u_\mu=(a,0,0,0)$, and equating with Eq. (7), and taking the 00-component of the equality (keeping also in mind that $g_{00}=-a^2(\eta)$ in the conformal frame), we obtain

$$\rho_{\rm vac}(M)=\rho_\Lambda(M)+\frac{\langle T^{\delta\phi}_{00}\rangle_{\rm Ren}(M)}{a^2}. \tag{27}$$

We write the explicit dependence in the renormalization point M since we are talking about the renormalized quantity at that scale. Equation (27) means that

[c]We do not pretend to compute the renormalized couplings from first principles, in particular the VED. Renormalization program allows us to compare the theory at different renormalization points but, at the end, an input from the experiment is needed to predict its value at another scale.

the total VED at an arbitrary scale M is not only receiving contributions from the renormalized cosmological term but also from the quantum fluctuations of fields (i.e. from the renormalized ZPE of the scalar field, in our simplified model). Subtracting the renormalized result at two scales, M and M_0, and using (25), we find:

$$\begin{aligned}
&\rho_{\rm vac}(M)-\rho_{\rm vac}(M_0)=\rho_\Lambda(M)-\rho_\Lambda(M_0)+\frac{\langle T_{00}^{\delta\phi}\rangle_{\rm Ren}(M)-\langle T_{00}^{\delta\phi}\rangle_{\rm Ren}(M_0)}{a^2}\\
&=f_{\rho_\Lambda}(m,M,M_0)+\frac{f_{G_N^{-1}}(m,M,M_0)G_{00}+f_{\rho_\Lambda}(m,M,M_0)g_{00}+f_{a_1}(M,M_0)H_{00}^{(1)}}{a^2}\\
&=\frac{f_{G_N^{-1}}(m,M,M_0)}{a^2}G_{00}+\frac{f_{a_1}(M,M_0)}{a^2}H_{00}^{(1)}\\
&=\frac{3\mathcal{H}^2}{a^2}\,f_{G_N^{-1}}(m,M,M_0)-\frac{18}{a^4}\left(\mathcal{H}'^2-2\mathcal{H}''\mathcal{H}+3\mathcal{H}^4\right)\,f_{a_1}(M,M_0)\,. \qquad (28)
\end{aligned}$$

As we see the term $f_{\rho_\Lambda}(m,M,M_0)$ has disappeared. Finally, from (26) we obtain[26]

$$\begin{aligned}
\rho_{\rm vac}(M)=\rho_{\rm vac}(M_0)&+\frac{3}{16\pi^2}\overline{\xi}H^2\left[M^2-M_0^2-m^2\ln\frac{M^2}{M_0^2}\right]\\
&+\frac{9}{16\pi^2}\overline{\xi}^2\left(\dot{H}^2-2H\ddot{H}-6H^2\dot{H}\right)\ln\frac{M^2}{M_0^2}\,. \qquad (29)
\end{aligned}$$

In addition, we have used Eq. (44) from Appendix to write the final result in terms of the Hubble function in cosmic time ($H=\mathcal{H}/a$). The result (29) is the value of the VED at a particular energy scale M, related with the value of the VED at another renormalization scale M_0, i.e. it expresses the 'running' of the VED. Notice that if $\xi=1/6$ ($\overline{\xi}=0$), then the VED is independent of the renormalization scale. However, this is not likely to happen since one also has to consider the contribution from fermions and vector boson fields. It is also important to notice that the running is slow for small H, as it depends as $\mathcal{O}(H^2)$ times a mass scale squared and on $\mathcal{O}(H^4)$ contributions. Finally, we remark that there is no contributions of quartic mass scales.

7. Running vacuum connection

As explained in a footnote in previous sections, the result we were seeking (represented now by Eq. (29)) was not the calculated value of the VED at a given scale, e.g. it says nothing on the actual value of $\rho_{\rm vac}(M_0)$ and hence it has nothing to do with the cosmological constant problem mentioned in the Introduction. In other words, we have not provided the calculation of the value itself of the vacuum energy at particular point of the cosmic history. This result can nevertheless be useful to study the 'running' of the VED from one scale to another. We can rephrase this by saying that if $\rho_{\rm vac}$ is known at some scale M_0, Eq. (29) can be used to obtain the value of $\rho_{\rm vac}$ at another scale M. Such connection was suggested long ago from renormalization group arguments in curved spacetime[27–29] – see[30,31] and references therein for a review of the running vacuum model (RVM). What is more, it can even

set a framework for the possible variation of the so-called fundamental constants of nature[58] with the evolution of the universe. In the next subsection we are going to suggest a possible interpretation of Eq. (29) in the context of the RVM. For this purpose, let us assume that we set one arbitrary scale to the renormalized VED at some Grand Unified Theory (GUT) scale (i.e., set $M_0 = M_X$, where $M_X \sim 10^{16}$ GeV). This value is associated also with the inflationary scale. It is natural to assume that fundamental parameters, such as e.g. $\rho_{\rm vac}$, are defined at that primeval scale, related with the very beginning in the cosmological history. Additionally, a large scale such as the GUT scale insures that all particle masses can be active degrees of freedom to some extent.

7.1. *RVM in the currect universe*

Equation (29) can, in principle, be used to explore the value of the VED throughout the cosmological history. However, for the study of the very early universe (in particular, inflation) other contributions can appear, which will not be addressed here since in the present work we are just going to study the current universe dynamics in order to compare with the late time RVM phenomenology. For related studies in different contexts, cf.[59–62]. See also[42–45] for a stringy version of the RVM with implications on the mechanism of inflation.

Consider $\rho_{\rm vac}(M_X)$, the value of the VED at $M_0 = M_X$. The value of this energy density is unknown, but our aim is to relate it with the current value of the VED, $\rho^0_{\rm vac} \equiv \rho_{\rm vac}(H_0)$, by fixing the numerical value of the second scale at $M = H_0$, where H_0 today's value of the Hubble function– it can be considered an estimation for the energy scale associated to the the present FLRW universe. This association is commonly made in the aforementioned references on the RVM.[30] So, (29) applied to the present universe is

$$\rho^0_{\rm vac} \approx \rho_{\rm vac}(M_X) - \frac{3}{16\pi^2}\overline{\xi} H_0^2 \left[M_X^2 + m^2 \ln \frac{H_0^2}{M_X^2}\right]. \tag{30}$$

Here we ignore all terms of order $\mathcal{O}(H^4)$ (including $\dot{H}^2, H\ddot{H}$ and $H^2\dot{H}$) for the present universe ($H = H_0$). We can use this relation to find the value of $\rho_{\rm vac}(M_X)$, and the result is

$$\rho_{\rm vac}(M_X) = \rho^0_{\rm vac} - \frac{3\nu_{\rm eff}}{8\pi} H_0^2 M_P^2 , \tag{31}$$

where we have defined $\nu_{\rm eff}$, the 'running parameter' for the VED:

$$\nu_{\rm eff} = -\frac{\overline{\xi}}{2\pi}\frac{M_X^2}{M_P^2}\left(1 + \frac{m^2}{M_X^2}\ln\frac{H_0^2}{M_X^2}\right). \tag{32}$$

Notice that for $\xi = 1/6$ (or $\overline{\xi} = 0$), it vanishes and there is no running, as mentioned previously. In the case $\xi = 0$ (or $\overline{\xi} = -1/6$) and $m^2/M_X^2 \ll 1$ we obtain $\nu_{\rm eff} \simeq \frac{1}{12\pi}\frac{M_X^2}{M_P^2} \ll 1$. More in general, the structure obtained for $\nu_{\rm eff}$ is very similar to that one obtained previously in other works with the RVM approach, see.[30]

In these contexts, the parameter is related with the one-loop β-function for the renormalization group equation of $\rho_{\rm vac}$. Although, in our case, there is and additional logarithmic contribution $\ln H_0^2/M_X^2$, coming from the direct QFT calculation developed here. At the end of the day it does not make significant differences in practice since $\nu_{\rm eff}$ is a constant parameter which is fitted directly to cosmological data as an effective coefficient. It is natural to expect a small $\nu_{\rm eff}$, i.e. $|\nu_{\rm eff}| \ll 1$, because of the ratio $M_X^2/M_P^2 \sim 10^{-6}$, but notice that $\nu_{\rm eff}$ depends on ξ and also on contributions from other fields (fermions and bosons) and their multiplicities. Heavy fields of the order of the GUT scale can contribute in a significant way ($m \sim M_X$). As mentioned, $\nu_{\rm eff}$ needs to be fitted the RVM to tbe cosmological data, and this has been done in detail e.g. in,[15,16] the results indicate that $\nu_{\rm eff} \sim 10^{-3}$.

Now, we can us Eq. (29) and (31) to study the late universe. By ignoring $\mathcal{O}(H^4)$, we may estimate the current VED by taking $M = H$ around the present times:

$$\rho_{\rm vac}(H) = \rho_{\rm vac}^0 - \frac{3\nu_{\rm eff}}{8\pi}\, H_0^2\, M_P^2 + \frac{3\nu_{\rm eff}(H)}{8\pi}\, H^2\, M_P^2\,, \tag{33}$$

where

$$\nu_{\rm eff}(H) = -\frac{\overline{\xi}}{2\pi}\frac{M_X^2}{M_P^2}\left(1 + \frac{m^2}{M_X^2}\ln\frac{H^2}{M_X^2}\right). \tag{34}$$

Notice that the last expression is not constant as a difference from (32). However, since the dynamical behaviour of $\nu_{\rm eff}(H)$ is logarithmic, and considering a value of H close to H_0, we can approximate $\nu_{\rm eff}(H)$ by (32). Then, equation (33) may be written as[55]

$$\rho_{\rm vac}(H) \simeq \rho_{\rm vac}^0 + \frac{3\nu_{\rm eff}}{8\pi}\,(H^2 - H_0^2)\, M_P^2 = \rho_{\rm vac}^0 + \frac{3\nu_{\rm eff}}{8\pi G_N}\,(H^2 - H_0^2)\,. \tag{35}$$

This is exactly the canonical form of the RVM formula.[30] Such approximation holds fine even if we study the CMB epoch, since the difference between $\nu_{\rm eff}(H)$ from $\nu_{\rm eff}$ can be estimated to be less than 8% (for $m \simeq M_X$) or much less when $m \ll M_X$. This is the typical parametrization that has been used in the literature about the RVM.[15,16] As a matter of fact, this parametrization can be promoted to a more general form, by considering also a term proportional to $\dot{H}$ in the running equation for the VED. In the following subsection we are going to give grounds for the appearence of these kind of factors, not yet present in (35).

7.2. *More geometric structures for vacuum in curved spacetime*

Using the definition of the EMT associated to vacuum given in (7) we have derived the expression of the vacuum energy density in equation (27). However, we expect that the definition (7) can be generalized as follows:

$$\left\langle T_{\mu\nu}^{\rm vac}\right\rangle = T_{\mu\nu}^{\Lambda} + \left\langle T_{\mu\nu}^{\delta\phi}\right\rangle + \alpha_1 R g_{\mu\nu} + \alpha_2 R_{\mu\nu} + \mathcal{O}(R^2). \tag{36}$$

$\mathcal{O}(R^2)$ represents tensors of adiabatic order 4, that is R^2, $R_{\mu\nu}R^{\mu\nu}$, ... and α_i are parameters of dimension +2 in natural units. This new form for the vacuum EMT

can be justified from the phenomenological point of view, but we also remind the reader that in a more realistic picture, contributions from other fields (bosons and fermions) are also expected, and general covariance leads to a generic form as represented in (36). Generation of new terms is also possible by considering string-inspired mechanisms as it has been shown recently in.[40–43]

Let us work with the more general form for the vacuum EMT, (36). It is useful to redefine the coefficients of that expression as $\alpha_i(M) \equiv \frac{\lambda_i}{16\pi^2} M^2$. We can check in Appendix the expression of R and R_{00} in flat FLRW spacetime, we obtain after a straightforward calculation:

$$\rho_{\rm vac}(H) \simeq \rho^0_{\rm vac} + \frac{3}{8\pi G_N}\left(\tilde{\nu}_{\rm eff}\, H^2 + \bar{\nu}\,\dot{H}\right), \tag{37}$$

where

$$\tilde{\nu}_{\rm eff} = \frac{1}{2\pi}\,\frac{M_X^2}{M_P^2}\left[\left(\frac{1}{6}-\xi\right)\left(1+\frac{m^2}{M_X^2}\ln\frac{H_0^2}{M_X^2}\right)+4\lambda_1+\lambda_2\right] \tag{38}$$

and

$$\bar{\nu} = \frac{2\lambda_1+\lambda_2}{2\pi}\,\frac{M_X^2}{M_P^2}\,. \tag{39}$$

As done before, the logarithmic part of $\tilde{\nu}_{\rm eff}(H)$ can be neglected and we may approximate $\tilde{\nu}_{\rm eff}(H_0) \simeq \tilde{\nu}_{\rm eff}$. The parameter $\bar{\nu}$ is treated as constant here, but we can not discard also a possible running of λ_i, acquiring a dependence in M. Although, if this were the case, it is reasonable to expect a logarithmic evolution of the renormalization effects. The above formula is a generalization of Eq. (35) incorporating the additional coefficient $\bar{\nu}$, accompanying $\sim \dot{H}$. Finally, let us comment that several generalized forms of the RVM beyond the usual one containing the H^2 term has been studied before in the literature, see for instance.[13,14]

8. Discussion and conclusions

In this presentation we have investigated the possible dynamics of vacuum in the context of QFT in FLRW spacetime. Specifically, we have revisited the calculation of the renormalized energy-momentum tensor (EMT) of a real quantum scalar field non-minimally coupled to the FLRW background.[26] The approach is based on adiabatic regularization and renormalization of the EMT, starting from the WKB approximation of the field modes in curved spacetime. The renormalized EMT is defined as the difference of its on-shell value and its value at an arbitrary renormalization point M up to $4th$ adiabatic order. It is sufficient with this subtraction since the divergent terms are present up to $4th$ adiabatic order. The renormalized EMT is perfectly finite and acquires a dependence on M. We can use this fact to compare the renormalized result at different times of the history of the universe characterized by different energy scales. At this point we can identify the VED from the renormalized EMT. Such VED depends on $\rho_\Lambda(M)$ but also in the ZPE part involving

the quantum fluctuations of the scalar field. An interesting implication is that the combination of both quantities is free from terms $\sim m^4$, well-known sources of large contributions to the VED.

This QFT calculation leads us to a renormalized VED which has the usual form of the running vacuum models (RVM's),[30] in which $\rho_{\rm vac} = \rho_{\rm vac}(H)$ consists of an additive constant plus a series of powers of H (the Hubble rate) and its time derivatives. In previous works, the RVM was motivated from general renormalization group arguments in QFT in curved spacetime (cf.[30] and references therein). But, in this work, we have reviewed proof that the RVM form of the VED for the current universe emerges also from this calculation of QFT in the FLRW spacetime involving adiabatic regularization. It is found that the powers of H (and its time derivatives) in the EMT carry an even number of time derivatives of the scale factor, which is mandatory if we impose the general covariance of the action. In particular, the lowest order dynamical component of the VED is $\sim \nu\, H^2$. The dimensionless coefficient ν is expected to be small ($|\nu| \ll 1$). However, at the end, the model has to be fitted with the help of a complet set of cosmological data. This lower order term $\sim H^2$ has the main role in the study of the dynamics of the vacuum in the late universe, whereas the higher order terms may play a major role in the very early universe, for example to describe inflation (despite the fact that we have not exploited this idea in this work). In previous works, the RVM has been succesfully confronted to a large number of cosmological data and the effective parameter ν has been fitted. The encountered results say that ν is positive and around $\sim 10^{-3}$, see[13–16] . To conclude, let us remark that our QFT calculation has some limitations, for instance it has been simplified by the use of just one single field in the form of a real quantum scalar field. For this reason, further investigations have to be done in order to generalize these results for multiple fields involving scalar, fermionic and vectorial degrees of freedom. However, we do not expect major changes beyond computational details and the main results presented here are likely to be maintained.[55]

Acknowledgements

This work is based on the invited talk presented in the CM3 parallel session: "Status of the H_0 and σ_8 Tensions: Theoretical Models and Model-Independent Constraints" of the MG16 Marcel Grossmann virtual Conference, July 5-10 2021. We would like to thank the organizers of MG16 as well as the chairpersons of the session for the excellence of the event and for the invitation.

Appendix: Conventions, geometrical quantities and useful formulas

Through this work we have used natural units. This means that the gravitational constant is written as $G_N = 1/M_P$, being M_P is the Planck mass and $\hbar = c = 1$.

Conventions regarding the geometrical quantities can be summarized as follows: the metric has the signature $(-,+,+,+)$; the Riemann tensor is $R^{\lambda}{}_{\mu\nu\sigma} = \partial_\nu \Gamma^{\lambda}_{\mu\sigma} + \Gamma^{\rho}_{\mu\sigma}\Gamma^{\lambda}_{\rho\nu} - (\nu \leftrightarrow \sigma)$; the Ricci tensor is $R_{\mu\nu} = R^{\lambda}{}_{\mu\lambda\nu}$; and finally, Ricci scalar reads $R = g^{\mu\nu}R_{\mu\nu}$. These elections correspond to $(+,+,+)$ in the Misner-Thorne-Wheeler[63] conventions.

On the other hand, the Einstein tensor is defined as $G_{\mu\nu} = R_{\mu\nu} - \frac{1}{2}Rg_{\mu\nu}$ and the field equations are $G_{\mu\nu} + \Lambda g_{\mu\nu} = 8\pi G_N T_{\mu\nu}$. The (non-vanishing) Christoffel symbols, with a line element in terms of the conformal time $ds^2 = a^2(\eta)\eta_{\mu\nu}dx^\mu dx^\nu$ and $\eta_{\mu\nu} = \mathrm{diag}(-1,+1,+1,+1)$, are:

$$\Gamma^0_{00} = \mathcal{H}, \qquad \Gamma^0_{ij} = \mathcal{H}\delta_{ij}, \qquad \Gamma^i_{j0} = \mathcal{H}\delta^i_j\,. \tag{40}$$

The Ricci scalar and the 00-components of the curvature tensors are:

$$R = 6\frac{a''}{a^3} = \frac{6}{a^2}\left(\mathcal{H}' + \mathcal{H}^2\right) = 6\left(\frac{\dot{a}^2}{a^2} + \frac{\ddot{a}}{a}\right) = 6(2H^2 + \dot{H}) \tag{41}$$

and

$$R_{00} = -3\mathcal{H}' = -3a^2(H^2 + \dot{H})\,, \qquad G_{00} = 3\mathcal{H}^2 = 3a^2H^2\,. \tag{42}$$

Primes are indicating differentiation with respect to conformal time, meanwhile we use dots to represent derivatives with respect cosmic time. The process of renormalization introduces the need for the higher order curvature tensor $H^{(1)}_{\mu\nu}$, obtained by the variation of R^2 with respect the metric in the higher derivative vacuum action:

$$H^{(1)}_{\mu\nu} = \frac{1}{\sqrt{-g}}\frac{\delta}{\delta g^{\mu\nu}}\int d^4x\sqrt{-g}R^2 = -2\nabla_\mu\nabla_\nu R + 2g_{\mu\nu}\Box R - \frac{1}{2}g_{\mu\nu}R^2 + 2RR_{\mu\nu}\,. \tag{43}$$

In particular, the 00-component is related with the vacuum energy density and in the conformally flat metric is

$$H^{(1)}_{00} = \frac{-18}{a^2}\left(\mathcal{H}'^2 - 2\mathcal{H}''\mathcal{H} + 3\mathcal{H}^4\right) = -18a^2\left(\dot{H}^2 - 2H\ddot{H} - 6H^2\dot{H}\right)\,. \tag{44}$$

Computing integrals with powers of $1/\omega_k$

The following expression is useful to compute all the finite ($n > N$) and UV-divergent ($n \leq N$) integrals involved in the EMT computation:

$$I(n,Q) \equiv \int \frac{d^Nk}{(2\pi)^N}\frac{1}{(k^2+Q^2)^{n/2}} = \frac{1}{(4\pi)^{N/2}}\frac{\Gamma\left(\frac{n-N}{2}\right)}{\Gamma\left(\frac{n}{2}\right)}\left(Q^2\right)^{\frac{N-n}{2}}\,, \tag{45}$$

where $k \equiv |\mathbf{k}|$ and Q is an arbitrary scale. We have corrected typos in this formula as compared to that of Appendix B of,[26] with no consequences in the calculation.

We present an analysis of the Brans-Dicke cosmological model with a cosmological constant and cold dark matter (BD-ΛCDM). We find that the BD-ΛCDM is favored by the overall cosmological data (SNIa+BAO+$H(z)$+LSS+CMB) when it is compared with the standard model of cosmology. The BD-ΛCDM model can be viewed from the GR perspective as a Running Vacuum Model (RVM) with a time evolving vacuum energy density. Due to this fact and also to its time evolving effective gravitational coupling, the model can alleviate the σ_8 and the H_0 tensions at a time. We also present the results for different types of RVM's when they are tested in the light of the cosmological data and we show that a mild dynamics for the vacuum energy density can help to smooth out the aforementioned tensions, thus improving the performance of ΛCDM model.

Keywords: Cosmology, Dark Energy, General Relativity.

1. Introduction

The high quality observations performed during the last two decades, have allowed to demonstrate, with a high confidence range, that the Universe is in expansion and to be more precise in accelerated expansion.[1,2] The standard model of cosmology, the so-called ΛCDM, is based on the assumption that the observed accelerated expansion is due to the existence of a repulsive force, exerted by the Λ term, which counteracts the attractive gravitational force and pushes the clusters of galaxies at a speed that increases with the cosmic expansion. This term, which is called the cosmological constant (CC), is associated with a mysterious form of energy, usually called dark energy (DE) presumably permeating all corners of the Universe as a whole. The cosmological constant is not the only element beyond the conventional matter, namely: baryons, photons and neutrinos, demanded by the observations since it is also essential the presence of large amounts of what is commonly call, cold dark matter (CDM). It is important to remark that the concordance model is

[*]Speaker

defined in the framework of General Relativity (GR), whose field equations were found by Einstein in 1915.[3] The fact that the ΛCDM model, with so few ingredients (encoded in 6 degrees of freedom), has remained robust and unbeaten for a long time turns out to be pretty impressive. It is consistent with a large body of very accurate cosmological data, like the cosmic microwave background (CMB), the baryonic acoustic oscillations (BAO) or the large scale structure (LSS) data.

However, this does not mean at all that we really understand the primary (dynamical) cause for such an acceleration or that we are in position to propose a cosmological model explaining the speeding up of the cosmos at the level of fundamental physics, say quantum field theory (QFT) in curved spacetime, quantum gravity or string theory. For instance, if we try to explain the origin of the cosmological constant in the context of QFT we will immediately realize that we have to face the well-known old cosmological constant problem. This problem was formulated by Zel'dovich[4,5] (see also[6–9]) and basically consists in the tremendous mismatch between the computed value of the vacuum energy density, considering different contributions from QFT, and the experimental measure, being the discrepancy between both values in natural units of at least 55 orders of magnitude.

Thus, in spite of the many virtues of the ΛCDM model, the lack of an explanation for the presence of the CC, leads inevitably to an unsatisfactory theoretical picture which has motivated the search of a wide range of alternatives beyond the standard model. What is more, aside from the theoretical problems some persisting tensions with the cosmological data (being the most important ones, the tension on the local value of the H_0 parameter[10,11] and the one affecting the LSS data[12]) point out that the ΛCDM model might be performing insufficiently at the observational level.

Here we study two alternatives where the aforementioned tension could be alleviated. It has been suggested that it would help to alleviate the tensions if DE would be a dynamical quantity (see for instance the possibility of an early dark energy[13,14]), i.e. slowly evolving with the cosmic expansion. This could be achieved, for example, through scalar field models[15–20] (see[21] for an updated analysis), where the energy density associated to the Λ term is replaced by the energy density of the scalar field, which varies throughout the cosmic history. In this paper, instead of considering a scalar field model we focus on another promising possibility, namely that vacuum energy density $\rho_{\rm vac} = \Lambda/8\pi G_N$ might be a time evolving quantity whose dynamics is triggered by the quantum effects coming from the matter fields. We call these types of models Running Vacuum Models (RVM's). Phenomenologically, these models, have recently been carefully confronted against the wealth of the cosmological data, obtaining a significant success.[22–27]

On the other hand there exists the possibility to consider a completely different approach, where a theoretical framework, different from GR, is assumed. In this regard, Brans & Dicke[28] proposed the first historical attempt to extend Einstein's GR by promoting the Newtonian coupling G_N into a variable one in the cosmic time $G(t)$. Gravity is then not only mediated by the metric but also by an scalar field

denoted by ψ. The theory contains an extra *d.o.f.* encoded in ψ and a dimensionless parameter $\omega_{\rm BD}$. In order to recover GR a necessary (though not sufficient) condition is to demand large values of $\omega_{\rm BD}$. We consider the presence of the CC and all the species considered in the standard model, so we call the model studied in the context of Brans-Dicke (BD) gravity, BD-ΛCDM.

In this work we present a summary of the main results recently obtained by confronting the overall cosmological observations with the BD-ΛCDM model and related RVM's and we show how they deal with the aforementioned tensions. See the original references[?, 27, 29, 30] for more details.

2. Background equations for the BD-ΛCDM model

We will consider the original BD-action extended with a cosmological constant density term as it is essential to mimic the conventional ΛCDM model based on GR and reproduce its main successes. We call this the 'BD-ΛCDM model', i.e. the version of the ΛCDM within the BD paradigm. The BD action reads, written in the Jordan frame, as follows [a]:

$$S_{\rm BD} = \int d^4x\sqrt{-g}\left[\frac{1}{16\pi}\left(R\psi - \frac{\omega_{\rm BD}}{\psi}g^{\mu\nu}\partial_\nu\psi\partial_\mu\psi\right) - \rho^0_{\rm vac}\right] + S_m\,. \tag{1}$$

For the sake of convenience we denote the constant vacuum energy density as $\rho^0_{\rm vac}$. The (dimensionless) factor in front of the kinetic term of ψ, i.e. $\omega_{\rm BD}$, will be referred to as the BD-parameter and we consider the canonical option, $\omega_{\rm BD}$ =const. The last term of (1) stands for the matter action S_m, which is constructed from the Lagrangian density of the matter fields. There is no potential for the BD-field ψ in the original BD-theory, but we admit the presence of a CC term associated to $\rho^0_{\rm vac}$.

The modified field equations (with respect to GR) can be obtained after performing variation of the action (1) with respect to both the metric and the scalar field ψ. While the first variation yields

$$\psi\, G_{\mu\nu} + \left(\Box\psi + \frac{\omega_{\rm BD}}{2\psi}\left(\nabla\psi\right)^2\right) g_{\mu\nu} - \nabla_\mu\nabla_\nu\psi - \frac{\omega_{\rm BD}}{\psi}\nabla_\mu\psi\nabla_\nu\psi = 8\pi\left(T_{\mu\nu} - g_{\mu\nu}\rho^0_{\rm vac}\right)\,, \tag{2}$$

the second variation gives the wave equation for ψ

$$\Box\psi = \frac{8\pi}{2\omega_{\rm BD}+3}\left(T - 4\rho^0_{\rm vac}\right)\,. \tag{3}$$

We have used the definition $(\nabla\psi)^2 \equiv g^{\mu\nu}\nabla_\mu\psi\nabla_\nu\psi$. In the first equation, $G_{\mu\nu} = R_{\mu\nu} - (1/2)Rg_{\mu\nu}$ is the Einstein tensor, and on its *r.h.s.* $T_{\mu\nu} = -(2/\sqrt{-g})\delta S_m/\delta g^{\mu\nu}$ is the energy-momentum tensor of matter, being $T \equiv T^\mu_\mu$ its trace. The total energy-momentum tensor is the sum of the matter and vacuum contributions and it takes

[a] We use natural units, $\hbar = c = 1$ and $G_N = 1/m^2_{\rm Pl}$, where $m_{\rm Pl} \simeq 1.22\times10^{19}$ GeV is the Planck mass. As for the geometrical quantities, we adopt the $(+,+,+)$ convention of the popular classification by Misner, Thorn and Wheeler.[31]

the perfect fluid form:

$$\tilde{T}_{\mu\nu} = T_{\mu\nu} - \rho^0_{\rm vac} g_{\mu\nu} = p\, g_{\mu\nu} + (\rho + p) u_\mu u_\nu \,, \tag{4}$$

with $\rho \equiv \rho_m + \rho_\gamma + \rho_{\rm ncdm} + \rho^0_{\rm vac}$ and $p \equiv p_m + p_\gamma + p_{\rm ncdm} + p^0_{\rm vac}$. The matter part $\rho_m \equiv \rho_b + \rho_{\rm cdm}$, contains the pressureless contribution from baryons and cold dark matter and photons are of course relativistic, so $p_\gamma = \rho_\gamma/3$. The functions $\rho_{\rm ncdm}$ and $p_{\rm ncdm}$ ('ncdm' means non-CDM) include the effect of massive and massless neutrinos, and therefore must be computed numerically. As in GR, we have considered a constant vacuum energy density, $\rho^0_{\rm vac}$, in the BD-action (1), being its equation of state $p^0_{\rm vac} = -\rho^0_{\rm vac}$ the usual one.

Let us write down the field equations in the flat (to know more about the nonflat models see the references[32–44]) FLRW metric, $ds^2 = -dt^2 + a^2 \delta_{ij} dx^i dx^j$. Using the previous definitions for the total energy density ρ and pressure p we get the two independent equations:

$$3H^2 + 3H\frac{\dot{\psi}}{\psi} - \frac{\omega_{\rm BD}}{2}\left(\frac{\dot{\psi}}{\psi}\right)^2 = \frac{8\pi}{\psi}\rho \tag{5}$$

and

$$2\dot{H} + 3H^2 + \frac{\ddot{\psi}}{\psi} + 2H\frac{\dot{\psi}}{\psi} + \frac{\omega_{\rm BD}}{2}\left(\frac{\dot{\psi}}{\psi}\right)^2 = -\frac{8\pi}{\psi}p \,, \tag{6}$$

whereas from (3) we obtain

$$\ddot{\psi} + 3H\dot{\psi} = \frac{8\pi}{2\omega_{\rm BD} + 3}(\rho - 3p) \,. \tag{7}$$

Here dots stand for derivatives with respect to the cosmic time and $H = \dot{a}/a$ is the Hubble rate. In the limit $\psi \to 1/G_N$ and $\omega_{\rm BD} \to \infty$ we recover the standard equations. The connection between GR and the $\omega_{\rm BD} \to \infty$ limit is sometimes not as straightforward as one might naively think .[45,46]

Matter and the BD-field are not in interaction, as a result, the local conservation law adopts the usual form:

$$\dot{\rho} + 3H(\rho + p) = \sum_N \left[\dot{\rho}_N + 3H(\rho_N + p_N)\right] = 0 \,, \tag{8}$$

where the sum is over all components, i.e. baryons, dark matter, neutrinos, photons and vacuum. We assume that all of the components are separately conserved in the main periods of the cosmic evolution. For convenience, we will use a dimensionless BD-field, φ, and the inverse of the BD-parameter, according to :

$$\varphi(t) \equiv G_N \psi(t) \,, \qquad\qquad \epsilon_{\rm BD} \equiv \frac{1}{\omega_{\rm BD}} \,. \tag{9}$$

As stated before G_N gives the local value of the gravitational coupling. Note that a nonvanishing value of $\epsilon_{\rm BD}$ entails a deviation from GR. Being $\varphi(t)$ a dimensionless quantity, we can recover GR by enforcing the simultaneous limits $\epsilon_{\rm BD} \to 0$ *and* $\varphi \to 1$.

Note: The mean values and 68.3% confidence limits for the models under study using our Baseline dataset, which is comporsed by: the full Pantheon likelihood,[47] 13 BAO data points,[48–53] 31 data points on $H(z_i)$, at different redshifts,[54–61] 14 points on the observable $f(z_i)\sigma_8(z_i)$[50,52,62–66] and finally the full Planck likelihood for the CMB data.[10] We display the fitting values for the usual parameters, to wit: H_0, the reduced density parameter for baryons ($w_b = \Omega_b^0 h^2$) and also for CDM ($w_{\rm cdm} = \Omega_{\rm cdm}^0 h^2$), being $\Omega_i^0 = 8\pi G_N \rho_i^0/3H_0^2$ and h the reduced Hubble constant, the reionization optical depth $\tau_{\rm reio}$, the spectral index n_s and the current matter density rms fluctuations within spheres of radius $8h^{-1}$ Mpc, i.e. σ_8. We include also a couple of derived parameters, namely: the sound horizon at the baryon drag epoch r_s and $S_8 \equiv \sigma_8\sqrt{\Omega_m^0/0.3}$. For the RRVM's we provide the value of $\nu_{\rm eff}$, and for the type II and BD-ΛCDM[27] we also report the initial and current values of φ, $\varphi_{\rm ini}$ and φ_0, respectively. The parameter $\epsilon_{\rm BD} \equiv 1/\omega_{\rm BD}$ (inverse of the Brans-Dicke parameter[28]) controls the dynamics of the scalar field.[29,30] We finally provide the corresponding values of $\chi^2_{\rm min}$ and ΔDIC.

3. Connection of the BD-ΛCDM model with the Running Vacuum Model

So far, no analytical solutions to the system (5)-(7) have been found, for this reason our actual analysis proceeds numerically. However, it is possible to search for approximate solutions valid in the different epochs of cosmic history, which can provide a qualitative understanding of the numerical results obtained. Actually, a first attempt in this direction trying to show that BD-ΛCDM can mimic the Running Vacuum Model (RVM) was done in,[67,68] we refer the reader to these references for details. See also.[69,70] We are interested in looking for solutions in the Matter Dominated Epoch (MDE) in the form of a power-law ansatz in which the BD-field φ evolves very slowly:

$$\varphi(a) = \varphi_0\, a^{-\epsilon} \qquad (|\epsilon| \ll 1)\,. \tag{10}$$

The ϵ parameter must be a very small parameter in absolute value since $G(a) \equiv G(\varphi(a))$ cannot depart too much from G_N and $\varphi_0 \equiv \varphi(z=0)$. For $\epsilon > 0$, the effective coupling increases with the expansion and hence is asymptotically free

since $G(a)$ is smaller in the past, which is the epoch when the Hubble rate (with natural dimension of energy) is bigger. For $\epsilon < 0$, is the other way around and $G(a)$ decreases with the expansion.

Plugging the power-law ansatz into the cosmological equations we end up with the following pair of Friedmann-like equations to $\mathcal{O}(\epsilon)$:[67,68]

$$H^2 = \frac{8\pi G}{3}\left(\rho_m^0 a^{-3+\epsilon} + \rho_{\rm DE}(H)\right) \tag{11}$$

and for the acceleration equation

$$\frac{\ddot{a}}{a} = -\frac{4\pi G}{3}\left(\rho_m^0 a^{-3+\epsilon} + \rho_{\rm DE}(H) + 3p_{\rm vac}^0\right), \tag{12}$$

with $G = G_N/\varphi_0$. The first of the above equations can be understood as an effective Friedmann's equation with time-evolving cosmological term, in which the DE appears as if it were a dynamical quantity:

$$\rho_{\rm DE}(H) = \rho_{\rm vac}^0 + \frac{3\,\bar{\nu}_{\rm eff}}{8\pi G} H^2\,. \tag{13}$$

Here

$$\bar{\nu}_{\rm eff} \equiv \epsilon\left(1 + \frac{1}{6}\,\omega_{\rm BD}\epsilon\right) \tag{14}$$

is the coefficient controlling the dynamical character of the effective dark energy (13). The structure of this dynamical dark energy (DDE) is reminiscent of the Running Vacuum Model (RVM), see[71–73] and references therein. Notice from (11) that, to $\mathcal{O}(\epsilon)$:

$$\Omega_m + \Omega_\Lambda = 1 - \bar{\nu}_{\rm eff}\,, \tag{15}$$

so, due to the presence of $\bar{\nu}_{\rm eff}$, we find a slight deviation from the usual sum rule of GR. Only in the case $\epsilon = 0$, we have $\bar{\nu}_{\rm eff} = 0$ and then we recover the usual cosmic sum rule. As stated, the parameter $\bar{\nu}_{\rm eff}$ becomes associated to the dynamics of the dark energy. We shall see more about the most important features of the RVM in the next section. All in all, it turns out that the BD-RVM (we may call it in this way for convenience) can cure the H_0-tension due to the evolution of the effective gravitational $G_{\rm eff}$ and, additionally, by mimicking the RVM it can also alleviate the well-known σ_8-tension thanks to the role played by $\bar{\nu}_{\rm eff}$. Going a little further in this effective picture from (12) we can define the EoS parameter for the effective DDE:

$$w_{\rm eff}(z) = \frac{p_{\rm vac}^0}{\rho_{\rm DE}(H)} \simeq -1 + \frac{3\bar{\nu}_{\rm eff}}{8\pi G\rho_{\rm vac}^0}\,H^2(z) = -1 + \frac{\bar{\nu}_{\rm eff}}{\Omega_\Lambda}\,\frac{H^2(z)}{H_0^2}\,, \tag{16}$$

where use has been made of (13). As it is clear from the above equation the BD-RVM, unlike the original RVM, does not describe a dark energy of pure vacuum form but a DE whose EoS departs, in a mild way, from the pure vacuum. Actually, for $\epsilon > 0$ ($\epsilon < 0$) we have $\bar{\nu}_{\rm eff} > 0$ ($\bar{\nu}_{\rm eff} < 0$) and the effective DDE behaves quintessence (phantom)-like.

4. Background equations for the RVM's

In the following we are going to present the theoretical framework where the previously mentioned RVM's are placed[71–73] and references therein. We consider two types of dynamical vacuum energy (DVE) scenarios. In type I scenario the vacuum is in interaction with matter, in contrast, in type II matter is conserved at the expense of an exchange between the vacuum and a slowly evolving gravitational coupling $G(H)$. In both cases, the combined cosmological 'running' of these quantities insures the accomplishment of the Bianchi identity (and the local conservation law). Let us therefore consider a generic cosmological framework described by the spatially flat Friedmann-Lemaître-Robertson-Walker (FLRW) metric. The vacuum energy density in the RVM can be expressed as :[71,72]

$$\rho_{\rm vac}(H) = \frac{3}{8\pi G_N}\left(c_0 + \nu H^2 + \tilde{\nu}\dot{H}\right) + \mathcal{O}(H^4)\,. \tag{17}$$

The $\mathcal{O}(H^4)$ terms play no role in the post-inflationary epoch so they can be neglected. The expression (17) can be motivated from the explicit QFT calculations on a FLRW background.[74] The value of the additive constant c_0 is fixed by the boundary condition $\rho_{\rm vac}(H_0) = \rho^0_{\rm vac}$. The two dynamical components H^2 and $\dot{H}$ are dimensionally homogeneous and in principle independent. The dimensionless coefficients ν and $\tilde{\nu}$ encode the dynamics of the vacuum at low energy and we naturally expect for both of them $|\nu, \tilde{\nu}| \ll 1$. An estimate of ν in QFT indicates that it is of order 10^{-3} at most.[75] In the calculations performed in[74] these coefficients are expected to be of order $\sim M_X^2/m_{\rm Pl}^2 \ll 1$, being M_X of order of a typical Grand Unified Theory (GUT) scale. Taking into account the multiplicity of particles in a GUT, the theoretical estimate on ν could be much larger but still subject to a value below 1.

We are interested in a particular form for the vacuum energy density obtained by imposing $\tilde{\nu} = \nu/2$. Consequently

$$\rho_{\rm vac}(H) = 3/(8\pi G_N)\left[c_0 + \nu\left(H^2 + \frac{1}{2}\dot{H}\right)\right]. \tag{18}$$

We will call this form of the vacuum energy density the 'RRVM' since it realizes the generic RVM density (17) through the Ricci scalar $\mathcal{R} = 12H^2 + 6\dot{H}$, namely

$$\rho_{\rm vac}(H) = \frac{3}{8\pi G_N}\left(c_0 + \frac{\nu}{12}\mathcal{R}\right) \equiv \rho_{\rm vac}(\mathcal{R})\,. \tag{19}$$

Due to the fact that the condition $\mathcal{R}/H^2 \ll 1$ is fulfilled in the early epochs of the cosmological evolution we do not generate any conflict with the BBN nor with any other feature of the modern universe. Of course, early on the RVM has its own mechanism for inflation see[71, 72, 76, 77] for more details.

4.1. *Type I RRVM*

Taking into account, the dynamical character presented for the vacuum energy density, the Friedmann and the acceleration equations for the different species involved, read

$$3H^2 = 8\pi G_N\left(\rho_m + \rho_{\rm ncdm} + \rho_\gamma + \rho_{\rm vac}(H)\right), \tag{20}$$

$$3H^2 + 2\dot{H} = -8\pi G_N\left(p_{\rm ncdm} + p_\gamma + p_{\rm vac}(H)\right). \tag{21}$$

As for the BD-model, we define the total nonrelativistic matter density as the sum of the CDM component and the baryonic one: $\rho_m = \rho_{\rm cdm} + \rho_b$. Therefore the total (relativistic and nonrelativistic) matter density is $\rho_t = \rho_m + \rho_\gamma + \rho_{\rm ncdm}$. In a similar way, the total matter pressure reads $p_t = p_{\rm ncdm} + p_\gamma$ (with $p_\gamma = (1/3)\rho_\gamma$). Making use of the functions employed by the system solver `CLASS` [78] we distinguish between the contributions of the nonrelativistic neutrinos $\rho_h = \rho_{\rm ncdm} - 3p_{\rm ncdm}$ and the one from the relativistic neutrinos $\rho_\nu = 3p_{\rm ncdm}$. This separation allows to compute $\mathcal{R}/12 = H^2 + (1/2)\dot{H}$ appearing in (19) in terms of the energy densities and pressures using (20) and (21):

$$\mathcal{R} = 8\pi G_N\left(\rho_m + 4\rho_{\rm vac} + \rho_h\right). \tag{22}$$

We can safely neglect the contribution of neutrinos from (22) since it remains well below the contribution of CDM and baryons throughout the whole cosmic history. This fact allows us to solve for the vacuum density as a function of the scale factor a as follows:

$$\rho_{\rm vac}(a) = \rho^0_{\rm vac} + \frac{\nu}{4(1-\nu)}(\rho_m(a) - \rho^0_m)\,, \tag{23}$$

where ' 0' (used as subscript or superscript) always refers to current quantities. For $a = 1$ we confirm the correct normalization: $\rho_{\rm vac}(a = 1) = \rho^0_{\rm vac}$. Matter does not follow the standard dilution law, remember that it is in interaction with vacuum,

therefore $\rho_m(a)$ is not just $\sim a^{-3}$. The local conservation law for CDM and vacuum can be expressed as follows:

$$\dot{\rho}_{\rm cdm} + 3H\rho_{\rm cdm} = -\dot{\rho}_{\rm vac}\,. \tag{24}$$

We assume that baryons are self conserved, which implies $\dot{\rho}_b + 3H\rho_b = 0$, and as a consequence the total matter contribution (ρ_m) satisfies the same local conservation law (24) as CDM: $\dot{\rho}_m + 3H\rho_m = -\dot{\rho}_{\rm vac}$. Using it together with (23) we find

$$\dot{\rho}_m + 3H\xi\rho_m = 0 \tag{25}$$

where, for convenience, we have defined

$$\xi \equiv \frac{1-\nu}{1-\frac{3}{4}\nu}. \tag{26}$$

We encode the deviations with respect to the standard model in terms of the effective parameter $\nu_{\rm eff} \equiv \nu/4$:

$$\xi = 1 - \nu_{\rm eff} + \mathcal{O}\left(\nu_{\rm eff}^2\right)\,. \tag{27}$$

Having reached this point it is straightforward to find the expression for the matter energy densities:

$$\rho_m(a) = \rho_m^0 a^{-3\xi}\,, \quad \rho_{\rm cdm}(a) = \rho_m^0 a^{-3\xi} - \rho_b^0 a^{-3}\,. \tag{28}$$

As expected, by setting $\xi = 1$ ($\nu_{\rm eff} = 0$) we recover the ΛCDM expressions. The small departure is precisely what gives allowance for a mild dynamical vacuum evolution:

$$\rho_{\rm vac}(a) = \rho_{\rm vac}^0 + \left(\frac{1}{\xi} - 1\right)\rho_m^0\left(a^{-3\xi} - 1\right)\,. \tag{29}$$

The vacuum becomes rigid if $\xi = 1$ ($\nu_{\rm eff} = 0$).

4.2. *Type II RRVM*

Unlike the first kind of models presented, for type II models matter is conserved. However, vacuum can still evolve provided the gravitational coupling also evolves with the expansion: $G = G(H)$. Let us define an auxiliary variable $\varphi = G_N/G$ – in the manner of a Brans-Dicke, without being really so. Notice that $\varphi \neq 1$ in the cosmological domain, but remains very close to it, see Tables 1 and 2. The modified Friedmann's equation for type-II model can be written as

$$3H^2 = \frac{8\pi G_N}{\varphi}\left[\rho_t + C_0 + \frac{3\nu}{16\pi G_N}(2H^2 + \dot{H})\right]\,, \tag{30}$$

with $C_0 = 3c_0/(8\pi G_N)$. The link between the dynamics of φ and that of $\rho_{\rm vac}$ is given by the Bianchi identity:

$$\frac{\dot{\varphi}}{\varphi} = \frac{\dot{\rho}_{\rm vac}}{\rho_t + \rho_{\rm vac}}\,, \tag{31}$$

where ρ_t is as before the total matter energy density and $\rho_{\rm vac}$ adopts exactly the same form as in (19). In the absence of an analytical expression for the vacuum energy density, we can show its approximate behaviour close to the present time by keeping only the terms linear in $\nu_{\rm eff}$ (recall that $|\nu_{\rm eff}| \ll 1$):

$$\rho_{\rm vac}(a) = C_0(1 + 4\nu_{\rm eff}) + \nu_{\rm eff}\rho_m^0 a^{-3} + \mathcal{O}(\nu_{\rm eff}^2)\,. \tag{32}$$

Again, for $\nu_{\rm eff} = 0$ the vacuum energy density is constant, but otherwise it shows a moderate dynamics of $\mathcal{O}(\nu_{\rm eff})$ as in the type I case (29). One can also show that $\rho_{\rm vac}(a) \ll \rho_r(a) = \rho_r^0 a^{-4}$ for $a \ll 1$ and therefore the $\rho_{\rm vac}$ for the type II model does not perturb the normal thermal history (as in the type I model). Regarding the auxiliary variable φ, in the current epoch it exhibits a very mild evolution, almost logarithmic.

4.3. *Threshold redshift scenario for type I models*

One possibility that has been explored in the literature is to consider that vacuum is a dynamical quantity only close to the present time and that remains constant for the rest of the cosmic history (see e.g.[79,80]). So, in this scenario, we keep deactivated the interaction between the vacuum energy density and the CDM until the late universe when dark energy becomes apparent. We denote the threshold value of the scale factor when the activation takes places by a_*. According to this scenario the vacuum energy density was constant prior to $a = a_*$ and it just started to evolve for $a > a_*$. It is important to remark that while $\rho_{\rm vac}$ is a continuous function, its derivative is not. We mimic such situation through a Heaviside step function $\Theta(a - a_*)$. Therefore, we assume that in the range $a < a_*$ (hence for $z > z_*$) we have

$$\begin{aligned} &\rho_{\rm cdm}(a) = \rho_{\rm cdm}(a_*)\left(\frac{a}{a_*}\right)^{-3}, \\ &\rho_{\rm vac}(a) = \rho_{\rm vac}(a_*) = \text{const.} \qquad\qquad (a < a_*)\,, \end{aligned} \tag{33}$$

where $\rho_{\rm cdm}(a_*)$ and $\rho_{\rm vac}(a_*)$ are computed from (28) and (29), respectively. In the complementary range, instead, i.e. for $a > a_*$ ($0 < z < z_*$) near our time, the original equations (28) and (29) are the ones considered.

The threshold procedure is only applied within type I models with the main purpose of preserving the standard evolution law for the matter energy density when the redshift is sufficiently high. In fact, the threshold redshift value does not need to be very high and when it is fixed by optimization it turns out to be of order $z_* \simeq 1$. An important consequence of such threshold is that the cosmological physics during the CMB epoch is exactly as in the ΛCDM. On the contrary for type II models there is still some evolution (very mild though) of $\rho_{\rm vac}$ at the CMB epoch, but the matter density follows the same law as in the standard model.

5. Cosmological perturbations

In order to perform a complete analysis of the different models under study we need to consider the evolution of the perturbed cosmological quantities throughout the cosmic history. We refer the reader to the references[23, 25, 30, 81] to know for the details of the perturbation equations since here we just display some basic equations. We consider the perturbed, spatially flat, FLRW metric $ds^2 = a^2(\eta)[-d\eta^2 + (\delta_{ij} + h_{ij})dx^i dx^j]$, in which h_{ij} represents the metric fluctuations which are coupled to the matter density perturbations $\delta_m = \delta\rho_m/\rho_m$ and $d\eta = dt/a$ is the conformal time. In the case of the BD model, at deep subhorizon scales, the differential equation for the matter density contrast is:

$$\delta_m'' + \mathcal{H}\delta_m' - 4\pi G_{\rm eff}(\bar{\varphi})a^2\bar{\rho}_m\delta_m = 0, \tag{34}$$

where here $()' \equiv d()/d\eta$ and $\mathcal{H} = aH$. In this section when we add a bar over a quantity we indicate that it is a background quantity. We have employed the definition:

$$G_{\rm eff} = \frac{G_N}{\bar{\varphi}}\left(\frac{4+2\omega_{\rm BD}}{3+2\omega_{\rm BD}}\right), \tag{35}$$

which represents the effective coupling that modifies the Poisson term of the perturbed equation with respect to the standard model.

In the case of the type I RRVM since baryons do not interact with the time evolving vacuum energy density their perturbed conservation equations are not directly affected. On the other hand the equation for the CDM takes the following form:

$$\delta_{\rm cdm}' + \frac{h'}{2} - \frac{\rho_{\rm vac}'}{\rho_{\rm cdm}}\delta_{\rm cdm} = 0, \tag{36}$$

which is obviously affected by the dynamics of the vacuum in a nontrivial way. We will present the details of the perturbation equations for the type II RRVM elsewhere.

6. Data and methodology

We fit the BD-ΛCDM, the different RVM's together with the standard model to the wealth of the cosmological data compiled from distant type Ia supernovae (SNIa), baryonic acoustic oscillations (BAO), different values of the Hubble function $H(z_i)$, the large scale structure (LSS) formation data embodied in the $f(z_i)\sigma_8(z_i)$ observable and the CMB data from the Planck satellite, see the references in the caption of Table 1. In order to compare the theoretical predictions with the available cosmological data we define the total χ^2 function as:

$$\chi^2_{\rm tot} = \chi^2_{\rm SNIa} + \chi^2_{\rm BAO} + \chi^2_H + \chi^2_{f\sigma_8} + \chi^2_{\rm CMB}. \tag{37}$$

The above terms are defined in the standard way from the data including the corresponding covariance matrices. In particular, the χ^2_H part may contain or not the

H_0 value measured by[11] depending on the setup indicated in the tables. To obtain the posterior distributions and the corresponding constraints for the dataset described above we have run the Monte Carlo sampler `MontePython`[82] together with the Einstein-Boltzmann system solver `CLASS`.[78] The latter has been properly modified in order to implement the background and the linear perturbation equations for the different models.

7. Discussions and conclusions

The main fitting results of our analysis are displayed in Tables 1 and 2 and in Figure 1. In the tables we compare, for two different datasets denoted as "Baseline" and "Baseline+H_0" (see the corresponding captions for more details), the concordance ΛCDM model with different RRVM's and with the BD-ΛCDM model.

In order to make a fair comparison between models with a different numbers of free parameters we employ the Deviance Information Criterion (DIC):[83] $\Delta\mathrm{DIC} = \mathrm{DIC}_{\Lambda\mathrm{CDM}} - \mathrm{DIC}_{\mathrm{X}}$, representing X one of the nonstandard models under study. The DIC is defined as

$$\mathrm{DIC} = \chi^2(\overline{\theta}) + 2p_D\,. \tag{38}$$

Here $p_D = \overline{\chi^2} - \chi^2(\overline{\theta})$ is the effective number of parameters of the model, and $\overline{\chi^2}$ and $\overline{\theta}$ the mean of the overall χ^2 distribution and the parameters, respectively. As it can be seen from the definition of ΔDIC, if $\Delta\mathrm{DIC} < 0$, means that the ΛCDM fits better the cosmological data, whereas for $\Delta\mathrm{DIC} > 0$ is the other way around.

Taking a look at the first table, it can be appreciated that a mild dynamics of the vacuum is very much welcome, specially in the case where the time evolution of ρ_{vac} is activated close to the moment when the contribution of this quantity becomes relevant, namely at $z \simeq 1$. It is in this particular scenario where the impact on the description of the cosmological data string SNIa+BAO+$H(z)$+LSS+CMB becomes extraordinary significant on statistical terms, since $\Delta\mathrm{AIC} > +10$ which means that a very strong evidence, in favor of this model, is found, when it is compared with the ΛCDM model. At very high redshift the physics of the type I RRVM with a threshold remain basically unaltered with respect to the ΛCDM, however, the activation of the dynamics of the vacuum at $z_* \simeq 1$ allows to suppress an exceedingly amount of structure in the universe, thus leading to a better description of the $f(z)\sigma_8(z)$ data set. On the contrary, non of the other models beyond the standard one is preferred by the cosmological data, and the DIC indicates moderate evidence against them ($-5 < \mathrm{DIC} < -2$). We would like to remark that even if the RRVM's under study are not favoured by the data, in all cases the values of $S_8 \equiv \sigma_8(0)\sqrt{\Omega_m^0/0.3}$ (or the analogous observable $\tilde{S}_8 \equiv S_8/\sqrt{\varphi_0}$ for the type II RRVM and the BD-ΛCDM models) remain compatible with recent weak lensing and galaxy clustering measurements,[84] hence smoothing out the σ_8-tension. Just by including the H_0 prior in

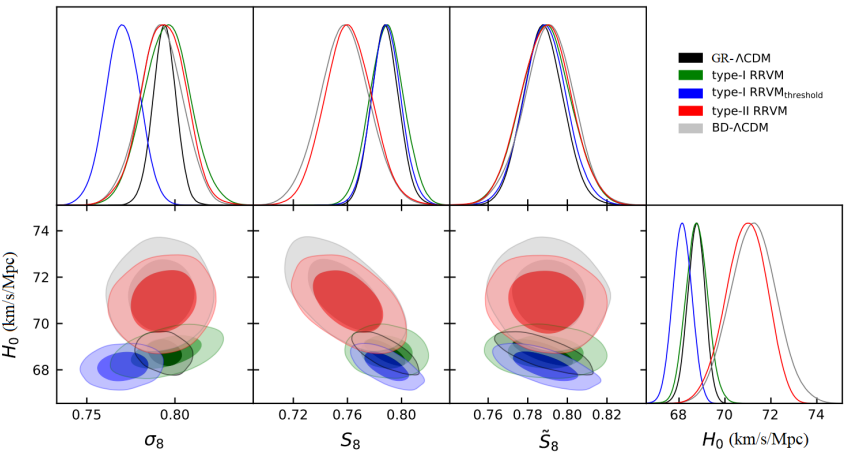

Fig. 1. The contour plots at 1σ and 2σ confidence level in the H_0-$\sigma_8, S_8, \tilde{S}_8$ planes and the corresponding one-dimensional posteriors for the GR- and BD-ΛCDM and the RRVM's obtained from the fitting analyses with our Baseline+H_0 data set. The type II model manifestly alleviates the H_0 tension without spoiling the σ_8 one, whereas the type I model with threshold redshift $z_* \simeq 1$ can fully solve the latter but cannot address the former.

the data set the results change in a very significant way as it can be observed from Table 2. The ΛCDM model, as well as, the two versions of the type I RRVM model are not able to accommodate high values of the H_0 parameter, hence, all of them show their inability to alleviate the H_0-tension. However, the DIC still decides very strongly in the case of the type I RRVM with threshold. On the other hand, the type II RRVM and the BD-ΛCDM model seem to have no problem to fit the H_0 prior since in both cases the fitting value for this parameter is $\simeq 71$km/s/Mpc. To fully appreciate how the cosmological models deal with the H_0 and the σ_8 tensions simultaneously, we have included Figure 1, where we have depicted the contour plots for the different models in the H_0-$\sigma_8, S_8, \tilde{S}_8$ planes of the parameter space. As mentioned before, the RRVM's are able to keep the values of the different parameters related with the structure formation $(\sigma_8, S_8, \tilde{S}_8)$ at an intermediate value between Planck measurements[10] and cosmic shear data.[84] Remarkably enough, in the case of the type II RRVM and the BD-ΛCDM models, the contour lines in Figure 1 show a preference for relatively high values of H_0 (the tension is lowered at $\sim 1.6\sigma$) while keeping $\sigma_8 \equiv \sigma_8(0)$ in the low value range (the tension remains at $\sim 0.4\sigma$), thus smoothing out both tensions at a time. We conclude that the models studied in this paper provide very interesting alternatives, either considering a time-evolving vacuum energy density or by extending the paradigm of General Relativity, to alleviate the H_0 and the σ_8 tensions. The better performance of the aforementioned models is reconfirmed by the Deviance Information Criterion, which points out that in some cases a very strong evidence in favor of a nonstandard model is found.

Acknowledgments

I would like to thank J. Solà Peracaula and A. Gómez-Valent for inviting me to speak in the CM3 parallel sesion "Status of the H_0 and σ_8 Tensions: Theoretical Models and Model-Independent Constraints of the MG16 Marcel Grossman Virtual Conference, July 5-10 2021. We also would like to thank the organizers of the MG16 for their great effort organizing such a great event. JdCP is supported by a FPI fellowship associated to the project FPA2016-76005-C2-1-P. JSP and CMP are partially supported by projects FPA2016-76005-C2-1-P (MINECO), 2017-SGR-929 (Generalitat de Catalunya) and MDM-2014-0369 (ICCUB). CMP is partially supported by the fellowship 2019 FI-B 00351. AGV is funded by the INFN – Project number 22425/2020.

Cosmological tensions: Hints for a new concordance model?

E. Di Valentino

School of Mathematics and Statistics, University of Sheffield, Hounsfield Road, Sheffield S3 7RH, United Kingdom
E-mail: e.divalentino@sheffield.ac.uk

The Cosmic Microwave Background (CMB) temperature and polarization anisotropy measurements have provided strong confirmation of the ΛCDM model of structure formation. Even if this model can explain incredibly well the observations in a vast range of scales and epochs, with the improvement of the experimental sensitivity, a few interesting tensions between the cosmological probes, and anomalies in the CMB data, have emerged with different statistical significance. While some portion of these discrepancies may be due to systematic errors, their persistence across probes strongly hints at cracks in the standard ΛCDM cosmological scenario. The most statistically significant is the Hubble constant puzzle and I will show a couple of interesting extended cosmological scenarios that can alleviate it.

Keywords: CMB; cosmology; H_0 tension.

1. Introduction

The aphorism "All the models are wrong, but some are useful" it is particularly true for the standard model adopted in cosmology. Actually, the model that has now practically been selected as the "standard" cosmological model is the Lambda Cold Dark Matter (ΛCDM) scenario, where Λ is the cosmological constant, that provides a remarkable fit to the bulk of available cosmological data.

However, despite its incredible success, ΛCDM harbours large areas of phenomenology and ignorance. For example, it still cannot explain key concepts in our understanding of the structure and evolution of the Universe, at the moment based on unknown quantities, that are also its largest components. In addition, their physical evidence comes from cosmological and astrophysical observations only, without strong theoretical motivations. In particular, the ΛCDM models is based on three unknown pillars:

- *Inflation*: an early stage of accelerated expansion which produces the initial, tiny, density perturbations, needed for structure formation,
- *Dark Matter*: a clustering matter component to facilitate structure formation,
- *Dark Energy*: an energy component to explain the current stage of accelerated expansion.

Furthermore, the ΛCDM model is based on the simplest form for these unknown quantities, mostly motivated by the computational simplicity, i.e. the theoretical

predictions under CDM for several observables are, in general, easier to compute and include fewer free parameters than most other solutions. These specific solutions for ΛCDM are:

- Inflation is given by a single, minimally coupled, slow-rolling scalar field;
- Dark Matter (DM) is a pressureless fluid made of cold, i.e., with low momentum, and collisionless particles;
- Dark Energy (DE) is a cosmological constant term.

Therefore, the 6 parameter ΛCDM model lacks the deep underpinnings a model requires to approach fundamental physics laws. It can be rightly considered, at best, as an effective theory of an underlying physical theory, yet to be discovered. In this situation, we must be careful not to cling to the model too tightly or to risk missing the appearance of departures from the paradigm. With the improvement of the number and the accuracy of the observations, deviations from ΛCDM may be expected. And, actually, discrepancies among key cosmological parameters of the models have emerged with different statistical significance. While some proportion of these discrepancies may have a systematic origin, their persistence across probes should require multiple and unrelated errors, strongly hinting at cracks in the standard cosmological scenario and the necessity of new physics. These tensions can indicate a failure of the canonical ΛCDM model.

2. The H_0 tension

The most statistically significant, long-lasting and widely persisting tension is the H_0 disagreement between the Planck estimate obtained assuming a "vanilla" ΛCDM cosmological model, i.e. $H_0 = 67.27 \pm 0.60$ km/s/Mpc at 68% CL,[1] and the local measurements obtained by the SH0ES collaboration, the so called R19[2] ($H_0 = 74.03 \pm 1.42$ km/s/Mpc at 68% CL) or R20[3] using the parallax measurements of Gaia EDR3 ($H_0 = 73.2 \pm 1.3$ km/s/Mpc at 68% CL).

However there are other many important measurements of the H_0 parameter. On the same side of Planck, i.e. preferring smaller values of H_0 we have the ground based CMB telescope, South Pole Telescope (SPT-3G)[4] that gives $H_0 = 68.8 \pm 1.5$ km/s/Mpc at 68% CL in ΛCDM, or Atacama Cosmology Telescope (ACT-DR4) + Wilkinson Microwave Anisotropy Probe (WMAP)[5] finding $H_0 = 67.6 \pm 1.1$ km/s/Mpc at 68% CL in ΛCDM. Moreover, there are the Baryon Acoustic Oscillations (BAO) + Big Bang Nucleosynthesis (BBN) from BOSS and eBOSS estimates,[6] that provide $H_0 = 67.35 \pm 0.97$ km/s/Mpc at 68% CL. These estimates are CMB independent but still ΛCDM dependent.

Moreover, we have many other direct late time measurements on the same side of SH0ES, i.e. preferring higher values of H_0 (see for example the compilation in Ref.[7] and references therein). For example, we have the measurements obtained from the Supernovae calibrated with the Cepheids,[3,8–10] or with the Tip of the Red Giant

Branch (TRGB),[8,11–14] where we find the well discussed Freedman et al. 2020 measurement[12] or the more updated Freedman 2021[15] that is completely in the middle between early and late measurements, so it can't really say anything about the tensions. Moreover, this TRGB-SNIa measurement has been reanalysed independently by Ref.[16] and we can see a shift towards higher values, more in agreement with SH0ES. Then we have the measurements obtained from the Supernovae calibrated with MIRAS,[17] variable red giant stars from older stellar populations, or the Megamaser Cosmology Project,[18] that measures H_0 avoiding any distance ladder and by providing the geometric distance directly into the Hubble flow. We have also measurements of the Hubble constant based on the Tully-Fisher Relation,[19,20] that are using as calibrators Cepheids and TRGB, or on the Surface Brightness Fluctuation,[21,22] that are substitutive distance ladder for long range indicator, and can be calibrated by both Cepheids and TRGB giving the same result,[21] or on Type II Supernovae[23] used as standardisable candles and calibrated again with both Cepheids and TRGB. Finally we have the strong lensing results, and, while the previous H0LiCOW[24] and STRIDES[25] results were more in agreement with SH0ES, the latest TDCOSMO+SLAC[26] constraints are shifted towards lower values, but with error bars much more weak, so they are not able to discriminate between SH0ES and Planck. This happens because the previous analyses were assuming a specific form for the mass density profile of the lens, and while this assumption is relaxed in a more agnostic approach, the constraints change significantly. This means that these kinds of measurements, even if cosmological model independent, are instead astrophysical model dependent.

The robustness of the H_0 disagreement can be proven considering several combinations of the late time measurements, as it has been done in Ref.,[7] where it is shown that also removing some of the most precise and strong measurements the discordance ranges between $\sim 3-6\sigma$, making it very difficult to be explained by systematic errors. Actually, we see a high precision and consistency of the data at both ends, the indirect ones preferring a lower value and the direct ones a higher value. Therefore, a possible solution should have enough rigor to explain multiple observations. A recent Review[15] seems to suggest that the situation is improving during the last 4 decades, with the H_0 measurement converging towards the same value. However, while in the past the tension was within the same types of measurements and at the same redshifts and thus pointing directly to systematics, now there are no late universe measurements below the early ones and vice versa, as expected in case of a scatter around the true value. Therefore, since it is hard to believe that a single type of systematic error could effectively resolve the Hubble constant tension, and because the discordance is robust under the removal of the measurements of any single type of object, mode or calibration, it is difficult to believe that unrelated systematic errors could coherently bias the measurements in the same direction and solve the H_0 puzzle.

3. Solutions

An alternative possibility for solving the Hubble tension is instead to change the assumptions about the cosmological model considered to derive the indirect constraints, modifying directly the three unknown pillars on which the standard vanilla ΛCDM is based.

3.1. *First pillar: Dark matter*

For example, we can consider modifications in the dark matter sector.

A classical extension is the effective number of relativistic degrees of freedom $N_{\rm eff}$,[27] i.e. additional relativistic matter at recombination, corresponding to a modification of the expansion history of the universe at early times, before the recombination epoch. The radiation density ρ_r can be recast as a function of the photon density ρ_γ, where we it is assumed the ratio $T_\nu/T_\gamma = (4/11)^{1/3}$ between the background temperatures of neutrinos and photons under the approximation of instantaneous neutrino decoupling:

$$\rho_r = \rho_\gamma \left[1 + \frac{7}{8}\left(\frac{4}{11}\right)^{4/3} N_{\rm eff}\right]. \tag{1}$$

The expected value is $N_{\rm eff} = 3.046$,[28–32] if we assume standard electroweak interactions and three active massless neutrinos, but can be larger in presence of extra relativistic particles at recombination, such as, for example, sterile neutrinos[33–37] or thermal axions,[38–45] or decaying dark matter.[46–48] Additional relativistic degrees of freedom other than the three standard model neutrinos will produce more radiation, smearing and shifting of the acoustic peaks in the damping tail of the CMB temperature power spectrum, and delaying the matter to radiation equivalence,[49,50] with a corresponding increase of the early Integrated Sachs-Wolfe (eISW) effect, and therefore of the amplitude of the peak around multipoles $\ell \sim 200$. This parameter was often considered to increase the H_0 estimate because of the strong positive correlation present between these two quantities. However, $N_{\rm eff}$ should be around $N_{\rm eff} \approx 3.95$ in order to obtain a value of H_0 from Planck 2018 + BAO + Pantheon in perfect agreement with SH0ES,[51] and this value is significantly excluded by the latest Planck 2018 data. In particular, even when $N_{\rm eff}$ can vary freely, the H_0 tension is still above 3.6σ, and therefore this is no longer a suitable solution.

3.2. *Second pillar: Dark energy*

For example, we can consider modifications in the dark energy sector.

A classical extension is a varying dark energy equation of state, that is a modification of the expansion history of the universe at late times, after the recombination

epoch. In this case we replace the cosmological constant Λ in the expansion rate of the Universe with a Dark Energy with an equation of state w free to vary. A dark energy component with a time-varying equation of state $w \equiv p_{\rm DE}/\rho_{\rm DE}$ modifies the Hubble rate through the first Friedmann equation:

$$H^2(z) = H_0^2 \left[\Omega_r(1+z)^4 + \Omega_m(1+z)^3 + \Omega_{\rm DE}(1+z)^{3(1+w)} + \Omega_k(1+z)^2\right] \quad (2)$$

where Ω_r, Ω_m, $\Omega_{\rm DE}$ and Ω_k are the density parameters, evaluated at present time, for radiation, matter, dark energy and curvature for, and for the case $w = -1$ the dark energy component acts as a cosmological constant of density parameter $\Omega_{\rm DE}$. Changing the dark energy equation of state w, we are introducing a geometrical degeneracy with the Hubble constant that will be unconstrained using the CMB data only, resulting in agreement with SH0ES within 2σ at the price of a phantom dark energy with $w < -1$. Actually, a likelihood analysis of Planck 2018 gives $w = -1.58^{+0.16}_{-0.35}$ at 68% CL and $H_0 > 69.9\,{\rm km\,s^{-1}\,Mpc^{-1}}$ at 95% CL.[1] A phantom Dark energy implies that the energy density of this component increases with time in an expanding universe that will end in a Big Rip.[52] Moreover, it has many theoretical problems, but there exist models that expect an effective energy density with a phantom equation of state that can avoid them.

3.3. *Third pillar: Inflation*

For example, we can consider modifications in the inflationary sector.

Actually, a strong correlation is present between the scalar spectral index n_s of the primordial density fluctuations and the Hubble constant H_0. Therefore it is natural to ask if the simple Harrison-Zel'dovich model is able to solve the Hubble tension, or if there is support for a more complicated perturbation spectrum.

The inflationary theory predicts that the primordial spectrum should be a power law with a value of the spectral index to be nearly one, $n_s \sim 1$, reflecting the constancy of the Hubble horizon during inflation, but at the same time not exactly one, due to the dynamics of the inflaton field. An exact value of $n_s = 1$ is indeed not expected in inflation and would coincide with the phenomenological model proposed by Harrison,[53] Zel'dovich,[54] and Peebles and Yu,[55] known as Harrison - Zel'dovich (HZ) spectrum, proposed well before the formulation of inflation, and corresponding to perfect scale-invariance of the fluctuations. This model has one parameter fewer than standard vanilla ΛCDM model, and it is therefore less complicated (from the point of view of the number of parameters). While it is still possible to have inflationary models with spectral index nearly identical to HZ, a measurement of n_s close to, but different from, one should be considered as a further corroboration of inflation. The presence of the Hubble tension in current cosmological data does not rule out a HZ spectrum at high statistical significance because it predicts a Hubble constant value in agreement with SH0ES.[56] See also Ref.[57] for an updated analysis of the available CMB data in light of the different inflationary scenarios.

3.4. *Examples of formally successful models in solving H_0*

It is possible to classify the formally successful models in solving H_0 looking at the Hubble constant that a model predicts once the Planck 2018 data are analysed (see Table B1 of Ref.[58]). In this case, without any consideration about the goodness of the fit, excellent solutions in solving the H_0 tensions are late time solutions, i.e. mostly Dark Energy and Modified gravity models.

In these class of models we can find for example the Parker Vacuum Metamorphosis (VM),[59–61] which has a phase transition in the nature of the vacuum, is physically motivated by quantum gravitational effects and can mimic a phantom DE behaviour at low redshifts. This model can solve the Hubble tension in an excellent way.[62–64] For this model the expansion rate above and below the phase transition for a flat universe is for $z > z_t$:

$$\frac{H^2}{H_0^2} = \Omega_m(1+z)^3 + \Omega_r(1+z)^4 - M\left\{1 - \left[3\left(\frac{4}{3\Omega_m}\right)^4 M(1-M-\Omega_r)^3\right]^{-1}\right\}, \quad (3)$$

and for $z \leq z_t$:

$$\frac{H^2}{H_0^2} = (1-M)(1+z)^4 + M\,, \quad (4)$$

where $M = m^2/(12H_0^2)$ and the redshift of the phase transition is

$$z_t = -1 + \frac{3\Omega_m}{4(1-M-\Omega_r)}\,. \quad (5)$$

Therefore, above the phase transition, the universe behaves as one with matter and radiation plus a constant, and after the phase transition it effectively has a dark radiation component that rapidly redshifts away leaving a de Sitter phase. The original model did not include an explicit high redshift cosmological constant and therefore we have:

$$\Omega_m = \frac{4}{3}\left[3M(1-M-\Omega_r)^3\right]^{1/4}\,, \quad (6)$$

i.e. the parameter M is fixed and depends on the matter density, and this model has the same number of degrees of freedom as ΛCDM. For this model, the DE equation of state behaviour is phantom today, and more deeply phantom in the past. In the case without the cosmological constant, instead, there is no DE above the phase transition. If we now fit the current cosmological data with this model, we obtain H_0 exactly in agreement with SH0ES even if BAO and Pantheon SnIa data are included.[63] However, this considerably worsened the fit of the full Planck2018+BAO+Pantheon data combination because the model fails to recover the shape of H(z) at low redshifts.

Additionally, we can also consider an extended VM where M is an independent parameter. In this case, the massive scalar field has a vacuum expectation value

that manifests as a cosmological constant, and the conditions that the transition happens in the past plus the Ω_{DE} is always positive are assumed:

$$\frac{4}{3}(1-M-\Omega_r) \leq \Omega_m \leq \frac{4}{3}\left[3M(1-M-\Omega_r)^3\right]^{1/4} , \tag{7}$$

This more ad hoc VM model that includes a cosmological constant, i.e. allowing the vacuum criticality parameter M to float, is even better in fitting the CMB cosmological data alone,[63] but still can't recover the shape of H(z) at low redshifts preferred by BAO+Pantheon.

The problem is that BAO+Pantheon measurements constrain the product of H_0 and the sound horizon r_s. Therefore, in order to have a higher H_0 value in agreement with SH0ES, we need r_s near 137 Mpc. However, Planck, by assuming ΛCDM, prefers r_s near 147 Mpc. Therefore, a cosmological solution that can increase H_0 and at the same time can lower the sound horizon inferred from CMB data is promising to put in agreement all the measurements.[65] Therefore, the late time solutions, as wCDM, are disfavored by the full dataset combination because they increase H_0 but leave r_s unaltered. On the contrary, the early time solutions, as $N_{\rm eff}$ or Early Dark Energy,[66–68] move in the right direction both the parameters, but can't solve completely the H_0 tension with SH0ES, as we can see in Fig. 3 of Ref.[69]

At this point, it is possible to classify the formally successful models in solving H_0 looking at the Hubble constant that a model predicts once the Planck 2018 data combined with additional probes are analysed (see Table B2 of Ref.[58]). In this case, again without any consideration about the goodness of the fit, excellent solutions in solving the H_0 tensions are mostly early time solutions.

However, we should be careful in ruling out all the late time solutions because of the disagreement with the BAO data. Let's consider for example an Interacting model IDE, where DM and DE share interactions other than gravitational. Actually, dark matter and dark energy are described as separate fluids not sharing interactions beyond gravitational ones, even if from a microphysical perspective it is hard to imagine how non-gravitational DM-DE interactions can be avoided, if not forbidden by a fundamental symmetry. At the background level, the conservation equations for the pressureless DM and DE components can be decoupled into two separate equations with an inclusion of an arbitrary function, Q, known as the coupling or interacting function:

$$\dot{\rho}_c + 3\mathcal{H}\rho_c = Q , \tag{8}$$

$$\dot{\rho}_{DE} + 3\mathcal{H}(1+w)\rho_{DE} = -Q . \tag{9}$$

We assume the phenomenological form for the interaction rate:

$$Q = \mathcal{H}\xi\rho_{DE} \tag{10}$$

proportional to the dark energy density ρ_{DE} and the conformal Hubble rate $\mathcal{H}$, via a negative dimensionless parameter ξ quantifying the strength of the coupling, to

avoid early-time instabilities. In this scenario of IDE the tension on H_0 between the Planck satellite and SH0ES is completely solved. The coupling could affect the value of the present matter energy density Ω_m. Therefore, if within an interacting model Ω_m is smaller (because for negative ξ the dark matter density will decay into the dark energy one), a higher value of H_0 would be required in order to satisfy the peaks structure of CMB observations, which accurately determine the value of $\Omega_m h^2$ (see Table 1 of Ref.[70]). Therefore, we can safely combine the two datasets together, and we obtain a non-zero dark matter-dark energy coupling ξ at more than 5 standard deviations, i.e. $\xi = -0.66^{+0.09}_{-0.13}$ at 68% CL. For this model we have only an upper limit for the matter density Ω_m, however the IDE scenario is still in agreement with the local structures. Actually, within interacting cosmologies the growth of dark matter perturbations is larger than in uncoupled models.[71] This feature is general for models with negative coupling and in which the energy exchange among the dark sectors is proportional to ρ_{DE}, due to a suppression of the friction term and an enhancement of the source term in the differential growth equation.

For this model, the addition of low-redshift measurements, as BAO data, is extremely important, because it breaks the correlation between the parameters that can produce a fake detection for the coupling (see Ref.[72]). And Planck 2018 + BAO still hints at the presence of a coupling, albeit at a lower statistical significance. Also for these datasets the Hubble constant value is larger than that obtained in the case of a pure ΛCDM scenario, enough to bring the H_0 tension at 2.4σ.[73] This residual tension is however of difficult interpretation. In fact, BAO are formed in the early universe, when baryons are strongly coupled to photons, and the gravitational collapse due to the CDM is counterbalanced by the radiation pressure. Sound waves that propagate in the early universe imprint a characteristic scale on the CMB. Since the scale of these oscillations can be measured at recombination, BAO is considered a "standard ruler". These fluctuations have evolved and we can observe BAO at low redshifts in the distribution of galaxies. Since the data reduction process leading to these measurements requires assumptions about the fiducial cosmology, BAO is model dependent, and the model assumed to extrapolate the data is the standard ΛCDM scenario. In other words, the tension between Planck + BAO and SH0ES could be due to a statistical fluctuation in this case because the modified scenario of interacting dark energy could affect the BAO measurements. In fact, the full procedure which leads to the BAO constraints carried out by the different collaborations might be not necessarily valid in extended DE models. For instance, the BOSS collaboration advises caution when using their BAO measurements (both the pre- and post- reconstruction measurements) in more exotic dark energy cosmologies, because their reliability has been assessed only for modifications of the expansion history before recombination, and late modifications that can be parametrized by $w_0 w_a$. Therefore, BAO constraints themselves might need to be revised in a non-trivial manner when applied to constrain extended dark energy cosmologies, such as the IDE model that is showing a coupling different from ΛCDM at more than 5σ.

The IDE model can also solve the M_B tension. It has been pointed out in Ref.[74] that the SH0ES Collaboration, combining together anchors, cepheids and calibrators, produces a constraint on the SN absolute magnitude M_B, that depends on the astrophysical properties of the sources and is independent of cosmology. After that, in order to obtain the H_0 measurement, it uses the Hubble-ow supernovae in the redshift range $0.023 \leq z \leq 0.15$ to probe the luminosity distance-redshift relation, and it adopts a cosmography with $q_0 = 0.55$ and $j_0 = 1$. Therefore, the use of a prior on the Hubble constant could bias the conclusions about hockey-stick dark energy scenarios, i.e. models that have a transition at very-low redshift ($z \leq 0.1$), that can solve the Hubble tension producing a disagreement with M_B at more than 5σ.[75] Therefore, rather than explaining the H_0 tension, one should instead focus on the supernova absolute magnitude tension M_B, because the SH0ES team does not directly measure H_0. The M_B approach allows to skip the cosmography part, and to avoid the double counting of SN in the redshift range $0.023 \leq z \leq 0.15$ when combined with the Pantheon sample. Actually, imposing a H_0 prior, the whole information on the shape of the SN magnitude-redshift relation is lost, as also noticed by Ref.[76] If we consider the M_B parameter, instead, we have that the Planck constraint on the the SN absolute magnitude using the parametric-free inverse distance ladder predicts $M_B = -19.401 \pm 0.027$ mag, while the the SN measurements from SH0ES corresponds to $M_B = -19.244 \pm 0.037$ mag, corresponding to a 3.4σ tension. A classification of the models that can solve the M_B tension has been performed in Ref.,[77] finding that the best model is a closed universe with the electron mass free to vary.[78]

When an IDE model is considered, instead, the M_B tension is always at 2.4σ considering a combination of Pantheon + BAO + BBN, and is completely solved below 1σ when a gaussian prior on M_B is included, with an indication for a coupling different from zero at more than 95% CL.[79] Therefore, an IDE model can alleviate the M_B tension, as well as the H_0 disagreement, and as it is shown in Ref.[79] it is not disfavoured by the Pantheon magnitude-redshift relation.

4. Conclusions

To summarize the state-of-the-arte we have a long-standing Hubble tension that is presenting a serious limitation to precision cosmology. A solution to this problem is mandatory at this point.

On one side early time modifications of the standard models seem most promising for putting in agreement CMB and SH0ES, and agree also with BAO+Pantheon data, but unfortunately they don't completely solve the H_0 tension. On the other hand, late time modifications are instead more powerful in solving the H_0 tension, but are producing a disagreement with the additional BAO+Pantheon data. However, we can have working models, such as the simple IDE scenario, that can relieve the H_0 tension hinting to an interaction different from zero at more than 5σ. However, when BAO data are added in the analysis the Hubble constant tension is

restored at about 2.4σ, and this residual tension is difficult to interpret because of the reliability of the BAO data for this model. Alternative solutions can involve the inflationary paradigm, and in this context we saw that a HZ spectrum can solve the H_0 tension without new physics and with fewer parameters free to vary, but is disfavoured by a model comparison with the standard ΛCDM model.

Concluding, more than 300 models have been proposed (see Ref.[58]) to solve the Hubble tension, but at the moment no specific proposal makes a strong case for being highly likely or far better than all others. We therefore need new observations and the investigation of alternative theoretical models and solutions.

Solving both H_0 and σ_8 tensions in $f(T)$ gravity

Emmanuel N. Saridakis

E-mail: msaridak@noa.gr

We report how to alleviate both the H_0 and σ_8 tensions simultaneously within $f(T)$ gravity. In particular, we consider the parametrization $f(T) = -T - 2\Lambda/M_P^2 + \alpha T^\beta$, where two out of the three parameters are independent. This model can efficiently fit observations solving the two tensions. To our knowledge, this is the first time where a modified gravity theory can alleviate both H_0 and σ_8 tensions simultaneously, hence, offering an additional argument in favor of gravitational modification.

Keywords: H_0 tension; σ_8 tension; $f(T)$ gravity; MG16 Proceedings.

1. Introduction

It is now well established that the Universe at late times experienced the transition from the matter era to the accelerated expansion phase. Although the simplest explanation would be the consideration of the cosmological constant, the corresponding problem related to the quantum-field-theoretical calculation of its value, as well as the possibility of a dynamical nature, led to two main paths of constructing extended scenarios. The first is to maintain general relativity as the underlying theory of gravity, and consider new, exotic forms of matter that constitute the concept of dark energy.[1,2] The second is to construct extended or modified theories of gravity, that posses general relativity as a low-energy limit, but which in general provide the extra degrees of freedom that can drive the dynamical universe acceleration.[3,4]

With the accumulation of cosmological data, experimental tensions may arise within ΛCDM cosmology. If they were to remain under the increasing precision of experimental observations, they would constitute, in a statistical sense, clear indications of new physics beyond ΛCDM. One recently well-debated tension relates the value of the Hubble parameter at present time H_0 measured from the cosmic microwave background (CMB) temperature and polarization data by the Planck Collaboration[5] to be $H_0 = 67.37 \pm 0.54\ \mathrm{km\,s^{-1}\,Mpc^{-1}}$, to the one from local measurements of the Hubble Space Telescope[6] yielding $H_0 = 74.03 \pm 1.42\ \mathrm{km\,s^{-1}\,Mpc^{-1}}$. Recent analyses with the combination of gravitational lensing and time-delay effects data reported a significant deviation[7] at 5.3σ. Another potential tension concerns the measurements of the parameter σ_8, which quantifies the gravitational clustering of matter from the amplitude of the linearly evolved power spectrum at the scale of $8h^{-1}$Mpc. Specifically, a possible deviation was noticed between measurements of CMB and LSS surveys, namely, between Planck[5] and SDSS/BOSS.[8,9] Although these two tensions could in principle arise from unknown systematics, the possibility

of physical origin puts the standard lore of cosmology into additional investigations, by pointing to various extensions beyond ΛCDM.

In this work we consider systematically the H_0[10] and σ_8[11] tensions, and report how to alleviate both simultaneously within $f(T)$ gravity, based on the analysis of.[12] We exploit the effective field theory (EFT) of torsional gravity, a formalism that allows for a systematic investigation of the background and perturbations separately. This approach was first developed early for curvature gravity,[13] and recently it was extended to torsional gravity.[14,15] In order to address cosmological tensions, we identify the effects of gravitational modifications within the EFT on the dynamics of the background and of linear perturbation levels. This will allow us to construct specific models of $f(T)$ gravity providing adequate deviation from ΛCDM that can alleviate H_0 and σ_8 tensions.

2. Effective field theory approach

We start our analysis by the question of whether both tensions can be alleviated simultaneously via gravitational modifications in a much general framework. Indeed, the H_0 tension reveals a universe that is expanding faster at late times than that from a cosmological constant preferred by CMB data, while a lower value of σ_8 than the one of CMB most likely ΛCDM would imply that matter clusters either later on or less efficiently. Hence, these two observations seem to indicate that there might be "less gravitational power" at intermediate scales, which phenomenologically advocates a possible modification of gravitation. Accordingly, in this work we address the aforementioned question within the EFT framework for torsional gravity.

For a general curvature-based gravity, the action following the EFT approach in the unitary gauge, invariant by space diffeomorphisms, which expanded around a flat FRW metric $ds^2 = -dt^2 + a^2(t)\,\delta_{ij}dx^i dx^j$, is given by

$$\begin{aligned} S = \int d^4x \Big\{ \sqrt{-g}\Big[\frac{M_P^2}{2}\Psi(t)R - \Lambda(t) - b(t)g^{00} \\ + M_2^4(\delta g^{00})^2 - \bar{m}_1^3\delta g^{00}\delta K - \bar{M}_2^2\delta K^2 - \bar{M}_3^2\delta K^\nu_\mu \delta K^\mu_\nu \\ + m_2^2 h^{\mu\nu}\partial_\mu g^{00}\partial_\nu g^{00} + \lambda_1\delta R^2 + \lambda_2\delta R_{\mu\nu}\delta R^{\mu\nu} + \mu_1^2\delta g^{00}\delta R\Big] \\ + \gamma_1 C^{\mu\nu\rho\sigma}C_{\mu\nu\rho\sigma} + \gamma_2\epsilon^{\mu\nu\rho\sigma}C_{\mu\nu}{}^{\kappa\lambda}C_{\rho\sigma\kappa\lambda} \\ + \sqrt{-g}\Big[\frac{M_3^4}{3}(\delta g^{00})^3 - \bar{m}_2^3(\delta g^{00})^2\delta K + \cdots\Big]\Big\}\,, \end{aligned} \tag{1}$$

where $M_P = (8\pi G_N)^{-1/2}$ is the reduced Planck mass with G_N the Newtonian constant. R is the Ricci scalar corresponding to the Levi-Cività connection, $C^{\mu\nu\rho\sigma}$ is the Weyl tensor, δK^ν_μ is the perturbation of the extrinsic curvature, and the functions $\Psi(t)$, $\Lambda(t)$, $b(t)$ are determined by the background evolution.

When the underlying theory also includes torsion,[14] one can generalize the EFT action as[14,15]

$$S = \int d^4x\sqrt{-g}\Big[\frac{M_P^2}{2}\Psi(t)R - \Lambda(t) - b(t)g^{00} + \frac{M_P^2}{2}d(t)T^0\Big] + S^{(2)}\,. \tag{2}$$

To compare with the effective action for curvature-based gravity (1), one reads that at background level there is additionally the zeroth part T^0 of the contracted torsion tensor $T^{0\mu}_{\ \ \mu}$, with its time-dependent coefficient $d(t)$. Furthermore, the perturbation part $S^{(2)}$ contains all operators of the perturbation part of (1), plus pure torsion terms including δT^2, $\delta T^0 \delta T^0$, and $\delta T^{\rho\mu\nu}\delta T_{\rho\mu\nu}$, and extra terms that mix curvature and torsion, namely, $\delta T \delta R$, $\delta g^{00}\delta T$, $\delta g^{00}\delta T^0$, and $\delta K \delta T^0$, where $T \equiv \frac{1}{4}T^{\rho\mu\nu}T_{\rho\mu\nu} + \frac{1}{2}T^{\rho\mu\nu}T_{\nu\mu\rho} - T_{\rho\mu}{}^{\rho}T^{\nu\mu}{}_{\nu}$ is the torsion scalar. Adding the matter action S_m to the effective action of torsional-based gravity (2) and then performing variation, one obtains the Friedmann equations to be:[14]

$$H^2 = \frac{1}{3M_P^2}\big(\rho_m + \rho_{DE}^{\rm eff}\big) \ , \tag{3}$$
$$\dot{H} = -\frac{1}{2M_P^2}\big(\rho_m + \rho_{DE}^{\rm eff} + p_m + p_{DE}^{\rm eff}\big) \ ,$$

and where

$$\rho_{DE}^{\rm eff} = b + \Lambda - 3M_P^2\Big[H\dot{\Psi} + \frac{dH}{2} + H^2(\Psi - 1)\Big] \ , \tag{4}$$
$$p_{DE}^{\rm eff} = b - \Lambda + M_P^2\Big[\ddot{\Psi} + 2H\dot{\Psi} + \frac{\dot{d}}{2} + (H^2 + 2\dot{H})(\Psi - 1)\Big] \ ,$$

are, respectively, the effective DE density and pressure in the general torsional gravity. Moreover, we treat the matter sector as dust that satisfies the conservation equation $\dot{\rho}_m + 3H(\rho_m + p_m) = 0$, which in terms of redshift leads to $\rho_m = 3M_P^2 H_0^2 \Omega_{m0}(1+z)^3$, with Ω_{m0} the value of $\Omega_m \equiv 8\pi G_N \rho_m/(3H^2)$ at present.

3. Model independent analysis

In general, to avoid the H_0 tension one needs a positive correction to the first Friedmann equation at late times that could yield an increase in H_0 compared to the ΛCDM scenario. As for the σ_8 tension, we recall that in any cosmological model, at sub-Hubble scales and through the matter epoch, the equation that governs the evolution of matter perturbations in the linear regime is[16]

$$\ddot{\delta} + 2H\dot{\delta} = 4\pi G_{\rm eff}\rho_m \delta \ , \tag{5}$$

where $G_{\rm eff}$ is the effective gravitational coupling given by a generalized Poisson equation. In general, $G_{\rm eff}$ differs from the Newtonian constant G_N, and thus contains information from gravitational modifications (note that $G_{\rm eff} = G_N$ in ΛCDM cosmology). Solving for $\delta(a)$ provides the observable quantity $f\sigma_8(a)$, following the definitions $f(a) \equiv d\ln\delta(a)/d\ln a$ and $\sigma(a) = \sigma_8\delta(1)/\delta(a=1)$. Hence, alleviation of the σ_8 tension may be obtained if $G_{\rm eff}$ becomes smaller than G_N during the growth of matter perturbations and/or if the "friction" term in (5) increases.

To grasp the physical picture, we start with a simple case: $b(t) = 0$ and $\Lambda(t) = \Lambda = const$ [b and Λ are highly degenerate as shown in (4)], while $\Psi(t) = 1$. Hence, from (2), with the above coefficient choices, the only deviation from ΛCDM

at the background level comes from the term $d(t)T^0$, and we remind that in FRW geometry $T^0 = H$ when evaluated on the background. In this case, the first Friedmann equation in (3), using for convenience the redshift $z = -1 + a_0/a$ as the dimensionless variable and setting $a_0 = 1$, yields

$$H(z) = -\frac{d(z)}{4} + \sqrt{\frac{d^2(z)}{16} + H^2_{\Lambda\mathrm{CDM}}(z)}\ , \tag{6}$$

where $H_{\Lambda\mathrm{CDM}}(z) \equiv H_0\sqrt{\Omega_m(1+z)^3 + \Omega_\Lambda}$ is the Hubble rate in ΛCDM, with $\Omega_m = \rho_m/(3M_p^2H^2)$ the matter density parameter and primes denote derivatives with respect to z. Accordingly, if $d < 0$ and is suitably chosen, one can have $H(z \to z_{\mathrm{CMB}}) \approx H_{\Lambda\mathrm{CDM}}(z \to z_{\mathrm{CMB}})$ but $H(z \to 0) > H_{\Lambda\mathrm{CDM}}(z \to 0)$; i.e., the H_0 tension is solved [one should choose $|d(z)| < H(z)$, and thus, since $H(z)$ decreases for smaller z, the deviation from ΛCDM will be significant only at low redshift]. Additionally, since the friction term in (5) increases, the growth of structure gets damped, and therefore, the σ_8 tension is also solved [note that since we have imposed $\Psi = 1$, then $G_{\mathrm{eff}} = G_N$ as one can verify from (2) and (3); namely, the contributions from T^0 vanish at first order in perturbations].

Furthermore, for typical values that lie well within the 1σ intervals of the $H(z)$ redshift surveys, it is expected that CMB measurements will be sensitive to such a deviation from the ΛCDM scenario for nonvanishing T^0 at early times. Actually, the T^0 operator acts in a similar way as a conventional cosmological constant. Thus, it adds yet another new functional form to parametrize the background and leads to more flexibility in fitting redshift and clustering measurements.

4. $f(T)$ gravity and cosmology

In this section we propose concrete models of torsional modified gravity that can be applied to alleviate the two cosmological tensions based on the torsional EFT dictionary. In particular, we focus on the well-known class of torsional gravity, namely, the $f(T)$ gravity,[17] which is characterized by the action $S = \frac{M_P^2}{2}\int d^4x e f(T)$, with $e = \det(e^A_\mu) = \sqrt{-g}$ and e^A_μ the vierbein, and thus by the Friedmann equations

$$\begin{aligned} H^2 &= \frac{\rho_m}{3M_P^2} + \frac{T}{6} - \frac{f}{6} + \frac{Tf_T}{3} \\ \dot{H} &= -\frac{1}{2M_P^2}(\rho_m + p_m) + \dot{H}(1 + f_T + 2Tf_{TT}), \end{aligned} \tag{7}$$

with $f_T \equiv \partial f/\partial T$, $f_{TT} \equiv \partial^2 f/\partial T^2$, where we have applied $T = 6H^2$ in flat FRW geometry (we follow the convention of[14]). Therefore, $f(T)$ gravity can arise from the general EFT approach to torsional gravity by choosing $\Psi = -f_T$, $\Lambda = \frac{M_P^2}{2}(Tf_T - f)$, $b = 0$, $d = 2\dot{f}_T$,[14] and can restore GR by choosing $f(T) = -T - 2\Lambda/M_P^2$.

The above EFT approach holds for every $f(T)$ gravity by making a suitable identification of the involved time-dependent functions. For instance, we consider the following ansatz: $f(T) = -[T + 6H_0^2(1 - \Omega_{m0}) + F(T)]$, where $F(T)$ describes

the deviation from GR [note, however, that in FRW geometry, apart from the regular choice $F = 0$, the ΛCDM scenario can also be obtained for the special case $F(T) = c\,T^{1/2}$ too, with c a constant]. Under these assumptions, the first Friedmann equation becomes

$$T(z) + 2\frac{F'(z)}{T'(z)}T(z) - F(z) = 6H^2_{\Lambda CDM}(z)\ . \tag{8}$$

In order to solve the H_0 tension, we need $T(0) = 6H_0^2 \simeq 6(H_0^{CC})^2$, with $H_0^{CC} = 74.03\ \mathrm{km\,s^{-1}\,Mpc^{-1}}$ following the local measurements,[6] while in the early era of $z \gtrsim 1100$ we require the Universe expansion to evolve as in ΛCDM, namely $H(z \gtrsim 1100) \simeq H_{\Lambda CDM}(z \gtrsim 1100)$. This requirement follows from the fact that we are considering modifications kicking in only at late times, and therefore, the results in tension from CMB analysis performed within ΛCDM remain unaffected. This implies $F(z)|_{z\gtrsim 1100} \simeq cT^{1/2}(z)$ (the value $c = 0$ corresponds to standard GR, while for $c \neq 0$ we obtain ΛCDM too). Note that, in this case the effective gravitational coupling is given by[18]

$$G_{\rm eff} = \frac{G_N}{1 + F_T}\ . \tag{9}$$

Therefore, the perturbation equation at linear order (5) becomes

$$\delta'' + \left[\frac{T'(z)}{2T(z)} - \frac{1}{1+z}\right]\delta' = \frac{9H_0^2\Omega_{m0}(1+z)}{[1 + F'(z)/T'(z)]T(z)}\delta\ , \tag{10}$$

where $\delta \equiv \delta\rho_m/\rho_m$ is the matter overdensity. Since around the last scattering moment $z \gtrsim 1100$ the Universe should be matter-dominated, we impose $\delta'(z)|_{z\gtrsim 1100} \simeq -\frac{1}{1+z}\delta(z)$, while at late times we look for $\delta(z)$ that leads to an $f\sigma_8$ in agreement with redshift survey observations.

By solving (8) and (10) with initial and boundary conditions at $z \sim 0$ and $z \sim 1100$, we can find the functional forms for the free functions of the $f(T)$ gravity that we consider, namely, $T(z)$ and $F(z)$, that can alleviate both H_0 and σ_8 tensions. We find two such forms for $F(T)$. Both models approach the ΛCDM scenario at $z \gtrsim 1100$, with Model-1 approaching $F = 0$ and hence restoring GR, while Model-2 approaches $F \propto T^{1/2}$, and thus it reproduces ΛCDM. In particular, we find that we can well fit the numerical solutions of Model-1 by

$$F(T) \approx 375.47\Big(\frac{T}{6H_0^2}\Big)^{-1.65}\ , \tag{11}$$

and of Model-2 by

$$F(T) \approx 375.47\Big(\frac{T}{6H_0^2}\Big)^{-1.65} + 25T^{1/2}\ . \tag{12}$$

Note that, the first term of Model-2, which coincides with Model-1, provides a small deviation to ΛCDM at late times, while it decreases rapidly to become negligible in the early Universe. In addition, we examine $G_{\rm eff}$ given by (9) for the two models (11) and (12), which are displayed in Fig. 1. As expected, at high redshifts in both

models, $G_{\rm eff}$ becomes G_N, recovering the ΛCDM paradigm. At very low redshifts, $G_{\rm eff}$ becomes slightly higher than G_N, increasing slightly the gravitational strength. This gravitational modification is in competition at late times with the accelerating expansion. It turns out that the effect of an increased cosmic acceleration with respect to ΛCDM in our $f(T)$ gravity models dominates over the stronger gravitational strength in the clustering of matter. We check that both models can easily pass the BBN constraints (which demand[19] $|G_{\rm eff}/G_N - 1| \leq 0.2$), as well as the ones from the Solar System [which demand[20] $|G'_{\rm eff}(z=0)/G_N| \leq 10^{-3}h^{-1}$ and $|G''_{\rm eff}(z=0)/G_N| \leq 10^{5}h^{-2}$].

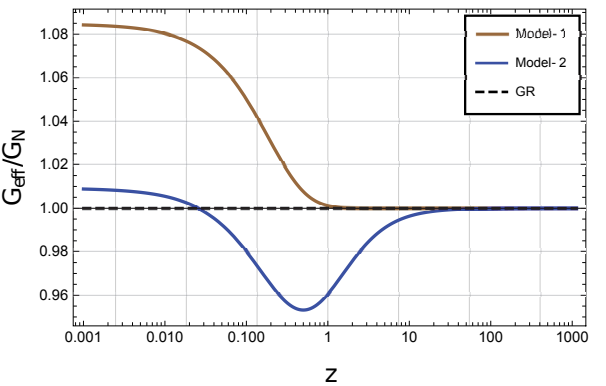

Fig. 1. Redshift evolution of $G_{\rm eff}/G_N$ in Model-1 (brown solid line) and Model-2 (blue solid line) and their comparison to the GR case (black dashed line).

Now we show how Model-1 and Model-2 can alleviate the H_0 and σ_8 tension by solving the background and perturbation equations. In Fig. 2 we present the evolution of $H(z)$, while in Fig. 3 the evolution of $f\sigma_8$, for two $f(T)$ models, and we compare them with ΛCDM. We stress that the H_0 tension can be alleviated as $H(z)$ remains statistically consistent for all CMB and CC measurements at all redshifts. We remind the reader that the two $f(T)$ models differing merely by a term $\propto T^{1/2}$, which does not affect the background as explained before, are degenerate at the background level. However, at the perturbation level, the two models behave differently as their gravitational coupling $G_{\rm eff}$ differs.

We further stress that both models can alleviate the σ_8 tension, and fit efficiently to BAO and LSS measurements. Note that at high redshifts ($z \geq 2$), Model-2 approaches ΛCDM slower than Model-1, but in a way that is statistically indistinguishable for present-day data. Nevertheless, future high-redshift surveys such as eBOSS for quasars and Euclid[24] for galaxies have the potential to discriminate among the predictions of $f(T)$ gravity and the ΛCDM scenario. Moreover, the clusters and CMB measurements on σ_8 are in good agreement in our models, as the CMB preferred values in ΛCDM get further lowered than local ones from rescaling

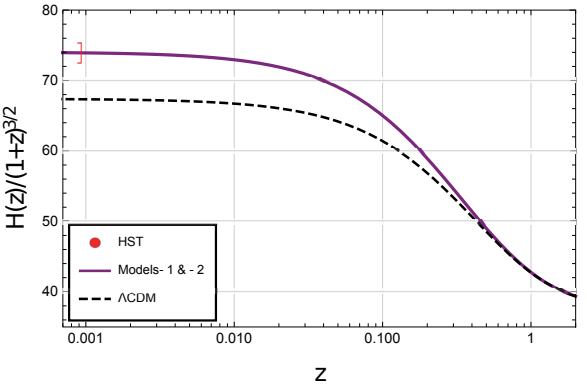

Fig. 2. Evolution of the Hubble parameter $H(z)$ in the two $f(T)$ models (purple solid line) and in ΛCDM cosmology (black dashed line). The red point represents the latest data from extragalactic Cepheid-based local measurement of H_0 provided in.[6]

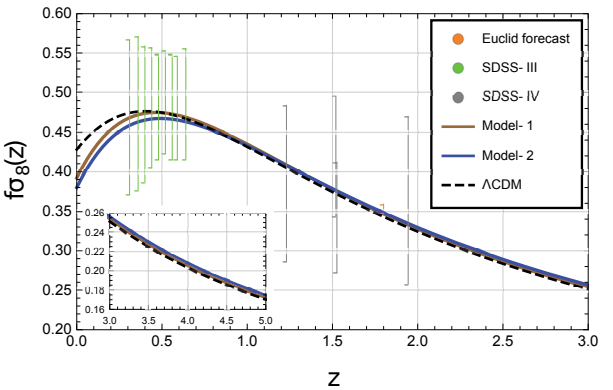

Fig. 3. Evolution of $f\sigma_8$ in Model-1 (brown solid line) and Model-2 (blue solid line) of $f(T)$ gravity and in ΛCDM cosmology (black dashed line). The green data points are from BAO observations in SDSS-III DR12,[21] the gray data points at higher redshift are from SDSS-IV DR14,[22] while the red point around ~ 1.8 is the forecast from Euclid.[23] The subgraph in the left bottom displays $f\sigma_8$ at high redshift $z = 3 \sim 5$, which shows that the curve of Model-2 is above the one of Model-1 and ΛCDM scenario and hence approaches ΛCDM slower than Model-1.

σ_8 by the ratio of the growth factors in $f(T)$ gravity and ΛCDM. More explicitly,

$$\sigma_8^{f(T)}(z=0) = \frac{D^{f(T)}(z=0)}{D^{\Lambda}(z=0)} \frac{D^{\Lambda}(z_{\rm eff})}{D^{f(T)}(z_{\rm eff})} \sigma_8^{\Lambda}(z=0), \tag{13}$$

where $D(z)$ is the growth factor, $f(T)$ and Λ denote our models and ΛCDM respectively, and $z_{\rm eff}$ is the effective redshift of the measurements ($z_{\rm eff} \sim 0.1$ for clusters experiments and $z_{\rm eff} \sim 1100$ for CMB temperature fluctuations observations). It turns out that, as at high redshift, $z_{\rm eff} \sim 1100$, the growth factor is the same in either our $f(T)$-models or in ΛCDM, but at low redshift, $z_{\rm eff} \sim 0.1$, the growth factor is approximately 1.03 bigger in the later compared to the formers, cluster

σ_8-measurements get bigger by about such an amount reducing the gap with CMB preferred value in this modified gravity scenario.

In short summary, we conclude that the class of $f(T)$ gravity: $f(T) = -T - 2\Lambda/M_P^2 + \alpha T^\beta$, where only two out of the three parameters Λ, α, and β are independent (the third one is eliminated using Ω_{m0}), can alleviate both H_0 and σ_8 tensions with suitable parameter choices. Moreover, such kinds of models in $f(T)$ gravity could also be examined through galaxy-galaxy lensing effects,[25] strong lensing effects around black holes[26] and gravitational wave experiments.[15]

5. Conclusions

In this work we reported how $f(T)$ gravity can alleviate both H_0 and σ_8 tensions simultaneously. Working within the EFT framework, torsional gravity theories can be identified as the EFT operators that allow us to extract the evolution equations of the background and of the perturbations in a model-independent manner. This allows us to address in a systematic way how tensions amongst the observational measurements, such as the ones on H_0 and σ_8, can be relaxed. Following these considerations, we constructed concrete models from specific Lagrangians in $f(T)$ gravity, describing cosmological scenarios where these tensions fade away. Imposing initial conditions at the last scattering that reproduce the ΛCDM scenario, and imposing the late-time values preferred by local measurements, we reconstructed two particular forms of $f(T)$. These models are well described by the parametrization: $f(T) = -T - 2\Lambda/M_P^2 + \alpha T^\beta$. To our knowledge, this is the first time where both H_0 and σ_8 tensions are simultaneously alleviated by a modified gravity theory.

We present a fully relativistic framework to evaluate the impact of stochastic inhomogeneities on the prediction of the Hubble-Lemaître diagram. In this regard, we relate the fluctuations of the luminosity distance-redshift relation in the Cosmic Concordance model to the intrinsic uncertainty associated to the estimation of cosmological parameters from high-redshift surveys (up to z = 4). Within this framework and according to the specific of forthcoming surveys as Euclid Deep Survey and LSST, we show that the cosmic variance associated with the measurement of the Hubble constant will not exceed 0.1 %. Thanks to our results, we infer that deep surveys will provide an estimation of the the Hubble constant H_0 which will be more precise than the one obtained from local sources, at least in regard of the intrinsic uncertainty related to a stochastic distribution of inhomogeneities.

Keywords: Cosmology; Large Scale Structure; Inhomogeneous Universe; Hubble tension

1. Introduction

Along this work, we will summarize the results obtained in Fanizza et al. (2021)[1] and presented at the parallel session *"Status of the H_0 and σ_8 Tensions: Theoretical Models and Model-Independent Constraints"* of the 16th Marcel Grossmann meeting. In particular, we will quantify the cosmic variance concerning the estimation of H_0 from forthcoming high redshift survey with limited sky coverage.

Indeed, the best-fit of the CMB data[2] allows us to infer the value of few cosmological parameters with the highest precision achievable so far in cosmology. Among these parameters, the estimation of H_0, namely the current expansion rate of the Universe, has gained great interest for the cosmologists because of an increasing tension emerging against the value of H_0 itself as estimated from local measurements.[3]

This tension is almost of 5σ, since CMB measurements provide[2] a value for $H_0 = 67.36 \pm 0.54$ km s^{-1} Mpc^{-1}, whereas late time estimations based on local probes, such as Supernovae Ia (SnIa), return[3] $H_0 = 73.2 \pm 1.3$ km s^{-1} Mpc^{-1}.

Given this tension and working within the conservative framework of ΛCDM model, our main interest is to understand whether, in view of the forthcoming Large Scale Structure (LSS) surveys, there could be any theoretical bias increasing the standard deviation in order to alleviate the above-mentioned tension. A first attempt to address this point has been provided in Ben-Dayan et al. (2014),[4] where

the effect of velocity dispersion of local SnIa (at redshift lower than 0.1) has been studied and it has been shown that it can introduce a further intrinsic error in the local estimation of H_0 of $\sim 1\%$. This result is in agreement with subsequent analysis,[5] leading to an effect which is large but unfortunately not enough to resolve the tension. Our goal here is to extend the analysis to higher redshifts ($z \leq 3.85$), including then also lensing effects to the analysis, in order to forecast the estimated precision for forthcoming surveys, just like Euclid Deep Survey (EDS) and LSST. To this aim, we will assume that the new generation of standard candles known as Superluminous Supernovae (SLSNe) will provide a suitable dataset, following what has been recently claimed in Inserra et al. (2021).[6]

In Sect. 2 we present the estimator for the cosmic variance in realistic high redshift surveys. In Sect. 3, we recall and discuss the analytic tool, such as the 2-point correlation function of the luminosity distance-redshift relation and its monopole, needed for our estimation. In Sect. 4, we generate a survey according to the specific of forthcoming surveys and forecast the expected cosmic variance. In Sect. 5 our results are summarized and discussed.

2. Local measurements

In order to extend the analysis of Ben-Dayan et al. (2014)[4] to higher redshift, we first need to go beyond the linear relation between luminosity distance and redshift $d_L = z/H_0$. To this aim, we then refer to the luminosity distance-redshift relation $d_L(z)$ in the homogenous and isotropic ΛCDM model

$$d_L(z) = \frac{1+z}{H_0} \int_0^z \frac{dz'}{\sqrt{\Omega_{m0}(1+z')^3 + 1 - \Omega_{m0}}}, \tag{1}$$

where H_0 is indeed the Hubble constant and Ω_{m0} is the energy density of the matter today. Eq. (1) then provides an estimator for H_0 at higher redshifts as

$$H_0 = \frac{1+z}{d_L(z)} \int_0^z \frac{dz'}{\sqrt{\Omega_{0m}(1+z')^3 + 1 - \Omega_{0m}}}\,. \tag{2}$$

By assuming then *a priori* the value of Ω_{m0} and given that d_L and z can be independently observed, a measurement of H_0 can be directly inferred from the high-redshift surveys thanks to Eq. (2).

Eq. (2) provides also the starting point to estimate the intrinsic uncertainty associated to H_0 given by the presence of inhomogeneities all around our observed Universe. This is the lowest theoretical uncertainty we can reach, according to the sample of sources we have access to and is usually named *cosmic variance*. We hence have that, if we take into account also inhomogeneities in the Universe, the luminosity distance-redshift relation is modified accordingly as

$$\widetilde{d_L}(z, \mathbf{n}) = d_L(z) \left[1 + \delta^{(1)}(z, \mathbf{n}) + \delta^{(2)}(z, \mathbf{n})\right], \tag{3}$$

where $\mathbf{n}$ is the observed direction of the given source and $\delta^{(1)}$ and $\delta^{(2)}$ are linear and second order corrections to the luminosity distance-redshift relation.

At this point, the inhomogeneous value of the Hubble constant $\widetilde{H_0}$ can be evaluated as

$$\widetilde{H_0} \equiv \frac{1+z}{\widetilde{d_L}(z)} \int_0^z \frac{dz'}{\sqrt{\Omega_{0m}(1+z')^3 + 1 - \Omega_{0m}}} = H_0 \left[1 - \delta^{(1)} - \delta^{(2)} + \left(\delta^{(1)}\right)^2 \right](z, \mathbf{n}) \,. \tag{4}$$

We notice that $\widetilde{H_0}$ is now a function of z and $\mathbf{n}$. This is in line with the fact that inhomogeneities may render the estimation of H_0 biased by local structures. In principle, these inhomogeneities may affect not only the precision but also the accuracy of H_0 and then shift its averaged value within the sample. Here we neglect this effect since the correction to the Hubble diagram due to the non-linearities has been shown to be small in the regime of redshift of our interest.[7–9]

Because of these fluctuations, it is possibile to define an estimator for the variance associated to the background value of H_0 inferred from a finite survey of N sources observed at positions $(z_i, \mathbf{n}_i)$, where $i = 1, \ldots, N$ runs over the number of the sources. Indeed, the variance associated to the average value of $\widetilde{H_0}$ inferred from a finite survey of N sources will be then

$$\sigma^2_{H_0} = \overline{\left(\sum_{i=1}^{N} \frac{\widetilde{H_0}(z_i, \mathbf{n}_i)}{N} - H_0 \right) \left(\sum_{j=1}^{N} \frac{\widetilde{H_0}(z_j, \mathbf{n}_j)}{N} - H_0 \right)} = \frac{1}{N^2} \sum_{i,j=1}^{N} \overline{\left(\widetilde{H_0}(z_i, \mathbf{n}_i) \widetilde{H_0}(z_j, \mathbf{n}_j) - H_0^2 \right)} = \frac{H_0^2}{N^2} \sum_{i,j=1}^{N} \overline{\delta^{(1)}(z_i, \mathbf{n}_i)\, \delta^{(1)}(z_j, \mathbf{n}_j)} \,. \tag{5}$$

where $\overline{\cdots}$ represents the *ensemble average* over all the possibile configurations of perturbations. Last equality of Eq. (5) states that our estimator for the cosmic variance of H_0 precisely corresponds to the sum of the 2-point correlation function of the luminosity distance-redshift relation over all the possible pairs of sources in the survey. It then links the details of the surveys, such as angular and redshift distributions of the sources, to the theoretical expressions of the inhomogeneities. We also notice that nonlinear terms in Eq. (5) exactly cancel.

In the next section, these general preliminaries will be applied to the case of linear perturbations of the luminosity distance. This will provide the explicit expression for $\sigma^2_{H_0}$ due to all the linear relativistic corrections.

3. Analytical expressions for leading order effects

Eq. (5) explicitly shows that the cosmic variance $\sigma^2_{H_0}$ is sourced at the leading order only by linear perturbations. It is then enough to take into account the linear relativistic corrections involved in the $\delta^{(1)}$. By restricting our analysis to scalar

perturbations as given in the Longitudinal Gauge without anisotropic stress[a], the relativistic effects occurring at linear level are well-known:[12–15] we have lensing of the photon geodesics along the line-of-sight due to cosmic structures, peculiar velocity (also known as Doppler) due to the free falling motion of the sources within local inhomogeneities and then fluctuations of the gravitational potential around the source position and along the photon geodesics, leading to local and integrated Sachs-Wolfe effects and time delay. However, effects due to gravitational potentials are negligible with respect to lensing and peculiar velocity. We then focus the rest of our discussion only to the lensing and peculiar velocity.

The impact of the these effects on $\sigma^2_{H_0}$ is then given by

$$\frac{\sigma^2_{H_0}}{H_0^2} = \frac{1}{N^2}\sum_{i,j}\sum_{E,E'}\int \frac{dk}{k}\mathcal{P}_\psi(k)\mathcal{W}_{Ei,E'j}\,, \tag{6}$$

where $i,j = 1,\ldots,N$ and E and E' label the leading relativistic effects such as Lensing ($E,E' = L$) or Peculiar Velocity ($E,E' = PV$). $\mathcal{P}_\psi(k)$ in Eq. (6) is the so-called dimensionless power spectrum of gravitational perturbations in Fourier space

$$\mathcal{P}_\psi(k) \equiv \frac{k^3}{2\pi^2}|\psi_k|^2\,. \tag{7}$$

We remark that kernels $\mathcal{W}_{Ei,E'j}$ are functions of the (times) redshifts of the i-th and j-th sources (η_i) z_i and (η_j) z_j and their angular separation $\nu \equiv \mathbf{n}_i\cdot\mathbf{n}_j$. In this way, the only terms involved in our analysis are the auto-correlations of lensing and peculiar velocity

$$\begin{aligned}\mathcal{W}_{PVi,PVj} &= \Xi_i\Xi_j G_i G_j k^2\left\{\frac{\Delta\eta_i\,\Delta\eta_j(1-\nu^2)}{R^2}j_2(kR)\right.\\ &\left.+\frac{\nu}{3}\left[j_0\left(kR\right)-2j_2\left(kR\right)\right]\right\}(\eta_i,\eta_j,\nu)\\ \mathcal{W}_{Li,Lj} &= \frac{1}{\Delta\eta_i}\frac{1}{\Delta\eta_j}\int_{\eta_i}^{\eta_o}d\eta\frac{\eta-\eta_i}{\eta_o-\eta}\int_{\eta_j}^{\eta_o}d\eta'\frac{\eta'-\eta_j}{\eta_o-\eta'}\frac{g(\eta)g(\eta')}{g^2(\eta_o)}\left[k^4H^4j_4(kR)\right.\\ &\left.-8k^3H^2L\,j_3(kR)+k^2\left(8L^2-6H^2\right)j_2(kR)+4\,k\,L\,j_1(kR)\right](\eta,\eta',\nu)\,,\end{aligned} \tag{8}$$

and their cross-correlation

$$\begin{aligned}\mathcal{W}_{PVi,Lj} = \frac{\Xi_i}{\Delta\eta_j}G_i\int_{\eta_j}^{\eta_o}d\eta\frac{\eta-\eta_j}{\eta_o-\eta}\frac{g(\eta)}{g(\eta_o)}&\left\{-k^3\Delta\eta^2\frac{(\Delta\eta_i-\nu\Delta\eta)(\Delta\eta-\nu\Delta\eta_i)^2}{R^3}j_3(kR)\right.\\ &+\,k^2\Delta\eta\left(3\Delta\eta\frac{\Delta\eta_i-\nu\,\Delta\eta}{R^2}-2\nu\right)j_2(kR)\\ &\left.-\frac{k\Delta\eta}{R}\left[k^2\Delta\eta(\Delta\eta_i-\nu\Delta\eta)-2\nu\right]j_1(kR)\right\}(\eta_i,\eta,\nu)\,,\end{aligned} \tag{9}$$

[a]This assumption is in line with the fact that we take into account sources located after the decoupling. General expressions in presence of anisotropic stress can be found in Marozzi et al. (2014)[10] for the non-linear luminosity distance-redshift relation and in Fanizza et al. (2018)[11] for the non-linear redshift.

where $j_n(x)$ are the spherical Bessel functions of n-th order and we define

$$\begin{aligned} R(\eta_x,\eta_y,\nu) =& \sqrt{\Delta\eta_x^2+\Delta\eta_x^2-2\Delta\eta_x\Delta\eta_y\nu} \\ L(\eta_x,\eta_y,\nu) = \frac{\Delta\eta_x\,\Delta\eta_y\nu}{R\,(\eta_x,\eta_y,\nu)}\,, &\qquad H(\eta_x,\eta_y,\nu) = \frac{\Delta\eta_x\,\Delta\eta_y\sqrt{1-\nu^2}}{R\,(\eta_x,\eta_y,\nu)} \\ G_i = \int_{\eta_{in}}^{\eta_i} d\eta\,\frac{a(\eta)}{a(\eta_i)}\frac{g(\eta)}{g(\eta_o)}\,, &\qquad \Xi_i = \left(1-\frac{1}{\mathcal{H}_i\Delta\eta_i}\right)\,, \end{aligned} \tag{10}$$

with $\Delta\eta_x \equiv \eta_o - \eta_x$. In Eqs. (10), R is the Euclidean distance between two sources and L and H are respectively the normalized scalar and (modulo of the) vector products between the two directions of the sources. Moreover, G_i is the growth factor for the velocity potential of the i-th source, $g(\eta)$ is the growth factor of the gravitational potential, $a(\eta)$ is the scale factor, $\mathcal{H}(\eta) = a'(\eta)/a(\eta)$ and η_o is the value of the conformal time today. The detailed analytic derivation for all the different contributions $\mathcal{W}_{Ei,E'j}$ is reported in Fanizza et al. (2021).[1] We just remark that the kernel $\mathcal{W}_{PVi,PVj}$ is in agreement with the one found in Ben-Dayan et al. (2014).[4]

The values of the 2-point correlation function

$$\xi_{E,E'}(z_i,z_j,\nu) \equiv \int \frac{dk}{k}\mathcal{P}_\psi(k)\mathcal{W}_{Ei,E'j} \tag{11}$$

for the kernels in Eqs. (8) and (9) are then shown in Fig. 1 for the particular cases of aligned ($\nu = 1$) and anti-aligned ($\nu = -1$) sources. In the regime of interest for us ($0.15 \leq z \leq 3.85$), it is clear from these plots that lensing is always leading with respect to the other terms when the sources are aligned, whereas peculiar velocity turns out to be the leading effect for the anti-aligned sources at redshift smaller than 1.

Another interesting feature emerging from Eqs. (8) and (9) regards the angular average of $\xi_{E,E'}$. It turns out that

$$\int_{-1}^{1} d\nu\,\xi_{E,L}(z_i,z_j,\nu) = 0 \tag{12}$$

where E may label all the relativistic effects such as lensing itself, peculiar velocity, time delay and (integrated) Sachs-Wolfe effect. This means that, in the limit of full sky coverage surveys and large number of sources[b], lensing does not affects at all the estimation $\sigma^2_{H_0}$. Hence, it follows that in this ideal case the leading contribution to the cosmic variance is entirely addressed to the monopole of $\xi_{PV,PV}$. This can be easily evaluated from the angular integration of the $\mathcal{W}_{PVi,PVj}$ in Eq. (8) and results are shown in Fig. 2. In this ideal case, σ_{H_0} is entirely given by the doppler 2-point correlation function.

[b]See Yoo (2020)[16] for a detailed discussion of this ideal case.

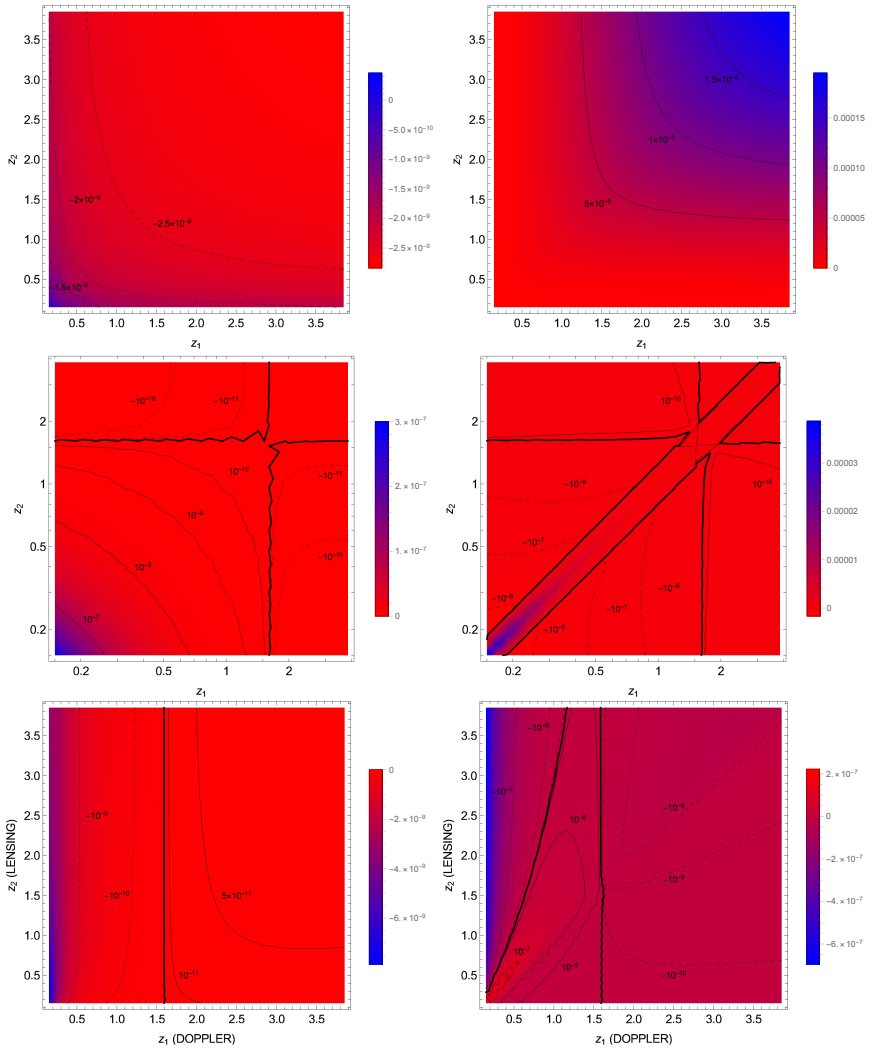

Fig. 1. 2-point correlation functions of Lensing (top panels), Peculiar Velocities (middle panels) and cross-correlation between Lensing and Peculiar Velocity (bottom panels). Left panels refer to anti-aligned sources ($\nu = -1$) wheres right ones consider aligned sources ($\nu = 1$). These plots are obtained by using linear power spectrum for the gravitational potential, following the cosmological parameters provided in Fanizza et al. (2021).[1]

However, realistic surveys deal with finite sky-coverages which can be also very narrow. In this case, monopole of the 2-point correlation functions of $\widetilde{d_L}(z, \mathbf{n})$ is no longer enough and higher multipoles must be taken into account for the evaluation of $\sigma^2_{H_0}$. We redirect the reader interested in the detailed multipoles analysis of $\xi_{E,E'}$ to Fanizza et al. (2021).[1] In the next section, we will apply the numerical results shown in Fig. 1 to the estimator for $\sigma^2_{H_0}$ in Eq. (6).

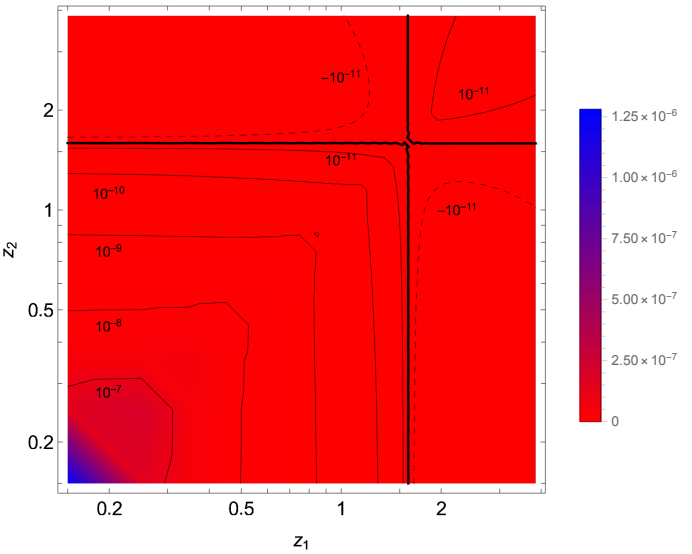

Fig. 2. Monopole of the doppler 2-point correlation function. Thick black lines indicate where function is 0. Dashed lines stand for negative values whereas continues lines refer to positive values.

4. Cosmic variance for next generation surveys

In this section, we apply the analytical and numerical results previously obtained to the case of Superluminous Supernovae (SLSNe). Following the specifics of forthcoming surveys like EDS[17] and LSST,[18] we consider the expected detection rate of SLSNe claimed in Inserra et al. (2021)[6] and reported in our Fig. 3. With these histograms in mind, we have generated two random surveys for the distribution of SLSNe with the following properties

- EDS: 135 sources in 7 redshift bins with $0.5 \leq z \leq 3.5$ and redshift bin width $\Delta z = 0.5$. For this survey, the angular distribution covers two

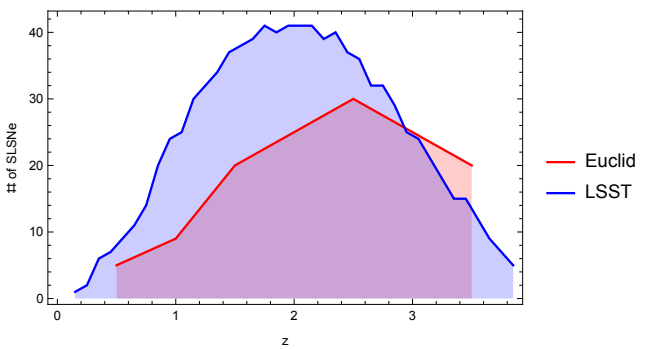

Fig. 3. Simulated SLSNe distributions for Euclid Deep Survey and LSST. From Inserra et al. (2021).[6]

line-of-sights at North and South Poles, with angular opening of 20 deg^2 per line-of-sight,

- LSST: 929 sources in 38 redshift bins with $0.15 \leq z \leq 3.85$ and redshift bin width $\Delta z = 0.1$. For this survey, the angular distribution spans a broad solid angle of 9000 deg^2.

Results are summarized in Table 1. Here we see that the dispersion associated to the measure of H_0, namely $\sigma_{H_0} \equiv \sqrt{\sigma^2_{H_0}}$ is of $\sim 0.2\%$ for EDS but its value drops of almost 1 order of magnitude for LSST, where it contributes with a dispersion of $\sim 0.03\%$. This difference is mainly addressed to the fact that, for larger sky coverage and large number of sources, the total effect due to lensing must tend to 0. The specific of LSST are indeed in line with regime: first of all, the number of sources adopted in our forecast of LSST is almost 1 order of magnitude higher than the one of EDS. Secondly, also the sky coverage is larger.

Table 1. Forecasts for the variance of H_0 in EDS and LSST. In the first line, lensing 2-point correlation function is considered. In the second line, the contributions from 2-point correlation function of peculiar velocities are shown. Values are reported for linear power spectrum truncated at $k_{UV} = 0.1h$ Mpc^{-1} and Non-Linear HaloFit model truncated at $k_{UV} = 10h$ Mpc^{-1}.

$\sigma^2_{H_0}/H_0^2$	EDS (Linear)	LSST (Linear)	EDS (Non-Linear)	LSST (Non-Linear)
Lensing	5.1×10^{-6}	7.6×10^{-8}	1.1×10^{-5}	7.8×10^{-7}
Doppler	2.1×10^{-9}	2.9×10^{-10}	-	-

Another fact that we underline is that doppler effect is always subdominant. Hence we have that the total cosmic variance due to lensing and doppler is

$$\sigma_{H_0} \approx \sigma_{H_0 L} \left[1 + \frac{1}{2} \frac{\sigma^2_{H_0 PV}}{\sigma^2_{H_0 L}} + \mathcal{O}\left(\left(\frac{\sigma^2_{H_0 PV}}{\sigma^2_{H_0 L}} \right)^2 \right) \right] . \tag{13}$$

Again from Table 1, we then get that the doppler effect corrects the total cosmic variance associated to H_0 by 0.2% for LSST and by 0.02% for EDS.

This analytical estimation can be naturally extended to $k_{UV} = 10\,h$ Mpc^{-1} where the HaloFit model[19,20] is taken into account to model the non-linear scales. Results for the lensing are reported again in Table 1 and show that $\sigma^2_{H_0\,NL} = 1.1 \times 10^{-5}\, H_0^2$ for EDS and $\sigma^2_{H_0\,NL} = 7.8 \times 10^{-7}\, H_0^2$ for LSST.

It follows then, for EDS, even if non-linear scales are expected to enhance the lensing correction by almost one order of magnitude, the intrinsic error associated to the measurement of H_0 is almost insensitive to the non-linear scales, since it becomes $\sigma_{H_0\,NL}/H_0 = 0.003$. On the contrary, non-linear scales increase by roughly a factor 3 the dispersion of H_0 within the specific of LSST, raising σ_{H_0} to the value $\sigma_{H_0\,NL}/H_0 = 0.0009$.

Our analysis, provides also a test for the claim done in Ben-Dayan et al. (2014)[4] about small redshift surveys: it has been stated there that the analysis is insensitive

to smaller scales fluctuations due to the incoherence of such contributions. According to our investigation, we conclude that this is a reasonable expectation only for EDS. We address this feature to the fact that EDS covers smaller regions in the sky with higher angular density of sources.

5. Summary and conclusions

In this work, we have studied the impact of cosmological inhomogeneities on the estimation of H_0 from the high redshift Hubble diagram. Our analysis considers the possibility, discussed in Inserra et al. (2021),[6] that EDS[17] and LSST[18] will have access to a statistically relevant number of Superluminous Supernovae in the next decade. In this regards, less conservative studies about the Hubble diagram at high redshifts ($z \leq 1.5$) have been also investigated by exploiting exact inhomogeneous models in general relativity[21–24] or by considering strongly inhomogeneous dynamical dark energy models.[25] These attempts look interesting especially in light of recent analysis done in Krishnan et al. (2020)[26] and Krishnan et al. (2021)[27] about H0LiCOW[28] and TDCOSMO[29] data and in Dainotti et al. (2021)[30] for the SNe Ia Pantheon sample, suggesting that H_0 could be a decreasing function of redshift already at late time.

However, our approach is more conservative, since it is based on linear perturbations within the Cosmic Concordance model. In this framework, the 2-point correlation function of luminosity distance-redshift relation has been analytically derived and investigated numerically. It turns out that lensing is the leading effect at the considered redshift, as one may expect.

Our first analytical estimations of the cosmic variance for limited-sky-coverage surveys indicate then that forthcoming high-redshift surveys are well-suited to provide a precise determination of cosmological parameters, such as H_0. Moreover, these forecasted errors for LSST and EDS are stable enough to be quite insensitive to the role of non-linearities in the matter power spectrum. Despite our analysis has been performed entirely within the ΛCDM model, from the geometrical structure of the light-cone 2 general features emerge:

- Lensing 2-point correlation function has vanishing monopole, hence in the limit of large sky coverage and huge number of sources, the cosmic variance must be dominated by Doppler effect also on high redshift surveys.
- As a consequence of line-of-sight integration and statistic isotropy, non-linear scales play an important role only when two sources are almost aligned.

However, realistic surveys deal with limited sky coverage and this makes lensing contribution no longer vanishing. In fact, according to the specific of EDS and LSST and to what has been claimed in Inserra et al. (2021),[6] we forecast that the intrinsic error from cosmic variance associated to H_0 is of $\sim 0.03\,\%$ for LSST and $0.3\,\%$ for EDS for the linear power spectrum. Non-linear scales contribute marginally to this

estimation within the specific of EDS. For what regard the specific of LSST, the situation is a way worse. Indeed, in this case, we get that non-linear scales enhance our forecast by almost a factor 3. This is a direct consequence of the fact that lensing 2-point correlation function strongly depends on small scales fluctuations for the diagonal entries of the covariance matrix.

Our analysis extends the one performed in Ben-Dayan et al. (2014),[4] where only close Supernovae (up to $z = 0.1$) have been considered. Indeed, we took into account also lensing corrections on top of the peculiar motion of the sources. In fact, the former is the leading relativistic effect expected at those redshifts.[7] Interestingly, our analysis points out that surveys have an intrinsic error for H_0 which tends to decrease when higher redshift sources are considered, whereas low redshift surveys discussed in Ben-Dayan et al. (2014)[4] admits a quite high dispersion for H_0 of $\sim 1\,\%$.

On one hand, our results are not able to alleviate the tension between local and distant measurements of the Hubble constant. However, they indicate that the analysis of fainter sources does not increase the theoretical uncertainty on H_0. The price to pay stands in the fact that the Hubble diagram at higher redshift is no longer model independent.

Primordial black holes arise when the inflaton falls

Keisuke Inomata
Kavli Institute for Cosmological Physics, The University of Chicago, Chicago, IL 60637, USA
E-mail: inomata@uchicago.edu

Primordial black holes (PBHs) can be produced when large density perturbations enter the horizon in the early universe. They can be dark matter (DM) and the black holes detected by the LIGO-Virgo collaborations. In this proceeding, we show that the large enhancement of the perturbations, required for the DM PBHs and LIGO/Virgo PBHs, can be realized in inflation models with a downward step. This enhancement mechanism is related to the particle production associated with the non-adiabatic evolution of the inflaton. This proceeding is based on our original paper.[1]

Keywords: Primordial black holes; inflaton; dark matter.

1. Introduction

Primordial black holes (PBHs) are one of the hottest topics in Cosmology because they are one of the candidates of dark matter (DM) and the black holes (BHs) detected by LIGO-Virgo collaborations.[2–7] PBHs are produced when the large density perturbations enter the horizon during a radiation- or matter-dominated era. The power spectrum of the density perturbations sensitively depends on the inflaton potential.

Throughout this proceeding, we focus on single-field inflation models. In the previous works, the large perturbations for the PBH scenarios are realized by the flat region in the inflaton potential.[8–25] When the inflaton rolls on the flat region, it gets decelerated due to the Hubble friction, which is called the ultra-slow-roll (USR) period. Once the inflaton gets decelerated, the perturbations are enhanced. This can be seen from the form of the power spectrum in the slow-roll approximation, $\mathcal{P}_\mathcal{R} \simeq H^2/(8\pi^2\epsilon M_{\rm Pl}^2)$, where H is the Hubble parameter and ϵ is the slow-roll parameter, related to the inflaton velocity through $\epsilon \equiv -\dot{H}/H^2 = \dot{\phi}^2/(2H^2M_{\rm Pl}^2)$.

On the other hand, in this proceeding, we show that a downward step in the inflaton potential can also realize the large enhancement of the perturbations. Although the perturbation enhancement with the step-like feature is discussed in previous works,[26,27] the $\mathcal{O}(10^7)$ enhancement of $\mathcal{P}_\mathcal{R}$, required for the PBH scenarios, has never been realized. One example of the inflaton potential with the downward step is shown in Fig. 1, whose concrete parameterization will be given in Sec. 3. In the following, we explain why the downward step can enhance the perturbations.

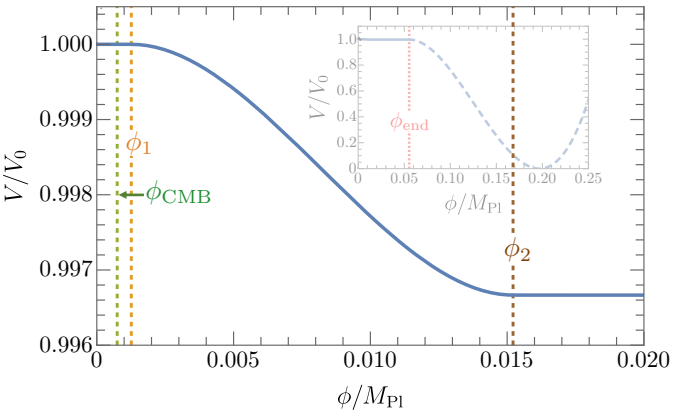

Fig. 1. The inflaton potential of Eq. (10) that realizes the large enhancement of perturbations, with the downward step at $\phi_1 \leq \phi \leq \phi_2$ highlighted and an inset for the full range. The parameters are $n_s = 0.97$, $\epsilon_1 = 7.43 \times 10^{-10}$, $\epsilon_2 = 0.01$, $\epsilon_3 = 10^{-9}$, and $\Delta N_{\rm step} = 0.5$. $\phi_{\rm end}$ denotes the end of inflation (red vertical dotted line) and corresponds to 50 e-folds from $\phi_{\rm CMB}$. This figure is taken from our original paper.[1]

2. A toy model

In this section, we explain the reason why the downward step causes the large enhancement by using a toy model. In canonical single-field inflation, the curvature perturbation $\mathcal{R}_k$ obeys the following equation:[26,28,29]

$$\mathcal{R}_k'' + (2+\eta)\mathcal{H}\mathcal{R}_k' + k^2\mathcal{R}_k = 0, \tag{1}$$

where $\eta \equiv \epsilon'/(\mathcal{H}\epsilon)$, $\mathcal{H}$ is the comoving Hubble parameter, and the prime denotes the derivative with respect to the conformal time, $d\tau \equiv dt/a$ with $\tau = 0$ at the end of inflation. We can rewrite this equation as

$$\frac{{\rm d}^2\mathcal{R}_k}{{\rm d}x^2} - \frac{2+\eta}{x}\frac{{\rm d}\mathcal{R}_k}{{\rm d}x} + \mathcal{R}_k \simeq 0, \tag{2}$$

where $x \equiv -k\tau$ and we have used the relation $\mathcal{H} \simeq -1/\tau$. Then, we obtain the general solution for the curvature perturbation:

$$\mathcal{R}_k \approx C_1 G_\nu^{(1)}(-k\tau) + C_2 G_\nu^{(2)}(-k\tau), \tag{3}$$

where $\nu = 3/2 + \eta/2$, C_1 and C_2 are constant in time, and $G_\nu^{(1)}$ and $G_\nu^{(2)}$ are defined with the Hankel functions of the first ($H_\nu^{(1)}$) and the second kind ($H_\nu^{(2)}$) as

$$G_\nu^{(j)}(-k\tau) \equiv (-k\tau)^\nu H_\nu^{(j)}(-k\tau), \tag{4}$$

with $j \in (1,2)$.

As a toy model, we consider the case where ϵ changes from $\epsilon_1 (\ll 1)$ to $\epsilon_2 (> \epsilon_1)$ with constant positive η and, after that, ϵ decreases with $\eta = -6$, which corresponds to a USR phase. Specifically, we parameterize η as

$$\eta = \eta_c \Theta(\tau - \tau_1)\Theta(\tau_2 - \tau) - 6\Theta(\tau - \tau_2). \tag{5}$$

Once ϵ_1/ϵ_2 is fixed, we have $\tau_2/\tau_1 = (\epsilon_1/\epsilon_2)^{1/\eta_c}$ and $\tau/\tau_2 = (\epsilon(\tau)/\epsilon_2)^{1/6}$ for $\tau > \tau_2$ with $\epsilon(\tau)$ being the value at τ. Substituting this into Eq. (2), we obtain the solution of the curvature perturbation,

$$\mathcal{R}_k = \begin{cases} D_1 G^{(1)}_{3/2}(-k\tau) & (\tau < \tau_1) \\ E_1 G^{(1)}_{\nu_c}(-k\tau) + E_2 G^{(2)}_{\nu_c}(-k\tau) & (\tau_1 \le \tau \le \tau_2) \\ F_1 G^{(1)}_{-3/2}(-k\tau) + F_2 G^{(2)}_{-3/2}(-k\tau) & (\tau_2 \le \tau) \end{cases},$$

where $\nu_c = 3/2 + \eta_c/2$. Imposing the Bunch-Davies vacuum condition as $D_1 = -\sqrt{\pi/2}H/(\sqrt{4k^3\epsilon_1}M_{\rm Pl})$ and the continuity of $\mathcal{R}$ and $\mathcal{R}'$ at τ_1 and τ_2, we determine the other coefficients. Hereafter, as the simplest case, let us consider the large limit of η_c, which corresponds to the step-function like downward step. In this limit, Eq. (1) in $\tau_1 < \tau < \tau_2$ can be approximated as

$$\mathcal{R}_k'' + \frac{\epsilon'}{\epsilon}\mathcal{R}_k' \approx 0. \tag{6}$$

From this relation, we can obtain $\mathcal{R}_k'(\tau_2) = (\epsilon_1/\epsilon_2)\mathcal{R}_k'(\tau_1)$. We can see that $\mathcal{R}_k'$ undergoes a jump down at the transition, by a relative factor of (ϵ_1/ϵ_2), while $\mathcal{R}$ itself is continuous, $\mathcal{R}_k(\tau_1) = \mathcal{R}_k(\tau_2)$, for any finite ϵ. From the relation between the curvature perturbation and the inflaton fluctuation $\delta\phi$ during the inflation, $\mathcal{R} \simeq \delta\phi/(\sqrt{2\epsilon}M_{\rm Pl})$, we can see that, while the curvature perturbations remain constant, the inflaton fluctuations get amplified during the increase of ϵ (the rolling down of the step). This amplification of the inflaton fluctuations can be regarded as the particle production. Note that the amplification of the curvature perturbations occurs after the rolling down phase ($\tau > \tau_2$) because the curvature perturbation evolves as $\mathcal{R}_k \propto 1/\sqrt{\epsilon}$ in $\tau > \tau_2$.

In the limit of $\eta_c \to \infty$, the coefficients F_1 and F_2 approach the following values:

$$\begin{aligned} F_{1,\rm lim} =& D_1 \frac{3\epsilon_2 + (2\epsilon_2+\epsilon_1)(-k\tau_1)^2 + i(\epsilon_2+\epsilon_1)(-k\tau_1)^3}{2\epsilon_2}, \\ F_{2,\rm lim} =& -D_1 {\rm e}^{-2ik\tau_1}(1 - i(-k\tau_1))\frac{(3\epsilon_2 - 3i\epsilon_2(-k\tau_1) + (\epsilon_1-\epsilon_2)(-k\tau_1)^2)}{2\epsilon_2}, \end{aligned} \tag{7}$$

where note $\tau_1 = \tau_2$ in this limit. Using these expressions, we derive the analytic form of the final power spectrum after the perturbations exit the horizon. Here, we define τ_3 as the time at the end of the USR phase so that $\epsilon_3 = \epsilon(\tau_3)$. After the USR phase, the inflation continues with $\epsilon = \epsilon_3$. In this case, the power spectrum in the large-scale limit, $k \ll 1/|\tau_1|$ becomes

$$\mathcal{P}_\mathcal{R}(k) \simeq \frac{H^2}{8\pi^2 M_{\rm Pl}^2\epsilon_1}\left[1 - \frac{2}{15}\sqrt{\frac{\epsilon_2}{\epsilon_3}}(-k\tau_1)^2 + \frac{1}{225}\frac{\epsilon_2}{\epsilon_3}(-k\tau_1)^4\right], \tag{8}$$

up to $\mathcal{O}((-k\tau_1)^4)$, and where we have also assumed $\epsilon_3/\epsilon_2 \ll 1$. On the other hand, for modes that were inside the horizon at the transition ($k \gtrsim 1/|\tau_1|$), the power spectrum finally becomes

$$\mathcal{P}_\mathcal{R}(k) \simeq A\frac{1-\cos(-2k\tau_1)}{2}, \quad A = \frac{H^2}{8\pi^2 M_{\rm Pl}^2\epsilon_1}\frac{\epsilon_2}{\epsilon_3}, \tag{9}$$

where we have assumed $\epsilon_1/\epsilon_2 \ll 1$. From this expression, we can see that the power spectrum is enhanced by a factor of $\mathcal{O}(\epsilon_2/\epsilon_3)$.

3. A concrete model

Next, we discuss a concrete inflaton potential with a downward step, which realizes the large perturbation enhancement. Specifically, we consider the following potential:

$$V(\phi) = V_b(\phi) F\left(\phi; \phi_1, \phi_2, h\right), \tag{10}$$

where V_b is the base potential and F induces the downward step. We take the following form of V_b:

$$V_b(\phi) \simeq V_0 \left(1 - \frac{\beta \phi^2/M_{\rm Pl}^2}{1 + \phi/\phi_{\rm CMB}}\right), \tag{11}$$

where we determine the parameters to make the power spectrum on large scales consistent with CMB observation, $\mathcal{P}_\mathcal{R} \simeq 2 \times 10^{-9}$ and $n_s = 0.97$. Note that the inflaton potential changes from this form around the end of the inflation, which is irrelevant to the enhancement mechanism. The concrete expression of the function F is given by

$$F(\phi; \phi_1, \phi_2, h) \equiv \begin{cases} 1 & (\phi < \phi_1) \\ 1 - hS\left(\frac{\phi - \phi_1}{\phi_2 - \phi_1}\right) & (\phi_1 \le \phi \le \phi_2) \\ 1 - h & (\phi > \phi_2) \end{cases}, \tag{12}$$

where $S(x) \equiv x^2(3 - 2x)$ and it changes from 0 to 1 with the change of x from 0 to 1. The parameter h determines the step height, normalized by V_0, and $\phi_2 - \phi_1$ determines the e-folds for the inflaton to pass through the step, which is denoted by $\Delta N_{\rm step}$. With this concrete inflaton potential, we numerically calculate the power spectrum and get the results in Fig. 2. The peak height of the power spectrum in Fig. 2 is $\mathcal{P}_\mathcal{R} \sim \mathcal{O}(10^{-2})$, which is large enough for the scenarios of the DM PBHs and the LIGO-Virgo PBHs.[30] From this figure, we can see that the power spectrum is enhanced by a factor of $\mathcal{O}(\epsilon_3/\epsilon_2)$, which is consistent with the analytical estimate in the previous section. We can also see that the perturbation enhancement does not occur on the very small scales, where Eq. (6) is invalid. This is because Eq. (6) is valid only when the transition timescale, $\tau_2 - \tau_1$, is much smaller than the timescale of the perturbation oscillation, $1/k$.

4. Conclusion

In this proceeding, we have proposed a new type of single-field inflation model for the PBH scenarios. We have shown that a downward step feature in the inflaton potential can enhance the power spectrum by a factor of $\mathcal{O}(10^7)$, required for the PBH scenarios. This perturbation enhancement can be interpreted as the particle production that occurs during the inflaton rolling down of the step.

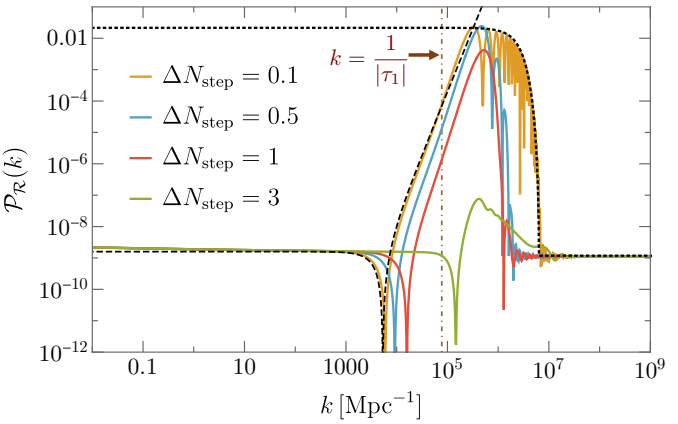

Fig. 2. The power spectrum in the inflaton potential of Eq. (10) with different $\Delta N_{\rm step}$. Except for $\Delta N_{\rm step}$, the parameters are the same as in Fig. 1. The black dotted and dashed lines are the approximate forms of the power spectrum. See our original paper[1] for details. This figure is taken from our original paper.[1]

Effects of the modification of gravity on the production of primordial black holes

The enhancement of the spectrum of primordial comoving curvature perturbation $\mathcal{R}$ can induce the production of primordial black holes (PBH) which could account for part of present day dark matter. As an example of the effects of the modification of gravity on the production of PBHs, we investigate the effects on the spectrum of $\mathcal{R}$ produced by the modification of gravity in the case of G-inflation, deriving the relation between the unitary gauge curvature perturbation ζ and the comoving curvature perturbation $\mathcal{R}$, and identifying a background dependent enhancement function $\mathcal{E}$ which can induce large differences between the two gauge invariant variables.

When ζ is not constant in time it is different from $\mathcal{R}$, for example on sub-horizon scales, or in models exhibiting an anomalous super-horizon growth of ζ, but since this growth cannot last indefinitely, eventually they will coincide. We derive the general condition for super-horizon growth of ζ, showing that slow-roll violation is not necessary. Since the abundance of PBHs depends on the statistics of the peaks of the comoving density contrast, which is related to the spectrum of $\mathcal{R}$, it is important to take into account these effects on the PBHs abundance in modified gravity theories.

Keywords: Modified gravity, primordial curvature perturbations, primordial black holes.

1. Introduction

The study of primordial perturbations is fundamental in any cosmological model, since it allows to make predictions of the conditions which provided the seeds for the anisotropies of the cosmic microwave background (CMB) radiation or for the process of structure formation. Among the different theoretical scenarios proposed to explain the accelerated expansion of the Universe, Horndeski's theory[1] has received a lot of attention, both in the context of inflation and dark energy.

The calculation of the equation for cosmological perturbations for these theories have been so far performed in the so called unitary gauge, also known as uniform field gauge. While the unitary gauge has some computational convenience in general relativity when only a scalar field is present, in general it is not directly related to observations, which depend on the comoving curvature perturbations $\mathcal{R}$. The production of PBHs[2–6] is an example of phenomenon depending on $\mathcal{R}$[7] and not on the unitary gauge curvature perturbations ζ. Another example are the numerical codes developed for the solution of the Boltzman's equations in a perturbed Friedman-Lemaître-Robertson-Walker (FLRW) Universe, which are using equations in the synchronous gauge,[8] which for adiabatic perturbations coincides

approximately with the comoving gauge,[9] justifying the use of the comoving slices gauge for early Universe calculations.

The comoving gauge can differ from the unitary gauge in modified gravity theories because the effective energy momentum tensor arising from the modification of gravity can produce some effective entropy terms, which are absent in $K(X)$ theories, but are present in any more complicated Hordenski's theory. In this letter we compute the general relation between $\mathcal{R}$ and ζ in G-Inflation.[10,11] As an application we use this relation to investigate the effects of the modification of gravity on the power spectrum of $\mathcal{R}$, and its implications on the production of PBHs.

2. G-inflation

In G-inflation the scalar field Φ is minimally coupled to gravity according to the action[10,12]

$$S = \int d^4x\sqrt{-g}\left(\frac{M_{Pl}^2}{2}R + L(\Phi, X)\right),$$

where $X = -g^{\mu\nu}\partial_\mu\Phi\partial_\nu\Phi/2$, R is the Ricci scalar and we use a system of units in which $c = \hbar = 1$. The Lagrangian density of the scalar field corresponds to

$$L(\Phi, X) = K(\Phi, X) + G(\Phi, X)\Box\Phi\,, \tag{1}$$

where K and G are arbitrary functions. The corresponding effective stress-energy-momentum tensor (EST) is given by

$$T_{\mu\nu} = L_{,X}\nabla_\mu\Phi\nabla_\nu\Phi + P_\Phi g_{\mu\nu} + \nabla_\mu\Phi\nabla_\nu G + \nabla_\nu\Phi\nabla_\mu G\,, \tag{2}$$

where

$$L_{,X} = \partial_X L = K_X(\Phi, X) + G_X(\Phi, X)\Box\Phi\,, \tag{3}$$

$$P_\Phi = L - \nabla_\mu\left(G\nabla^\mu\Phi\right) = K - g^{\mu\nu}\nabla_\mu\Phi\nabla_\nu G\,. \tag{4}$$

3. The perturbed effective energy-stress-momentum tensor

The most general scalar perturbations with respect to a flat FLRW background can be written as

$$ds^2 = a^2\Big\{-(1+2A)d\tau^2 + 2\partial_i B dx^i d\tau + \left[\delta_{ij}(1-2C) + 2\partial_i\partial_j E\right]dx^i dx^j\Big\}. \tag{5}$$

For the decomposition of the scalar field and the EST into their background and perturbation parts we use the notation

$$\Phi(x^\mu) = \phi(\tau) + \delta\phi(x^\mu)\,, \tag{6}$$

$$T^\mu{}_\nu = \overline{T}^\mu{}_\nu + \delta T^\mu{}_\nu\,. \tag{7}$$

The background components of the EST are

$$\overline{T}^0{}_0 = -\,\overline{\rho} = K(\phi,\chi) + \frac{3\mathcal{H}\phi'^3}{a^4}G_\chi(\phi,\chi) - \frac{\phi'^2}{a^2}\left[K_\chi(\phi,\chi) + G_\phi(\phi,\chi)\right]\,, \tag{8}$$

$$\overline{T}^0{}_i = \overline{T}^i{}_0 = 0\,, \tag{9}$$

$$\overline{T}^i{}_j = \delta^i{}_j\overline{P}\,,$$

$$\overline{P} = K(\phi,\chi) - \frac{\mathcal{H}\phi'^3}{a^4}G_\chi(\phi,\chi) + \frac{\phi'^2}{a^2}\left[G_\phi(\phi,\chi) + \frac{\phi''}{a^2}G_\chi(\phi,\chi)\right]\,, \tag{10}$$

where the primes stand for derivatives with respect to τ, χ is given by $\chi = \frac{\phi'^2}{2a^2}$, and the subscripts ϕ and χ denote partial derivatives with respect to these quantities, i.e. $G_\phi(\phi,\chi) = \partial_\phi G(\phi,\chi)$ and $G_\chi(\phi,\chi) = \partial_\chi G(\phi,\chi)$. In order to define the comoving slices gauge we need this component of the perturbed EST

$$\delta T^0{}_i = -\left(K_\chi + 2G_\phi - \frac{3\mathcal{H}\phi'}{a^2}G_\chi\right)\frac{\phi'^2}{a^2}\partial_i\delta\phi - \frac{\phi'^2}{a^4}G_\chi\partial_i\left(\delta\phi' - \phi' A\right)\,, \tag{11}$$

where $\mathcal{H} = a'/a$. The remaining components of the perturbed EST are not relevant to the computations done in this letter, and we will give them in a future work. Under a gauge transformation of the form $(\tau, x^i) \to (\tau + \delta\tau, x^i + \delta x,^i)$ the perturbations $\delta\phi$, A, B, C, and E transform according to[13]

$$\delta\phi \to \delta\phi - \phi'\delta\tau\,, \tag{12}$$

$$A \to A - \mathcal{H}\delta\tau - \delta\tau'\,, \tag{13}$$

$$B \to B + \delta\tau - \delta x'\,, \tag{14}$$

$$C \to C + \mathcal{H}\delta\tau\,, \tag{15}$$

$$E \to E - \delta x\,. \tag{16}$$

4. Evolution of curvature perturbations in the unitary gauge

In single scalar field models the unitary gauge is defined by the condition $\delta\phi_u = 0$. From the gauge transformation in eq.(12) we can see that the time translation $\delta\tau_u$ necessary to go to the unitary gauge is given by

$$\delta\tau_u = \frac{\delta\phi}{\phi'}\,. \tag{17}$$

Using eq.(15) we can compute the curvature perturbation in the unitary gauge ζ

$$\zeta \equiv -C_u = -C - \mathcal{H}\delta\tau_u = -C - \mathcal{H}\frac{\delta\phi}{\phi'}\,. \tag{18}$$

which is by construction gauge invariant. We can also define other gauge invariant quantities such as the unitary gauge lapse function

$$A_u \equiv A - \mathcal{H}\delta\tau_u - \delta\tau_u' = A - \mathcal{H}\frac{\delta\phi}{\phi'} - \left(\frac{\delta\phi}{\phi'}\right)'\,. \tag{19}$$

The second order action for ζ in Horndeski's theories was computed in[14]

$$S_\zeta^{(2)} = \int dt d^3x a^3 \left[\mathcal{G}_S \dot{\zeta}^2 - \frac{\mathcal{F}_S}{a^2} (\partial_i \zeta)^2 \right] , \tag{20}$$

where $\mathcal{G}_S$ and $\mathcal{F}_S$ are functions of $K(\phi, \chi)$ and $G(\phi, \chi)$ and their derivatives. The Lagrange equations for this action give the equation of motion of ζ

$$\zeta'' + \left(2\mathcal{H} + \frac{\mathcal{G}_S'}{\mathcal{G}_S} \right) \zeta' - c_s^2 \overset{(3)}{\Delta} \zeta = 0 , \tag{21}$$

where $c_s^2(\tau) = \mathcal{F}_S / \mathcal{G}_S$.

For the Fourier transform of the above equation we use the notation

$$\zeta_k'' + \left(2\mathcal{H} + \frac{\mathcal{G}_S'}{\mathcal{G}_S} \right) \zeta_k' + c_s^2 k^2 \zeta_k = 0 . \tag{22}$$

5. Comoving slices gauge in G-inflation

The comoving slices gauge is defined by the condition $\delta T^0{}_i = 0$. In G-inflation, combing eqs.(12-13) with eq.(11) we have that under an infinitesimal time translation

$$\delta T^0{}_i \to \delta T^0{}_i + \partial_i \left(\frac{\phi'^2}{a^4} D\delta\tau \right) , \tag{23}$$

where

$$D = a^2(2G_\phi + K_\chi) + G_\chi(-4\mathcal{H}\phi' + \phi'') , \tag{24}$$

from which we get the time translation $\delta\tau_c$ required to go to the comoving slices gauge

$$\delta\tau_c = \frac{1}{\phi' D} \Big[-\phi' G_\chi (3\mathcal{H}\delta\phi + \phi' A - \delta\phi') + a^2(2G_\phi + K_\chi)\delta\phi \Big] . \tag{25}$$

Note that in the particular case in which G does not depend explicitly on χ, i.e. $G(\phi, \chi) = G(\phi)$ the above transformation reduces to

$$\delta\tau_c = \frac{\delta\phi}{\phi'} , \tag{26}$$

and the comoving gauge coincides with the unitary gauge, since in this case the system is equivalent to a $K(X)$ theory.[15,16]

The comoving curvature perturbation $\mathcal{R}$ is then defined as

$$\mathcal{R} \equiv -C_c = -C - \mathcal{H}\delta\tau_c . \tag{27}$$

Our goal is to derive the relation between ζ and $\mathcal{R}$, and we can achieve this by performing the gauge transformation between the unitary and comoving slices gauge.

Using the general gauge transformation defined in eq.(25), when $\delta\phi = 0$ and $A = A_u$, we get

$$\delta\tau_{uc} = -\frac{\phi' G_\chi}{D} A_u , \tag{28}$$

from which we obtain

$$\mathcal{R} = \zeta + \mathcal{H}\frac{\phi' G_\chi}{D} A_u \,. \tag{29}$$

The gauge invariant variable A_u can be expressed in terms of ζ using the perturbed Einstein's equation $\delta G^0{}_i = \delta T^0{}_i / M_{Pl}^2$ in the unitary gauge, which using eq.(11) gives

$$-\zeta' + \mathcal{H} A_u = -\frac{\phi'^3 G_\chi}{2 M_{Pl}^2 a^2} A_u \,. \tag{30}$$

We can then combine eq.(29) and eq.(30) to obtain the relation between $\mathcal{R}$ and ζ only

$$\mathcal{R} = \zeta + \mathcal{H}\frac{\phi' G_\chi}{D}\left(\frac{\phi'^3 G_\chi}{2 M_{Pl}^2 a^2} + \mathcal{H}\right)^{-1} \zeta' = \zeta + \mathcal{E}(\tau)\zeta' \,, \tag{31}$$

where we have defined the enhancement factor $\mathcal{E}(\tau)$, a quantity depending only on the background, which can induce a significant difference between the curvature perturbations on comoving and uniform field slices. The relation between the power spectrum of ζ and $\mathcal{R}$ is then given by

$$P_\mathcal{R} = \frac{k^3}{2\pi^2}|\mathcal{R}_k|^2 = P_\zeta + \frac{k^3}{2\pi^2}\Delta \,, \tag{32}$$

where

$$\Delta = \left[\mathcal{E}\zeta^*\zeta' + \mathcal{E}^*\zeta'^*(\zeta + \mathcal{E}\zeta')\right] . \tag{33}$$

Note that the above relations are valid on any scale, since they are just based on gauge transformations, without assuming any sub or super horizon limit. This implies that the spectra of $\mathcal{R}$ and ζ could be different due to a change in the evolution of both sub-horizon and super-horizon modes during the time interval when $\mathcal{E}(\eta)$ is large. On sub-horizon scales the effect is always present, since ζ is oscillating and $\zeta' \neq 0$, while for super-horizon scales the effect could be suppressed if $\zeta \approx 0$, but even for models conserving ζ there could be an effect, since the freezing does not happen immediately after horizon crossing. We will discuss later the implication on the production of PBHs.

6. Conservation of $\mathcal{R}$ and ζ

From eq.(31) we can reach the important conclusion that

$$\zeta = const \Rightarrow \zeta = \mathcal{R} = const \,; \tag{34}$$

however the opposite is not true, i.e.

$$\mathcal{R} = const \nRightarrow \zeta = const \,, \tag{35}$$

which can have important implications for conservation laws of $\mathcal{R}$ and non-Gaussianity consistency conditions.[17] As explained previously, $\mathcal{R}$ is the quantity

related to observations, so it would be inconsistent to infer constraints on ζ from CMB observations for example, since the latter depend on $\mathcal{R}$. From a theoretical point of view the models approximately conserving ζ on super-horizon scales may be incompatible with observations for large enhancement functions $\mathcal{E}(\tau)$, because $\mathcal{R}$ could be not conserved, implying for example a violation of the non-Gaussianity consistency condition or a miss-estimation of PBHs abundance.

Nevertheless it should be noted that the super-horizon growth of perturbations cannot last indefinitely, or the entire perturbative treatment of the problem would breakdown, leading to inhomogeneities much larger than those imprinted in the CMB for example. For this reason it is expected that for any model compatible with observations the super-horizon growth of ζ should be only temporary, and according to eq.(34), at some time after horizon crossing $\zeta \approx \mathcal{R}$. This simplifies the calculation of $\mathcal{R}$, whose evolution can be then traced during and after reheating, too, contrary to ζ.

The only exception to this argument could be very small scales ζ modes which leave the horizon very late, and whose super-horizon growth could continue until horizon re-enter, without affecting the validity of the perturbative treatment of the problem. For these small scale modes the difference between $\mathcal{R}$ and ζ could be important, but it would still be computationally convenient to solve the equation for ζ and then obtain $\mathcal{R}$ using the gauge transformation given in eq.(31).

7. Enhancement of curvature perturbations

As already observed for comoving curvature perturbation $\mathcal{R}$ in general relativity for standard kinetic term single field models,[18] a temporary violation of slow-roll conditions can lead to the anomalous growth of what would normally be a decaying mode. A similar mechanism can induce the growth of ζ, as we will show in this section. We can re-write eq.(22) in the form

$$\frac{\mathrm{d}}{\mathrm{d}a}\left(a^3\mathcal{H}\mathcal{G}_S\frac{\mathrm{d}\zeta_k}{\mathrm{d}a}\right)+a\mathcal{F}_S\frac{k^2}{\mathcal{H}}\zeta_k=0\,, \tag{36}$$

from which it is possible to find a super-horizon scale solution of the form

$$\zeta_k=A+B\int\frac{\mathrm{d}a}{a}f\,,\quad f=\frac{1}{a^2\mathcal{H}\mathcal{G}_S}\,, \tag{37}$$

where A and B are constants. For standard slow-roll models the function f decreases as the scale factor increases, implying that ζ tend to a constant value, i.e. the second term in eq.(37) is a decaying mode. If the function f is a growing function of a then the second term in eq.(37) becomes a growing mode, and there can be a super-horizon growth. It follows that the general condition for super-horizon growth of ζ_k is then

$$\frac{\mathrm{d}f}{\mathrm{d}a}\geq 0\,, \tag{38}$$

or equivalently

$$\frac{\mathrm{d}f}{\mathrm{d}a} = \frac{1}{a'}\frac{\mathrm{d}f}{\mathrm{d}\tau} = \frac{1}{a\mathcal{H}}f' \geq 0\,. \tag{39}$$

During inflation $a\mathcal{H} > 0$ and this condition reduces to

$$f' \geq 0\,. \tag{40}$$

In the case of a minimally coupled single scalar field the unitary gauge and the comoving gauge coincide, and the general condition given above takes the form[18]

$$3 - \epsilon + \eta \leq 0\,, \tag{41}$$

where the slow-roll parameters are defined according to

$$\epsilon \equiv -\frac{a}{\mathcal{H}^2}\left(\frac{\mathcal{H}}{a}\right)' = \frac{a^2(\overline{\rho}+\overline{P})}{2M_{Pl}^2\mathcal{H}^2} \quad , \quad \eta \equiv \frac{\epsilon'}{\epsilon\mathcal{H}}\,. \tag{42}$$

In G-Inflation the condition given in eq.(40) implies that

$$f' = \frac{\mathrm{d}}{\mathrm{d}\tau}\left(\frac{1}{a^2\mathcal{H}\mathcal{G}_S}\right) = \frac{3 - \epsilon + \mathcal{G}_S'/\mathcal{H}\mathcal{G}_S}{a^2\mathcal{G}_S} = \frac{\gamma}{\delta} \leq 0\,, \tag{43}$$

which gives the general condition for super-horizon growth in an expanding Universe. For a contracting Universe the inequality would be inverted.

As can be seen from the above equation the super-horizon growth can be achieved in different cases, corresponding to γ and δ having opposite signs, contrary to what happened for the standard kinetic term single field scenario, in which δ sign is fixed. Note also that contrary to standard kinetic term single field models, the super-horizon growth does not depend only on the slow-roll parameters, implying that it can occur also during slow-roll.

The anomalous super-horizon growth of ζ, and consequently of $\mathcal{R}$, can increase the abundance of PBHs, since it affects the statistics of the density perturbations peaks which can seed the PBHs.

8. Production of primordial black holes

The super-horizon growth of $\mathcal{R}_k$ could produce primordial black holes which could possibly account for part of dark matter[2,4,7,19–26] and produce gravitational waves (GW) detectable with future GW detectors such as LISA.[5,7] In this session we will show how to obtain some approximate estimation of the effetcs of the modification of gravity on the PBH production, without considering any specific model, leaving this to a future work.

The mass M of PBHs produced by the mode $\mathcal{R}_k$ re-entering the horizon during the radiation domination can be approoximated as[7]

$$M = \gamma M_H\Big|_F\,, \tag{44}$$

where $\gamma \approx 0.2$ is a correction factor, and $M_H\Big|_F$ is the horizon mass $M_H \equiv (4\pi/3)\overline{\rho}(a\mathcal{H})^{-3}$ at the time of PBH formation, corresponding to the horizon crossing time

$$k = (a^2\mathcal{H})\Big|_F . \tag{45}$$

Note the above is just a rough estimation, and a more accurate treatment would involve the use of a scaling relation.[27,28]

The present time fraction f_{PBH} of PBHs of mass M against the total dark matter component can then be approximated as[7]

$$f = 2.7 \times 10^8 \left(\frac{\gamma}{0.2}\right)^{1/2} \left(\frac{g_{*F}}{106.75}\right)^{-1/4} \left(\frac{M}{M_\odot}\right)^{-1/2} \beta ,$$

where g_{*F} is the number of relativistic degrees of freedom at formation, the quantity β is the energy density fraction of PBHs at formation time

$$\beta \equiv \frac{\overline{\rho}_{PBH}}{\overline{\rho}}\Big|_F , \tag{46}$$

which can be written in terms of the probability of the density contrast $P(\delta)$ as[3,29]

$$\beta(M) = \gamma \int_{\delta_t}^{1} P(\delta) \mathrm{d}\delta , \tag{47}$$

where δ_t is the threshold for PBH formation. Assuming the density perturbations follow a Gaussian distribution β is given by

$$\beta(M) \approx \frac{\gamma}{\sqrt{2\pi}\nu(M)} \exp\left[-\frac{\nu(M)^2}{2}\right] , \tag{48}$$

where $\nu(M) \equiv \delta_t/\sigma(M)$, and $\sigma(M)$ is an estimation of the standard deviation of the density contrast on scale R from the variance

$$\sigma^2(M) = \int \mathrm{d}\ln k W^2(kR)\mathcal{P}_\delta(k) = \int \mathrm{d}\ln k W^2(kR) \left(\frac{16}{81}\right) (kR)^4 \mathcal{P}_\mathcal{R}(k) , \tag{49}$$

where $W(kR)$ is a window function smoothing over the comoving scale $R(M) = (a^2\mathcal{H})^{-1}\Big|_F = 2GM/a_F\gamma^{-1}$, and the relation between δ and $\mathcal{R}$ has been used in the second equality. It should be mentioned that eq.(48) can be used as a guideline, but more accurate calculations would involve the use of the results of numerical simulations.[30,31] The choice of the window function could also affect[32,33] the results of the calculation.

Our aim here is not make an accurate estimation of the PBHs abundance for a specific model, but to show why in general it can be impacted by the modification of gravity, and the approximations adopted so far are enough to serve this general purpose. According to the equations above, the PBH fraction β is affected by the

power spectrum of $\mathcal{R}$ since this can increase the standard deviation of the density field $\sigma(M)$. Note that the above approximations to estimate the PBHs abundance can receive important corrections depending on the shape of power spectrum, on non- gaussianity, and non-linear statistics.[34–36] Due to the importance of all these different effects it is difficult to find a general model independent analytical formula to estimate the PBHs abundance for a generic G-inflation theory, but any enhancement of the power spectrum is expected, according to eq.(32), to affect the probability of production of PBHs. Beside this, numerical relativity simulations of the PBHs formation are based on general relativity, so the effects of the modification of gravity on the process of gravitational collapse are at the moment not fully understood and would require investigations beyond the scope of this paper.[37]

At the end of its anomalous super-horizon growth, ζ will coincide with $\mathcal{R}$, and the consequent enhancement of the spectrum will lead to an increased PBH abundance. Contrary to what happens for standard kinetic term single field models in general relativity,[18] in the case of G-inflation this power spectrum enhancement can be achieved also during slow-roll, as long as the condition in eq.(43) is satisfied, which can be attained by an appropriate choice of the function $\mathcal{G}_S$. We expect a similar behavior for more complex modified gravity theories as well.

9. Conclusions

We have computed the effective energy-stress-tensor for G-inflation theories in the comoving slices gauge and have used it to derive a general relation between the unitary gauge curvature ζ and the comoving curvature perturbation $\mathcal{R}$, involving an enhancement function which depends on the evolution of the background, and which can cause a large difference between the two gauge invariant quantities.

When ζ is not constant in time it differs from $\mathcal{R}$, for example on sub-horizon scales, or in models exhibiting an anomalous super-horizon growth of ζ, but since this growth cannot last indefinitely, eventually they will coincide. We have derived the general condition for super-horizon growth of ζ, showing that slow-roll violation is not necessary, and discussed how the the enhancement of the spectrum of $\mathcal{R}$ can affect the PBH abundance.

We expect similar results to hold for other modified gravity theories such as other Horndeski's theories,[1] since also for these theories there can be effective entropy or anisotropy terms which can modify the evolution of curvature perturbations. In the future it will be interesting to extend this study to other modified gravity theories or to multi-fields systems, and to use observations to constraints the different types of theories. It would also be important to perform numerical simulations of the PBHs formation taking into account the non perturbative effects of the modification of gravity on the process of black hole formation.

In this work we will explore $U(1)$ local cosmic string solutions in the context of the generalized hybrid metric-Palatini theory of gravity in its scalar-tensor representation. Using a general static cillindrically symmetric metric to find the dynamical equations for this particular case, we will simplify the equations by imposing boost invariance along t and z directions. The physical and geometrical properties of the cosmic strings are determined by the two scalar fields, as well by an effective field potential, functionally dependent on both scalar fields. While for some forms of the potential, the dynamical equations can be solved exactly, for more general formas of the potential the solutions are found numerically. In this way, we obtain a large class of stable stringlike astrophysical configurations, whose basic parameters (string tension and radius) depend essentially on the effective field potential, and on the boundary conditions.

Keywords: Cosmic Strings, Modified Gravity, hybrid metric-Palatini theory

1. Introduction

The main motivation to investigate hybrid metric-Palatini theories resides on the fact that these theories are able to overcome flaws of both the metric and the Palatini approaches to $f(R)$ gravity. For example, in both the metric and the Palatini formalisms of $f(R)$ gravity, one is able to model the late-time cosmic acceleration period without invoking dark energy sources,[1] but both approaches present unavoidable disadvantages: the metric $f(R)$ was shown to be inconsistent with solar-system constraints unless chameleon mechanisms are considered,[2,3] whereas

the Palatini $f(R)$ gravity induces microscopic instabilities, surface singularities in polytropic star models, and is unable to describe the evolution of cosmological perturbations.[4,5] The HMPG successfully unifies the late-time cosmic acceleration period with the weak-field solar system dynamics without the need for chameleon mechanisms,[6] thus being a viable and relevant modification to GR. We refer the reader to Refs.[7–9] for recent reviews on the topic.

Inspired by the success of electroweak theory,[10–12] which unifies the weak and electromagnetic interaction under the gauge group $SU(2)\times U(1)$ at a scale of around $10^2 GeV$, Grand Unified Theories (GUT) propose the unification of electroweak and strong interactions under a more general symmetry that takes place at higher energy scales, around $10^{16} GeV$, the Grand Unification Scale. GUT theories are supported by the observation that the coupling "constants" of the Standard Model for Particle Physics seem to slowly vary with the energy scale, converging to a common value at the Grand Unification Scale.[13]

These symmetries presented at higher energies are spontaneously broken as the system lowers its energy state. In several GUT scenarios proposed, a universal covering group G, which would be effective above the GUT scale, would spontaneously break into the Standard Model $SU(3) \times SU(2) \times U(1)$, where $SU(3)$ is the symmetry group of quantum chromodynamics, describing the strong interaction, and $SU(2) \times U(1)$ is the aforementioned electroweak group.

These phase transitions may have left behind some relics that can help shed some light into earlier times of our Universe.[14] These relics are known as topological defects and are a well known, and studied, phenomena in physics, particularly in the context of condensed matter (namely metal crystallization,[15] liquid crystals,[16] superfluid helium-3 and helium-4,[17] and superconductivity[18]).

The underlying idea behind topological defect formation is the one of Spontaneous symmetry breaking, which is the principle behind the Higgs-Englert mechanism.[19]

Cosmic strings are one of the possible topological defects formed after spontaneous symmetry breaking (SSB) during phase transitions in the history of the Universe.

The type of strings to be considered in this work are local $U(1)$ cosmic strings, which are an extension of the global $U(1)$ strings to include gauge fields. Local strings differ from the global cosmic strings in what concerns the symmetry that is effective above the spontaneous breaking scale; in the case of local strings, the lagrangian remains invariant under local transformations of the type $\phi(x) \longrightarrow e^{i\alpha(x)}\phi(x)$.

The study of the properties and dynamics of cosmic strings in the context of modified theories of gravity is crucial in the advent of powerful observatories, such as LISA, as it may allow us to constrain both Modified Gravity theories and Grand Unified theories.

2. Generalized Hybrid Metric-Palatini Gravity

The generalized HMPG theory is described by an action S of the form

$$S = \frac{1}{2\kappa^2}\int_\Omega \sqrt{-g} f\left(R,\mathcal{R}\right) d^4x + \int_\Omega \sqrt{-g}\,\mathcal{L}_m d^4x, \tag{1}$$

where $\kappa^2 \equiv 8\pi G/c^4$, G is the gravitational constant and c the speed of light, Ω is the spacetime manifold described by a system of coordinates x^a, g is the determinant of the spacetime metric g_{ab}, where Latin indices run from 0 to 3, $R = g^{ab}R_{ab}$ is the Ricci scalar of the metric g_{ab} and where R_{ab} is the Ricci tensor, $\mathcal{R} \equiv \mathcal{R}^{ab}g_{ab}$ is the Palatini Ricci scalar, where the Palatini Ricci tensor $\mathcal{R}_{ab}$ is defined in terms of an independent connection $\hat{\Gamma}^c_{ab}$ in the usual form as $\mathcal{R}_{ab} = \partial_c\hat{\Gamma}^c_{ab} - \partial_b\hat{\Gamma}^c_{ac} + \hat{\Gamma}^c_{cd}\hat{\Gamma}^d_{ab} - \hat{\Gamma}^c_{ad}\hat{\Gamma}^d_{cb}$, where ∂_a denotes partial derivatives with respect to the coordinates x^a, $f\left(R,\mathcal{R}\right)$ is a well-behaved function of R and $\mathcal{R}$, and $\mathcal{L}_m$ is the matter Lagrangian density considered to be minimally coupled to the metric g_{ab}. Equation (1) depends on two independent variables, namely the metric g_{ab} and the independent connection $\hat{\Gamma}^c_{ab}$, and thus two equations of motion can be obtained.

Taking a variation of Eq. (1) with respect to the metric g_{ab} leads to the modified field equations

$$\frac{\partial f}{\partial R}R_{ab} + \frac{\partial f}{\partial \mathcal{R}}\mathcal{R}_{ab} - \frac{1}{2}g_{ab}f\left(R,\mathcal{R}\right) - \left(\nabla_a\nabla_b - g_{ab}\Box\right)\frac{\partial f}{\partial R} = \kappa^2 T_{ab}, \tag{2}$$

where ∇_a denotes covariant derivatives and $\Box = \nabla^a\nabla_a$ the d'Alembert operator, both with respect to g_{ab}, and T_{ab} is the energy-momentum tensor defined as usual:

$$T_{ab} = -\frac{2}{\sqrt{-g}}\frac{\delta(\sqrt{-g}\,\mathcal{L}_m)}{\delta(g^{ab})}\ . \tag{3}$$

On the other hand, taking a variation of Eq. (1) with respect to the independent connection $\hat{\Gamma}^c_{ab}$ yields

$$\hat{\nabla}_c\left(\sqrt{-g}\frac{\partial f}{\partial \mathcal{R}}g^{ab}\right) = 0\,, \tag{4}$$

where $\hat{\nabla}_a$ is the covariant derivative written in terms of the independent connection $\hat{\Gamma}^c_{ab}$. Since $\sqrt{-g}$ is a scalar density of weight 1, then $\hat{\nabla}_c\sqrt{-g} = 0$ and Eq. (4) can be rewritten in the form $\hat{\nabla}_c\left(\frac{\partial f}{\partial \mathcal{R}}g^{ab}\right) = 0$. This result implies the existence of a new metric, h_{ab}, conformally related to the metric g_{ab} via

$$h_{ab} = g_{ab}\frac{\partial f}{\partial \mathcal{R}}\,, \tag{5}$$

in such a way that the independent connection is the Levi-Civita connection of the metric h_{ab}, i.e., $\hat{\Gamma}^c_{ab}$ can be written as

$$\hat{\Gamma}^a_{bc} = \frac{1}{2}h^{ad}\left(\partial_b h_{dc} + \partial_c h_{bd} - \partial_d h_{bc}\right)\ . \tag{6}$$

2.1. *Scalar-tensor representation of generalized HMPG with matter*

It is sometimes useful to represent the generalized HMPG theory in a dinamically equivalent scalar-tensor representation in which the two extra scalar degrees of freedom of the theory are explicitly carried by two scalar fields. To obtain this representation, we introduce two auxiliary fields α and β into Eq. (1) and rewrite it in the form

$$S = \frac{1}{2\kappa^2}\int_\Omega \sqrt{-g}\left[f(\alpha,\beta) + \frac{\partial f}{\partial \alpha}(R-\alpha) + \frac{\partial f}{\partial \beta}(\mathcal{R}-\beta)\right] d^4x + \int_\Omega \sqrt{-g}\,\mathcal{L}_m d^4x. \tag{7}$$

At this point one verifies that if $\alpha = R$ and $\beta = \mathcal{R}$ one recovers Eq. (1). This equivalence between the two representations is only guaranteed if the determinant of the Hessian matrix of the function $f(\alpha,\beta)$ is non-zero, i.e., if $f_{\alpha\alpha}f_{\beta\beta} - f_{\alpha\beta}^2 \neq 0$, where the subscripts α and β denote partial derivatives with respect to these variables. Defining two scalar fields as $\varphi = \partial f(\alpha,\beta)/\partial\alpha$ and $\psi = -\partial f(\alpha,\beta)/\partial\beta$, where the negative sign in ψ is imposed to avoid the presence of ghosts, Eq. (7) takes the form

$$S = \frac{1}{2\kappa^2}\int_\Omega \sqrt{-g}\left[\varphi R - \psi\mathcal{R} - V(\varphi,\psi)\right] d^4x + \int_\Omega \sqrt{-g}\,\mathcal{L}_m d^4x, \tag{8}$$

where the function $V(\varphi,\psi)$ plays the role of an interaction potential between the two scalar fields and it is defined as

$$V(\varphi,\psi) = -f(\alpha,\beta) + \varphi\alpha - \psi\beta\,. \tag{9}$$

Recalling the conformal relation between h_{ab} and g_{ab} in Eq. (5), which can now be written in the form $h_{ab} = -\psi\, g_{ab}$ by taking into consideration the definition of ψ, one can derive a relationship between R and $\mathcal{R}$ as

$$\mathcal{R} = R + \frac{3}{\psi^2}\partial^a\psi\partial_a\psi - \frac{3}{\psi}\Box\psi\,, \tag{10}$$

which can be used to eliminate $\mathcal{R}$ from Eq. (8) and gives the final form of the action

$$S = \frac{1}{2\kappa^2}\int_\Omega \sqrt{-g}\Big[(\varphi-\psi)R - \frac{3}{2\psi}\partial^a\psi\partial_a\psi - V(\varphi,\psi)\Big] d^4x + \int_\Omega \sqrt{-g}\,\mathcal{L}_m d^4x. \tag{11}$$

Equation (11) is now a function of three independent variables, namely, the metric g_{ab} and the two scalar fields φ and ψ. Taking a variation of Eq. (11) with respect to the metric g_{ab} yields the modified field equations in the scalar-tensor representation. Varying the action (11) with respect to the metric g_{ab} provides the following gravitational equation

$$\begin{aligned}(\varphi-\psi)G_{ab} = {}& \kappa^2 T_{ab} + \nabla_a\nabla_b\varphi - \nabla_a\nabla_b\psi + \frac{3}{2\psi}\partial_a\psi\partial_b\psi \\ & - \left(\Box\varphi - \Box\psi + \frac{1}{2}V + \frac{3}{4\psi}\partial^c\psi\partial_c\psi\right) g_{ab}\,.\end{aligned} \tag{12}$$

Note that Eq. (12) could be obtained directly from Eq. (2) via the introduction of the definitions of φ, ψ and $V(\varphi,\psi)$, which further emphasizes the equivalence between the two representations.

Finally, the equations of motion for the scalar fields φ and ψ can be obtained via a variation of Eq. (11) with respect to these fields, respectively, which after algebraic manipulations can be written in the forms

$$\Box\varphi+\frac{1}{3}\left(2V-\psi V_{\psi}-\varphi V_{\varphi}\right)=\frac{\kappa^2 T}{3}\,, \tag{13}$$

$$\Box\psi-\frac{1}{2\psi}\partial^a\psi\partial_a\psi-\frac{\psi}{3}\left(V_{\varphi}+V_{\psi}\right)=0\,, \tag{14}$$

respectively.

Notice from Eq.(11) that the coupling between the scalar fields and the Ricci scalar is the combination $\varphi-\psi$. Since φ and ψ are arbitrary functions, it is not guaranteed that this combination preserves the positivity of the coupling. We thus introduce a redefinition of the scalar field φ as $\xi^2=\varphi-\psi$. With this redefinition, any solution obtained for which ξ is a real function preserves the positivity of the coupling $(\varphi-\psi)R$. Equations (12) to (14) thus become

$$\xi^2 G_{ab}=\kappa^2 T_{ab}+\nabla_a\nabla_b\xi^2+\frac{3}{2\psi}\partial_a\psi\partial_b\psi-\left(\Box\xi^2+\frac{1}{2}\bar{V}+\frac{3}{4\psi}\partial^c\psi\partial_c\psi\right)g_{ab}, \tag{15}$$

$$\Box\xi^2+\frac{1}{2\psi}\partial^a\psi\partial_a\psi+\frac{1}{6}\left(4\bar{V}-\xi\bar{V}_{\xi}\right)=\frac{\kappa^2 T}{3}, \tag{16}$$

$$\Box\psi-\frac{1}{2\psi}\partial^a\psi\partial_a\psi-\frac{\psi}{3}\left(\frac{1}{2\xi}\bar{V}_{\xi}+\bar{V}_{\psi}\right)=0, \tag{17}$$

where $\bar{V}(\xi,\psi)$ is the potential written in terms of the scalar fields ξ and ψ and the subscript ξ denotes a partial derivative with respect to this scalar field. In the next section, we will use the equations of motion (15)–(17) to find cosmic string solutions. Finally, one can also obtain a relationship between the potential $\bar{V}$ and the function $f(R,\mathcal{R})$ from Eq.(9) as

$$\bar{V}(\xi,\psi)=-f(R,\mathcal{R})+\xi^2 R+\psi\left(R-\mathcal{R}\right), \tag{18}$$

where we have used the fact that the scalar-tensor representation is only defined if $\alpha=R$ and $\beta=\mathcal{R}$. This equation becomes a PDE for $f(R,\mathcal{R})$ by replacing $\psi=f_{\mathcal{R}}$ and $\xi^2=f_R+f_{\mathcal{R}}$.

Hence Eq. (18) becomes

$$V\left(\sqrt{\frac{\partial f(R,\mathcal{R})}{\partial R}+\frac{\partial f(R,\mathcal{R})}{\partial\mathcal{R}}},\frac{\partial f(R,\mathcal{R})}{\partial\mathcal{R}}\right)=-f(R,\mathcal{R})+R\frac{\partial f(R,\mathcal{R})}{\partial R}+\mathcal{R}\frac{\partial f(R,\mathcal{R})}{\partial\mathcal{R}}. \tag{19}$$

3. Dynamical equations of local strings in hybrid metric-palatini using Vilenkin's approximation

In this work, we consider a straight infinite Abelian-Higgs cosmic string, using Vilenkin's approximation[20]

$$T_t^t = T_z^z = -\sigma(r)\,, \tag{20}$$

where σ is the string tension. We further assume cylindrical symmetry with a general metric of the form:

$$ds^2 = -e^{2(K-U)}dt^2 + e^{2(K-U)}dr^2 + e^{-2U}W^2 d\theta^2 + e^{2U}dz^2, \tag{21}$$

where t, r, θ and z denote the time, radial, angular and axial cylindrical coordinates, respectively, and K, U and W are functions of r alone. This metric is invariant under a set of transformations of the type: $x^0 \to x^0 + c_1$, $x^3 \to x^3 + c_2$, $x^0 \to -x^0$ and $x^3 \to -x^3$, where c_1 and c_2 are constants, which renders this metric static and cylindrically symmetric.

Since in this model the matter field couples minimally with curvature, it is possible to show that the energy conservation equation still holds, i.e.,

$$\nabla_a T^a{}_b = 0, \tag{22}$$

which provides $K'\sigma = 0$ and, apart from the trivial vacuum solution $\sigma = 0$, this implies that $K' = 0$, where the prime represents a differentiation w.r.t. r. Thus, we consider from now on that $e^K = 1$.

Note that local gauge strings preserve boost invariance along t and z,[20] so that this requires $U = 0$. Hence the only surviving non-trivial metric tensor component is $g_{\theta\theta} = W^2(r)$. From a geometric point of view $W(r)$ is the radius of the coordinate circles r = constant, z = constant, parameterized by the angle θ. Since in this geometry the perimeter of a circle equals $2\pi W$, in the following we will call the only remaining metric tensor component $W^2(r)$ a *circular radius*. On the other hand $W^2(r)$ also has the geometric meaning of a length that may be counted from any zero point, with its value at $r = 0$ not distinguished geometrically. Hence the metric of the cosmic string reduces to the form

$$ds^2 = -dt^2 + dr^2 + W^2(r)d\theta^2 + dz^2. \tag{23}$$

Applying this symmetry, the gravitational field equations simplify considerably. Equation (15) provides three independent field equations, which are

$$\xi^2\frac{W''}{W} + 2\xi\xi'\frac{W'}{W} + \frac{3\psi'^2}{4\psi} + 2\left(\xi'^2 + \xi\xi''\right) + \frac{\bar{V}}{2} = -\kappa^2\sigma, \tag{24}$$

$$2\xi\xi'\frac{W'}{W} - \frac{3\psi'^2}{4\psi} + \frac{\bar{V}}{2} = 0, \tag{25}$$

$$2\left(\xi'^2 + \xi\xi''\right) + \frac{3\psi'^2}{4\psi} + \frac{\bar{V}}{2} = \frac{d^2}{dr^2}\xi^2 + \frac{3\psi'^2}{4\psi} + \frac{\bar{V}}{2} = 0\,, \tag{26}$$

whereas the scalar field equations for ξ and ψ, provided by Eqs. (16) and (17), give

$$2\left(\xi'^2+\xi\xi''\right)+2\xi\xi'\frac{W'}{W}+\frac{\psi'^2}{2\psi}+\frac{1}{6}\left(\bar{V}-\xi\bar{V}_\xi\right)=-\frac{2\kappa^2}{3}\sigma, \tag{27}$$

$$\psi''+\frac{W'}{W}\psi'-\frac{\psi'^2}{2\psi}-\frac{\psi}{3}\left(\bar{V}_\psi+\frac{1}{2\xi}\bar{V}_\xi\right)=0\,. \tag{28}$$

The system of Eqs. (24)-(28) is a system of five equations from which only four are linearly independent. This statement can be proven by taking a radial derivative of Eq. (25), using Eq. (24) to cancel the factors W'', using Eq. (27) to cancel σ, and finally using Eqs. (26) and (28) to cancel the second-order derivatives of the scalar fields ξ'' and ψ'', respectively. As a result, one recovers Eq. (25), thus proving that the system of equations is linearly dependent. Thus, one only needs to consider four of these equations to completely determine the solution in the sections that follow. Given its complexity, we chose to discard Eq. (24) from the analysis.

Furthermore, an equation for the potential $\bar{V}$ can be obtained by summing the field equations in Eqs. (25) and (26), yielding

$$\bar{V}=-2\left(\xi'^2+\xi\xi''\right)-2\xi\xi'\frac{W'}{W}. \tag{29}$$

This equation is particularly useful to obtain an equation for W' in terms of the scalar fields ξ and ψ and their derivatives after setting an explicit form of the potential $\bar{V}$.

The system of basic equations describing the structure of a cosmic string can thus be reformulated in the form of a first-order dynamical system. By defining $\alpha=\xi^2$, and by introducing two extra dynamical variables as $u=\alpha'$ and $v=\psi'$, the dynamical system takes the form

$$\frac{d\alpha}{dr}=u,\qquad \frac{d\psi}{dr}=v, \tag{30}$$

$$\frac{dW}{dr}=\frac{1}{u}\left(\frac{3v^2}{4\psi}-\frac{\bar{V}}{2}\right)W, \tag{31}$$

$$\frac{du}{dr}=-\frac{3v^2}{4\psi}-\frac{\bar{V}}{2}, \tag{32}$$

$$\frac{dv}{dr}=-\frac{v}{u}\left(\frac{3v^2}{4\psi}-\frac{\bar{V}}{2}\right)+\frac{v^2}{2\psi}+\frac{\psi}{3}\left(\bar{V}_\psi+\frac{1}{2\sqrt{\alpha}}\bar{V}_{\sqrt{\alpha}}\right), \tag{33}$$

where Eq. (30) is the explicit definition of u and v, and Eqs. (31)–(33) are reformulations of Eqs. (25), (27), and (28), respectively. Once the functional form of the potential $\bar{V}(\xi,\psi)$ is specified, the system of Eqs. (30)-(33) represents a system of ordinary, strongly nonlinear, differential equations for the variables $\left(\alpha=\xi^2,\psi,W,u,v\right)$. To solve this system, one has to impose a set of boundary conditions at some radius $r=r_0$, i.e., $\alpha\left(r_0\right)=\alpha_0$, $\psi\left(r_0\right)=\psi_0$, $W\left(r_0\right)=W_0$, $u\left(r_0\right)=u_0$, and $v\left(r_0\right)=v_0$,

respectively, which specify the boundary values of the variables on, or nearby the string axis. Moreover, we will also impose the condition $u(r_0) \neq v(r_0)$. Once the system is solved, the string tension can be obtained from Eq. (27), and it is given by

$$\frac{2}{3}\kappa^2\sigma = \bar{V} - \frac{v^2}{2\psi} - \frac{1}{6}\left(\bar{V} - \sqrt{\alpha}\bar{V}_{\sqrt{\alpha}}\right). \tag{34}$$

An important physical characteristic of the string-like objects is their mass per unit length m_s, defined as

$$m_s(R_s) = \int_0^{2\pi} d\theta \int_0^{R_s} \sigma(r)W(r)dr = 2\pi \int_0^{R_s} \sigma(r)W(r)dr, \tag{35}$$

where R_s is the radius of the string, defined as the distance from the center where the string tension vanishes, $\sigma(R_s) = 0$, and $\sigma(r) \equiv 0, \forall r \geq R_s$. Note that, in general, the solutions obtained for σ do not satisfy the property $\sigma(r) \equiv 0, \forall r \geq R_s$, and this condition must be imposed manually by performing a matching between the string spacetime and an exterior cosmological spacetime. This matching must be performed via the use of the junction conditions of the theory, previously used in.[21] However, we do not pursue this analysis here as it is out of the scope of this paper. Using Eqs. (26) and Eq. (24) the mass per unit length of the string can be expressed as

$$\kappa^2 m_s(R_s) = 3\pi \int_0^{R_s} \left[\bar{V} - \frac{v^2}{2\psi} - \frac{1}{6}\left(\bar{V} - \sqrt{\alpha}\bar{V}_{\sqrt{\alpha}}\right)\right] W dr. \tag{36}$$

4. Solutions to the dynamical equations with specific potentials

In this section we will investigate the application of the set of equations deduced on the previous section to different potential configurations, for a more complete set of possible potential configurations, we refer the reader to the original article Ref. 22.

4.1. *Constant potential*

We consider the case when the potential V is a constant, so that $V = \Lambda = \text{constant}$. In this case Eq. (19) takes the form

$$-f(R,\mathcal{R}) + R\frac{\partial f(R,\mathcal{R})}{\partial R} + \mathcal{R}\frac{\partial f(R,\mathcal{R})}{\partial \mathcal{R}} = \Lambda, \tag{37}$$

and it has the general solution

$$f(R,\mathcal{R}) = Rg\left(\frac{\mathcal{R}}{R}\right) + \mathcal{R}h\left(\frac{R}{\mathcal{R}}\right) - \Lambda, \tag{38}$$

where g and h are arbitrary functions.

For a constant potential Eq. (28) simplifies to

$$\frac{W'}{W} = -\frac{\psi''}{\psi'} + \frac{1}{2}\frac{\psi'}{\psi}, \tag{39}$$

which allows us to write Eq. (25) in the form

$$\frac{d}{dr}\xi^2 = \frac{3\psi'^2/4\psi - \Lambda/2}{W'/W} = \frac{3\psi'^2/4\psi - \Lambda/2}{-\psi''/\psi' + (1/2)\psi'/\psi}. \tag{40}$$

To facilitate the analysis, we introduce now a new function $h = \psi'^2/\psi$. The radial derivative of this function can be written in terms of ψ and its derivatives as

$$h' = 2h\left(\frac{\psi''}{\psi'} - \frac{1}{2}\frac{\psi'}{\psi}\right). \tag{41}$$

This definition allows us to rewrite Eq. (40) in terms of h as

$$\frac{d}{dr}\xi^2 = -\frac{(3/4)h - \Lambda/2}{h'/2h}, \tag{42}$$

which can then be differentiated with respect to r and inserted into Eq. (26) to cancel the dependency in $d^2\xi^2/dr^2$ and ψ''. As a result, we obtain an equation depending solely in h of the form

$$\frac{(2\Lambda - 3h)\left(3h'^2 - 2hh''\right)}{4h'^2} = 0. \tag{43}$$

This equation is undefined for $h' = 0$, as the denominator vanishes in this case. Thus, in the following we ignore the solution corresponding to $h = 2\Lambda/3 =$ constant, giving $h' = 0$, and $W =$ constant. The general solution of Eq. (43) is given by

$$h(r) = \frac{c_2}{(r + 2c_1)^2}, \tag{44}$$

where c_1 and c_2 are arbitrary integration constants. Recalling that $h' = \psi'^2/\psi$, Eq. (44) becomes a separable ODE for ψ which can be directly integrated and provides the general solution

$$\psi(r) = \left[c_3 \pm \frac{\sqrt{c_2}}{2}\ln(r + 2c_1)\right]^2, \tag{45}$$

where c_3 is an arbitrary integration constant. Inserting Eq. (45) into Eq. (42) and integrating gives for ξ^2 the expression

$$\xi^2(r) = \xi_0^2 + \frac{1}{4}\left[3c_2\ln(r + 2c_1) - \Lambda r\,(r + 4c_1)\right], \tag{46}$$

where ξ_0^2 is an integration constant. Inserting Eq. (45) into Eq. (39) we obtain the solution for W

$$W(r) = W_0\,(r + 2c_1), \tag{47}$$

where W_0 is a constant of integration. Hence the cosmic string metric tensor component $W(r)$ is the same in both $V = 0$ and $V = \Lambda$ cases. Finally, the string tension can be computed via Eq. (27), leading to

$$\kappa^2\sigma = \frac{\Lambda}{2} - \frac{3c_2}{4\,(2c_1 + r)^2}. \tag{48}$$

On the string axis $r = 0$ we obtain for the string tension the value

$$\kappa^2\sigma_0 = \kappa^2\sigma(0) = \frac{\Lambda}{2} - \frac{3c_2}{16c_1^2}. \tag{49}$$

The condition of the positivity of the string tension imposes the condition $c_2/c_1^2 < 8\Lambda/3$ on the integration constants.

For $\Lambda = 0$ we reobtain the expression corresponding to the case $V = 0$. However, by an appropriate choice of the integration constants, and by assuming $\Lambda > 0$, the string tension can be made positive in this model for all $r > 0$. Moreover, $\lim_{r\to\infty}\sigma(r) = \Lambda/2\kappa^2$, and hence at infinity the string tension becomes equal to the cosmological constant. However, in this case one can obtain a finite radius string configuration, with the radius R_s determined by the condition $\sigma(R_s) = 0$, and given by

$$R_s = \sqrt{\frac{3}{2}\frac{c_2}{\Lambda}} - 2c_1. \tag{50}$$

For a positive string tension at the origin $r = 0$, the string radius is also positive.

As for the mass of the string we obtain

$$m_s(R_s) = \frac{2\pi W_0}{\kappa^2}\left\{\frac{1}{2}\Lambda\left[R_s + c_1(\Lambda W_0 + 2) - \frac{3c_2W_0}{8c_1}\right] - \frac{6c_1c_2}{8c_1\left[R_s + c_1(\Lambda W_0 + 2)\right] - 3c_2W_0}\right\}. \tag{51}$$

By an appropriate choice of the integration constants, giving the boundary conditions of the fields φ and ψ for $r = 0$, one can always satisfy the condition $m_s(R_s) > 0, \forall R_s$. In the limit $R_s \to \infty$, we obtain $m_s(R_s) \approx \left(\pi W_0\Lambda/\kappa^2\right)R_s$, that is, for large distances the mass of the string linearly increases with its radius.

4.2. $\bar{V}(\xi,\psi) = \bar{V}_0\xi^2\psi^2$

Next we will consider string type solutions in the Generalized Hybrid Metric Palatini Gravity under the assumption that the potential $\bar{V}$ is given by $\bar{V} = \bar{V}_0\xi^2\psi^2 = \bar{V}_0\alpha\psi^2$, with $\bar{V}_0$ constant. Equation (19) then becomes

$$-f(R,\mathcal{R}) + R\frac{\partial f(R,\mathcal{R})}{\partial R} + \mathcal{R}\frac{\partial f(R,\mathcal{R})}{\partial \mathcal{R}} = \bar{V}_0\frac{\partial f(R,\mathcal{R})}{\partial \mathcal{R}}\left(\frac{\partial f(R,\mathcal{R})}{\partial \mathcal{R}} + \frac{\partial f(R,\mathcal{R})}{\partial R}\right) \tag{52}$$

and a particular solution for the function $f(R,\mathcal{R})$ is

$$f(R,\mathcal{R}) = \sqrt{\frac{R}{\bar{V}_0}}(R - \mathcal{R}). \tag{53}$$

For this potential the field equations describing the string-like structure take the form

$$\frac{d\alpha}{dr} = u, \qquad \frac{d\psi}{dr} = v, \tag{54}$$

$$\frac{dW}{dr} = \frac{1}{2u}\left(\frac{3v^2}{2\psi} - \bar{V}_0\alpha\psi^2\right)W, \tag{55}$$

$$\frac{du}{dr} = -\frac{3v^2}{4\psi} - \frac{\bar{V}_0\alpha\psi^2}{2}, \tag{56}$$

$$\frac{dv}{dr} = -\frac{v}{u}\left(\frac{3v^2}{4\psi} - \frac{\bar{V}_0\alpha}{2}\right) + \frac{v^2}{2\psi} + \frac{2V_0}{3}\psi^2\left(\alpha + \frac{\psi}{2}\right). \tag{57}$$

For this model the string tension is given by

$$\frac{2\kappa^2}{3}\sigma = \frac{7}{6}\bar{V}_0\alpha\psi^2 - \frac{v^2}{2\psi}. \tag{58}$$

The metric function W^2 and the string tension σ are depicted in Fig. 1, for a varying initial condition $\psi'(0) = \psi_0$, while all the other initial conditions are fixed. In this case the radial metric function is an increasing function of the radial coordinate r, and its rate of increase is strongly dependent on the variations in the numerical values of ψ_0. Similarly to the previous cases, the string tension is a monotonically decreasing function of r, and it vanishes at a finite value of r, $r = R_s$, which uniquely defines the string radius. The string radius is weakly dependent on the variation of ψ_0, however, significant variations in σ do appear for small values of r.

The variations of the potential and of the function ψ are represented in Fig. 2. $\bar{V}$ is a slowly decreasing positive function of r, strongly dependent on the initial condition for ψ'. The function ψ takes negative values, and show a strong dependence on ψ_0.

The behavior of the function $\xi^2(r)$ is depicted in Fig. 3. ξ^2 is positive for $r \in [0, R_s]$, and thus the physical nature of the gravitational coupling in the present model is guaranteed. ξ^2 is a monotonically decreasing function of r, and its variation depends significantly on the numerical values of the initial conditions for $\psi'(0)$.

5. Conclusions

In this work we studied the existence and physical properties of local $U(1)$ cosmic strings in the context of the generalized hybrid metric-Palatini gravity. The theory is an extension to General Relativity, combining both metric and Palatini formalism. A main success of the theory is the possibility to generate long-range forces that pass the classical local tests of gravity at the Solar System level, thus avoiding some problematic features of the standard $f(R)$ theories. Another interesting advantage of the theory is that it admits an equivalent scalar-tensor representation, simplifying greatly the dynamical equations. The type of strings studied in this work are local gauge strings, using an approximation to the Vilenkin-prescribed energy-momentum tensor and different potential configurations.

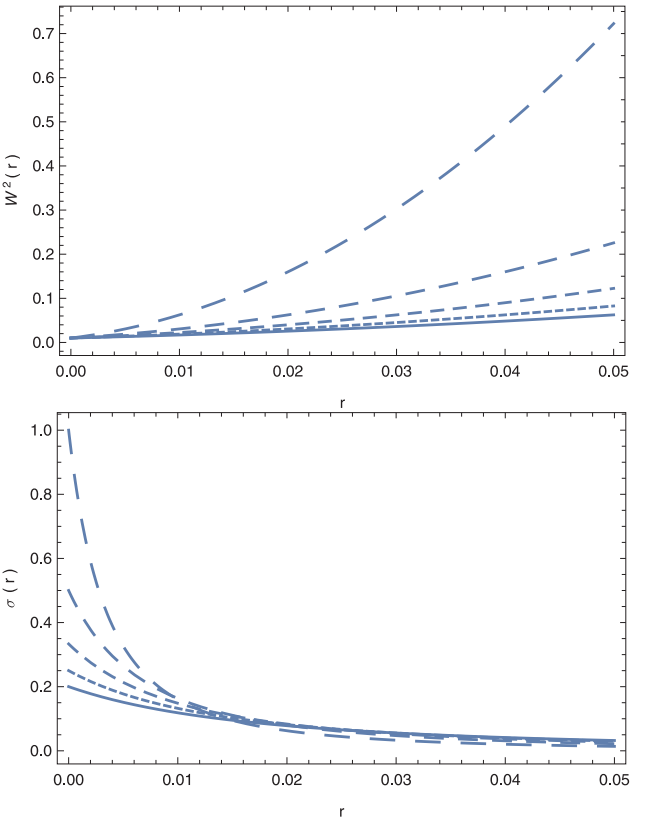

Fig. 1. Variations of the metric function $W^2(r)$ (top panel), and of the string tension $\sigma(r)$ (bottom panel) as a function of r (with all quantities in arbitrary units) for the $\bar{V}(\xi,\psi)=\bar{V}_0\xi^2\psi^2$ potential, for $\psi_0=-0.025$ (solid curve), $\psi_0=-0.020$ (dotted curve), $\psi_0=-0.015$ (short dashed curve), $\psi_0=-0.01$ (dashed curve), and $\psi_0=-0.005$ (long dashed curve), respectively. For $\bar{V}_0$ we have adopted the value $\bar{V}_0=10$, while the boundary conditions used to numerically integrate the field equations are $u_0=-0.01$, $\alpha_0=0.025$, $W(0)=0.10$, and $v_0=0.10$, respectively.

The field equations determine the string tension σ. These equations must be solved by choosing a functional form for the potential, and by imposing some appropriate boundary conditions at $r=0$ on the two scalar fields $\left(\xi^2,\psi\right)$, on their derivatives, and for $W^2(0)$. Since in the present approach these boundary conditions are arbitrary, and since the second order, strongly nonlinear system of the gravitational field equations is extremely sensitive to the variation of the boundary conditions, many types of cosmic string structures can be obtained by adopting some specific forms of V, and different sets of initial conditions.

The gravitational field equations describing cosmic string structures in generalized HMPG can be solved exactly in the simple cases of the vanishing and constant potentials.

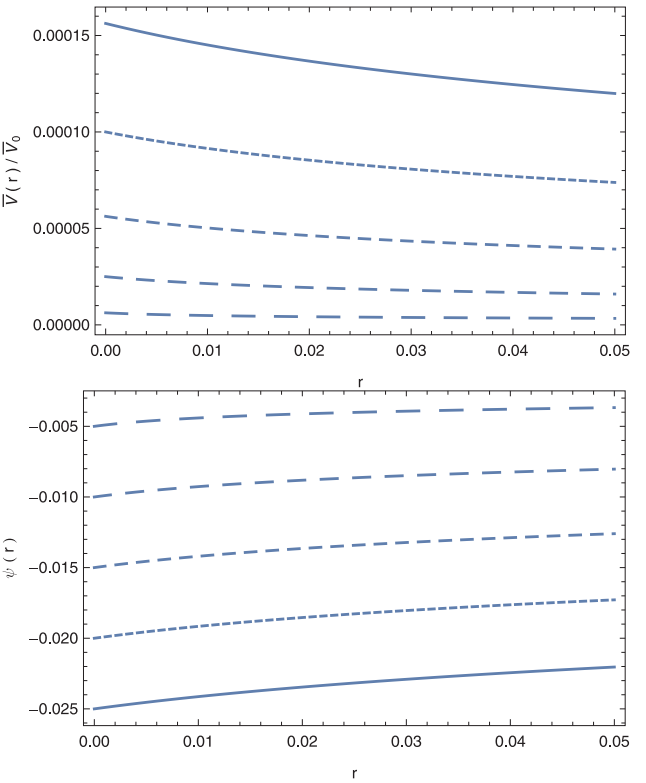

Fig. 2. Variations of the potential $\bar{V}(\xi,\psi)=\bar{V}_0\xi^2\psi^2$ (top panel), and of the function ψ (bottom panel) as a function of r (with all quantities in arbitrary units) for the $\bar{V}(\xi)=\bar{V}_0\xi^2\psi^2$ potential, for $\psi_0=-0.025$ (solid curve), $\psi_0=-0.020$ (dotted curve), $\psi_0=-0.015$ (short dashed curve), $\psi_0=-0.01$ (dashed curve), and $\psi_0=-0.005$ (long dashed curve), respectively. For $\bar{V}_0$ we have adopted the value $\bar{V}_0=10$, while the boundary conditions used to numerically integrate the field equations are $u_0=-0.01$, $\alpha_0=0.025$, $W(0)=0.10$, and $v_0=0.10$, respectively.

In the case of the constant, nonzero potential, the field equations can be solved exactly, and some simple expressions for the geometrical and physical parameters can be obtained. In this case, the string tension can be made positive by an appropriate choice of the potential. A solution with a constant string tension $\kappa^2\sigma=\Lambda/2$ can also be constructed, as well as a solution having $W(r)=W_0r$, which can describe the standard general relativistic string if $W_0^2=1-8\pi G\mu$. The string radius R_s can be uniquely defined, and it is given in terms of the constant potential, as well as two integration constants. Under the assumption that the string tension is positive in $r=0$, the string radius is also positive.

For other, more complicated forms of the potential it seems very difficult, if not impossible, to obtain exact analytical solutions of the field equations, and hence they must be solved numerically.

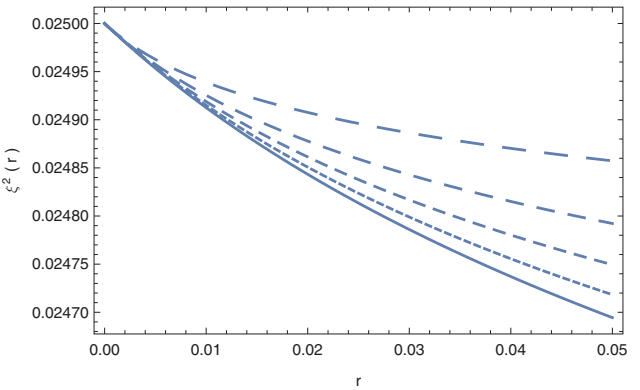

Fig. 3. Variation of ξ^2 as a function of r (with all quantities in arbitrary units) for the $\bar{V}(\xi,\psi) = \bar{V}_0\xi^2\psi^2$ potential, for $\psi_0 = -0.025$ (solid curve), $\psi_0 = -0.020$ (dotted curve), $\psi_0 = -0.015$ (short dashed curve), $\psi_0 = -0.01$ (dashed curve), and $\psi_0 = -0.005$ (long dashed curve), respectively. For $\bar{V}_0$ we have adopted the value $\bar{V}_0 = 10$, while the boundary conditions used to numerically integrate the field equations are $u_0 = -0.01$, $\alpha_0 = 0.025$, $W(0) = 0.10$, and $v_0 = 0.10$, respectively.

Since the potentials depend on at least one extra constant parameter, together with the five boundary conditions we obtain a very large boundary parameter space, containing from six to nine arbitrary parameters. The large number of parameters allows the construction of a large number of different numerical cosmic string models. However, we have restricted the set of parameters, as well as the physical nature of the solutions, by imposing three physical constraints, namely, that the string tension is positive inside the string, and it vanishes at the vacuum boundary, that the string must have a well defined and unique radius R_s, obtained from the condition $\sigma(R_s) = 0$, and that $\xi^2 > 0, \forall r \in [0, R_s]$. Even after imposing this set of restrictions, a large variety of string models in generalized HMPG theory can be obtained.

In conclusion, in the present work we have considered specific cosmic string models that are solutions of the field equations of the generalized HMPG theory. Modified gravity theories may have profound implications on the formation, properties and structure of cosmic strings, interesting and important topological objects that may have been generated in the early Universe. Hence, the theoretical investigations of strings in modified gravity models may therefore be a worthwhile pathway for future research.

New evidence of the azimuthal alignment of quasars spin vector in Large Quasar Groups and cosmic strings

R. J. Slagter

ASFYON, Astronomisch Fysisch Onderzoek Nederland,
former: University of Amsterdam, Dept. Theor. Phys., The Netherlands
E-mail: info@asfyon.com

There has been observational evidence about spin axes of quasars in large quasar groups correlated over hundreds of Mpc. This is seen in the radio spectrum as well as in the optical range. There is not yet a satisfactory explanation of this "spooky" alignment. This alignment cannot be explained by mutual interaction at the time that quasars manifest themselves optically. A cosmological explanation could be possible in the formation of superconducting vortices (cosmic strings) in the early universe, just after the symmetry-breaking phase of the universe. We gathered from the NASA/IPAC and SIMBAD extragalactic databases the right ascension, declination, inclination, position angle and eccentricity of the host galaxies of 3 large quasar groups to obtain the azimuthal and polar angle of the spin vectors. The alignment of the azimuthal angle of the spin vectors of quasars in their host galaxy is confirmed in the large quasar group U1.27 and compared with two other groups in the vicinity, i.e., U1.11 and U1.28, investigated by Clowes (2013). It is well possible that the azimuthal angle alignment fits the predicted azimuthal angle dependency in the theoretical model of the formation of general relativistic superconducting vortices, where the initial axially symmetry is broken just after the symmetry breaking of the scalar-gauge field.

Keywords: Quasar groups; alignment spin vectors; host galaxy; cosmic strings; scalar-gauge field.

1. Introduction

A large quasar group (LQG) is a cluster of quasars that makes the largest astronomical structures in the current universe. Their sizes can be of the order of hundreds of Mpc. Astronomers believe that a quasar is an active galactic nuclei (AGN) with a vibrant eruption of radiation both optical and in radio range originated by a spinning (Kerr-) black hole, surrounded by an accretion disk. A LQG has an internal non-uniform distribution of spin vectors seen in the radio spectrum[1] and the optical spectrum as observed by Hutsemekers et al.[2,3] This coherence is mysterious and cannot be explained by mutual interaction at the time scale of primordial galaxies formation but rather by use of a more advanced method[4–6] In a recent study, Slagter[7] found that the azimuthal angle of the spin vector of quasars in their host galaxies in six quasar groups, show preferred directions. This is demonstrated through an emergent azimuthal angle dependency of the general relativistic Nielsen-Olesen (NO) vortices at the point after the symmetry breaking at grand unified theory (GUT)-scale. This review focuses on three more LQG, studied by

Clowes.[8,9] In section 2 we outline the theoretical model and in section 3 we present a theoretical proof of the breaking of the axial symmetry and in section 4 we present the data analysis.

2. The model

2.1. *The U(1) scalar-gauge field*

Superconductivity can be described by the famous Ginsburg-Landau model.[10] It is a beautiful example of a quantum field model, where a scalar field acts as an order parameter. This construction was made before the introduction of the scalar Higgs field of the Standard Model of particle physics! For the type II superconductivity of the Ginzburg-Landau (GL) theory,[11,12] the electro-magnetic (EM) gauge invariance is broken and the well-known Meissner effect occurs.[14] One says that the phase symmetry is spontaneously broken and the EM field acquires a length scale, which introduces a penetration depth of the gauge field A_μ in the superconductor and a coherence length of Φ. In the relativistic case one says that the photon acquires mass. Because we have three space dimensions, these solutions of the GL theory behave like magnetic flux vortices (or Nielsen-Olesen (NO) strings[13]) extended to tubes and carry a quantized magnetic flux $2\pi n$, with n an integer, the topological charge or winding number of the field. It was discovered by Abrikosov[14] that these vortices can form a lattice. These localized vortices (or solitons) in the GL-theory are observed in experiments. The phenomenon of magnetic flux quantization in the theory of superconductivity is characteristic for so-called ordered media. After the discovery of the electroweak unification, one could formulate the relativistic vortex solution, nicely expressed by Nielsen and Olesen. We write the scalar field and gauge field as

$$\Phi = \eta X(t,r)e^{in\varphi}, \qquad A_\mu = \frac{n}{e}\big[P(t,r)-1\big]\nabla_\mu\varphi,. \tag{1}$$

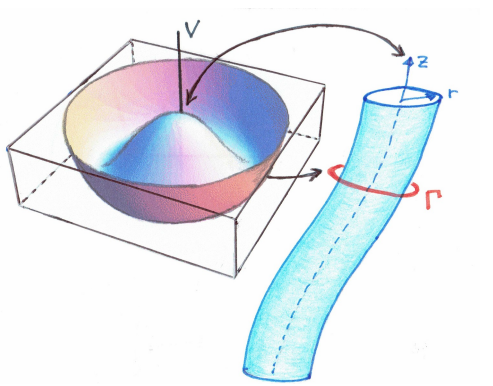

Fig. 1. Mapping the degenerated minima of the potential to position space.

The model is invariant under the group U(1) of local gauge transformations (of the second kind)

$$\Phi(\mathbf{x}) \to e^{i\chi(x)}\Phi(x), \qquad A_a(\mathbf{x}) \to A_a(x) + \frac{1}{e}\partial_a\chi(\mathbf{x}). \tag{2}$$

The scalar potential is the well-known "mexican hat" potential (see figure 1) $V(\Phi) = \frac{1}{8}\lambda\left(\Phi\Phi^* - \eta^2\right)^2$ with η the vacuum expectation value. Further, $\frac{m_\Phi}{m_A} = \frac{e^2}{\lambda}$ is the ratio of the scalar to gauge masses. This potential leads to a nonzero η and spontaneously breaking of the U(1) symmetry (note that the parameters are in general temperature dependent[a]. We say that the "false" vacuum for $\Phi = 0$ is broken and the true vacuum is then at the lowest points of the potential. The points of the false vacuum form one or more continuous curves or filaments in space. Such a filament of non-zero Higgs field energy is called a (cosmic-) string (CS) and first proposed by Kibble (1976). The mass and dimensions of the CS are largely determined by the energy scale at which the relevant phase transition occurs. The mass in the GUT scale can be of the order $10^{21} gcm^{-1}$ and there is no restriction for the length. The forces existing between the vortices are the electromagnetic- and scalar force. When the vortices get close together, the problem becomes non-linear and the resulting forces depends on the ratio $\frac{e^2}{\lambda}$. For details, see, for example, the text book of Felsager.[15]

The vortex solution possesses mass, so it will couple to gravity. The resulting self-gravitating cosmic strings (CS) still show all the features of superconductivity, but the stability conditions complicate considerably. The stability of the formed lattices depends critically on the parameters of the model, certainly when gravity comes into play. The force between the gauged vortices depends on the the strength of the self-interaction potential of the Higgs field, the gauge-coupling constant, the energy scale at which the phase transition takes place and the spacetime structure. When the mass of the Higgs field is greater than the mass of the gauge field, vortices will repel each other. So gravity could balance the vortices. The energy of the vortex

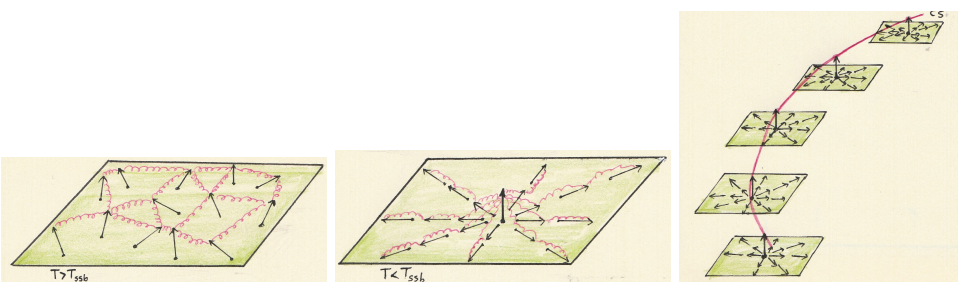

Fig. 2. Formation of the cosmic string. When the temperature drops, not all the "points" in the configuration can follow the dictated new symmetry.

[a]The string structure is cylindrical symmetric, so one uses the polar coordinates (t, r, z, φ). This choice is very convenient, when one considers rotating compact objects, such as a Kerr spacetime.

grows by increasing multiplicity n, so configurations with $n > 1$ can be seen as multi-soliton states and it is energetically favourable for these to decay into n well separated $n = 1$ solitons. Vortices with high multiplicity can be formed during the symmetry breaking. The total vortex number n is the sum of multiplicities $n_1, n_2, ..$ of isolated points (zero's of Φ).[12]

2.2. *The high-frequency approximation*

A linear approximation of wavelike solutions of the Einstein equations is not adequate when one is dealing with high curvature (or high energy scale), i.e., close to the horizons of black holes or in the early stage of the universe at the time of mass formation by the Higgs mechanism. There will be a "back-reaction" on the background spacetime. There is a powerful approximation method which can deal with these non linearities: the multiple-scale method. Pioneer work was done by ChoquetBruhat.[16] One expands the relevant fields[17]

$$V_i = \sum_{n=0}^{\infty} \frac{1}{\omega^n} F_i^{(n)}(\mathbf{x}, \xi), \tag{3}$$

where ω represents a dimensionless parameter ("frequency"), which will be large. Further, $\xi = \omega\Theta(\mathbf{x})$, with Θ a scalar (phase) function on the manifold. The small parameter $\frac{1}{\omega}$ can also be the ratio of the characteristic wavelength of the perturbation to the characteristic dimension of the background. On warped spacetimes it could also be the ratio of the extra dimension to the background dimension. In the vacuum case, we expand the metric

$$g_{\mu\nu} = \bar{g}_{\mu\nu} + \frac{1}{\omega} h_{\mu\nu}(\mathbf{x}, \xi) + \frac{1}{\omega^2} k_{\mu\nu}(\mathbf{x}, \xi) + ..., \tag{4}$$

where we defined

$$\frac{dg_{\mu\nu}}{dx^\sigma} = g_{\mu\nu,\sigma} + \omega l_\sigma \dot{g}_{\mu\nu}, \quad g_{\mu\nu,\sigma} = \frac{\partial g_{\mu\nu}}{\partial x^\sigma}, \quad \dot{g}_{\mu\nu} = \frac{\partial g_{\mu\nu}}{\partial \xi}, \tag{5}$$

with $l_\mu = \frac{\partial \Theta}{x^\mu}$. One then says that

$$V_i = \sum_{n=-m}^{\infty} \frac{1}{\omega^n} F_i^{(n)}(\mathbf{x}, \xi) \tag{6}$$

is an approximate wavelike solution of order n of the field equation, if $F_i^{(n)} = 0, \forall n$. One can substitute the expansion into the field equations. The Ricci tensor then expands as

$$R_{\mu\nu} \to \omega R_{\mu\nu}^{(-1)} + \left(\bar{R}_{\mu\nu} + R_{\mu\nu}^{(0)}\right) + \frac{1}{\omega} R_{\mu\nu}^{(1)} + ... \tag{7}$$

By equating the subsequent orders to zero, we obtain

$$R_{\mu\nu}^{(-1)} = 0 = \frac{1}{2} \bar{g}^{\beta\lambda} (l_\lambda l_\mu \ddot{h}_{\beta\nu} + l_\nu l_\beta \ddot{h}_{\mu\lambda} - l_\lambda l_\beta \ddot{h}_{\mu\nu} - l_\nu l_\mu \ddot{h}_{\beta\lambda}), \tag{8}$$

$$R^{(0)}_{\mu\nu} + \bar{R}_{\mu\nu} = 0, \qquad R^{(1)}_{\mu\nu} = 0, \qquad .... \tag{9}$$

Here we used $l_\mu l^\mu = 0$. The rapid variation is observed in the direction of l_μ. In the radiative outgoing Eddington-Finkelstein coordinates, we have $x^1 = u = \Theta(\mathbf{x}) = t - r$ and $l_\mu = (1, 0, 0, 0)$, while the bar stands for the background.

We now expand the scalar and gauge field

$$A_\mu = \bar{A}_\mu(\mathbf{x}) + \frac{1}{\omega} B_\mu(\mathbf{x}, \xi) + \frac{1}{\omega^2} C_\mu(\mathbf{x}, \xi) + ..., \tag{10}$$

$$\Phi = \bar{\Phi}(\mathbf{x}) + \frac{1}{\omega} \Psi(\mathbf{x}, \xi) + \frac{1}{\omega^2} \Xi(\mathbf{x}, \xi) + ..., \tag{11}$$

where we write the subsequent orders of the scalar field as

$$\bar{\Phi} = \eta \bar{X}(t, r) e^{in_1\varphi}, \quad \Psi = Y(t, r, \xi) e^{in_2\varphi}, \quad \Xi = Z(t, r, \xi) e^{in_3\varphi}, \tag{12}$$

with n_i the winding numbers. So we suppose that the winding numbers of the subsequent orders of the scalar field expansion coefficients are different. This can happen by the quantum fluctuations just after the symmetry breaking scale.

2.3. *The exitation and decay of the vortices*

The energy of the string in flat spacetime is given by

$$E = \frac{1}{2} \frac{n^2}{e^2 r^2} (\partial_r P)^2 + \frac{1}{2} \eta^2 (\partial_r X)^2 + \frac{1}{2} n^2 \eta^2 \frac{P^2 X^2}{r^2} + \frac{1}{8} \beta \eta^4 (X^2 - 1)^2. \tag{13}$$

The energy is proportional with n^2, so there can be no exact ground state for the string carrying multiple flux quanta (the expression changes when gravity comes into play and new features will emerge). So the configuration will dissociate into n well separated $n = 1$ vortices.

It turns out, when one evaluates the field equations, that an imprint will be left over of the azimuthal dependency of the orientation of the clustering of Abrikosov vortices. See figure 3. The azimuthal angle φ does not reach of course, the partial differential equations (PDE) in the unperturbed case. So the axial symmetry is dynamically broken. The azimuthal dependency emerges already to first order in the approximation. For example,

$${}^4T^{(0)}_{\varphi\varphi} = e^{-2\bar{\gamma}} r^2 \dot{Y} (\partial_t \bar{X} - \partial_r \bar{X}) \mathbf{cos}[(n_2 - n_1)\varphi] + e^{2\bar{\psi} - 2\bar{\gamma}} \frac{\dot{B}}{\bar{W}_1^2 \epsilon} (\partial_r \bar{P} - \partial_t \bar{P}). \tag{14}$$

However, in $T^{(1)}_{\varphi\varphi}$ there appears terms like $\cos(n_2 - n_1)\varphi$ and $\cos(n_3 - n_1)\varphi$. The perturbative appearance of a nonzero energy-momentum component $T_{t\varphi}$ can be compared with the phenomenon of bifurcation along the Maclaurin-Jacobi sequence of equilibrium ellipsoids of self-gravitating compact objects, signalling the onset of secular instabilities.[18] This shows a similarity with the Goldstone-boson modes of spontaneously broken symmetries of continuous groups. The recovery of the SO(2) symmetry from the equatorial eccentricity takes place at a time comparable to the

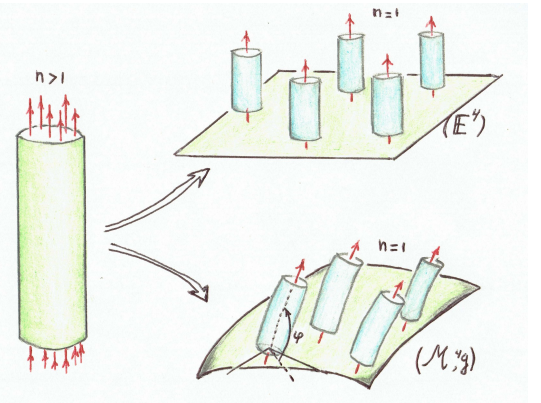

Fig. 3. Excitation and decay of a high multiplicity vortex into correlated vortices of unit flux $n = 1$. Top: the Abrikosov lattice in Euclidean space. Bottom: correlated vortices with preferred azimuthal angle φ in curved spacetime after the symmetry breaking.

emission of gravitational waves. The particular ellipsoid orientation in the frame (r, φ, z) expressed as $\varphi_0 \equiv \varphi(t_0)$, is at $t > t_0$ and determined by the transformation $\varphi \to \varphi_0 - Jt$, where J is the rotation frequency (circulation or "angular momentum") of the coordinate system. The angle φ_0 is fixed arbitrarily at the onset of symmetry breaking.

2.4. *Contribution from the bulk*

It is conjectured that the imprint of the azimuthal dependency will be to faint to contribute to observational evidence, after the expansion of the universe. However, let us consider the warped 5D spacetime

$$ds^2 = \mathcal{W}(t,r,y)^2\Big[e^{2(\gamma(t,r)-\psi(t,r))}(-dt^2+dr^2)+e^{2\psi(t,r)}dz^2 + r^2e^{-2\psi(t,r)}d\varphi^2\Big]+dy^2, \tag{15}$$

with $\mathcal{W} = W_1(t,r)W_2(y)$ is the warp factor. All standard model fields reside on the brane, while gravity can propagate into the bulk. An extended treatment of the warped five-dimensional spacetime and the effective gravitational equations can be found in Shiromizu et al.[19] and Slagter.[20] The warpfactor can be solved exactly in the case of the spacetime Eq.(15) from the 5D Einstein equations

$$\mathcal{W}^2 = W_2(y)^2W_1(t,r)^2 = \frac{e^{2\sqrt{-\frac{1}{6}\Lambda_5}(y-y_0)}}{\tau r} \cdot\Big(d_1e^{(\sqrt{2\tau})t}-d_2e^{-(\sqrt{2\tau})t}\Big)\Big(d_3e^{(\sqrt{2\tau})r}-d_4e^{-(\sqrt{2\tau})r}\Big), \tag{16}$$

If we inspect, for example, the several orders of the (t, φ) components of the energy momentum tensor

$${}^4\bar{T}_{t\varphi} = 0, \qquad {}^4T^{(0)}_{t\varphi} = \bar{X}\bar{P}\dot{Y}\mathbf{sin}[(n_2-n_1)\varphi] \tag{17}$$

$$
\begin{aligned}
{}^4T^{(1)}_{t\varphi} = &\Big[\partial_t\bar{X}Y(n_1-n_2-\bar{P})+\bar{X}(\bar{P}\partial_t Y+\epsilon B\dot{Y})\Big]\mathbf{sin}[(n_2-n_1)\varphi]\\
&+\bar{X}\bar{P}\dot{Z}\mathbf{sin}[(n_3-n_1)\varphi]+\frac{e^{2\bar{\psi}-2\bar{\gamma}}}{\bar{W}_1^2}\dot{Y}h_{14}(\partial_t\bar{X}-\partial_r\bar{X})\mathbf{cos}[(n_2-n_1)\varphi]\\
&+\bar{X}^2\bar{P}\epsilon B_0-\frac{1}{8}\beta(\bar{X}^2-\eta^2)^2h_{14}\\
&-\frac{e^{2\bar{\psi}-2\bar{\gamma}}}{2\bar{W}_1^2}h_{14}\Big[\frac{e^{2\bar{\psi}}}{r^2\bar{W}_1^2\epsilon^2}(\partial_t\bar{P}-\partial_r\bar{P})^2+\partial_r\bar{X}^2-\partial_t\bar{X}^2+e^{2\bar{\gamma}}\frac{\bar{X}^2\bar{P}^2}{r^2}\Big], \qquad (18)
\end{aligned}
$$

then it is observed that the warpfactor enters in the denominator for some terms. So the φ terms can dominate at late times (see also Eq.(14)). It will evident that an emergent imprint of a preferred azimuthal angle φ_0 is left over on the lattice of vortices when the ground state is reached ($n=1$). The configuration will become again axially symmetric.

3. A fundamental proof of the breaking of axially symmetry: The pure gravitational wave case

So far, we found that temporarily off-diagonal terms occurred in the perturbative approach of the Einstein scalar gauge field. What remains unclear is if the breaking of the axially symmetry already appears in the vacuum case like in the vicinity of the black hole spacetime. It is conjectured that the formation of primordial (Kerr-) black holes (and so quasars) happened in the early stages of the evolution of the universe before the stars were formed. Therefore, consider the radiative Vaidya spacetime in Eddington-Finkelstein coordinates [b]

$$
ds^2=-\Big(1-\frac{2M(u)}{r}\Big)du^2-2dudr+r^2(d\theta^2+\sin^2\theta d\varphi^2), \qquad (19)
$$

which is the Schwarzschild black hole spacetime with $u=t-r-2M\log(\frac{r}{2M}-1)$. Here we used $l_\mu l^\mu=0$. In the radiative coordinates, we have $x^1=u=\Theta(\mathbf{x})$ and $l_\mu=(1,0,0,0)$. From Eq.(8) we obtain

$$
h_{rr}=h_{r\theta}=h_{r\varphi}=0, \qquad h_{\varphi\varphi}=-\sin^2\theta h_{\theta\theta}. \qquad (20)
$$

From the zero-order equations Eq.(9) we obtain

$$
\ddot{k}_{rr}=0, \qquad \dot{h}_{\theta\theta}=r\partial_r\dot{h}_{\theta\theta}, \qquad \dot{h}_{\theta\varphi}=r\partial_r\dot{h}_{\theta\varphi}. \qquad (21)
$$

So one writes

$$
h_{\theta\theta}=r\alpha(u,\theta,\varphi,\xi), \quad h_{\theta\varphi}=r\beta(u,\theta,\varphi,\xi), \quad h_{\varphi\varphi}=-r\alpha\sin^2\theta. \qquad (22)
$$

Further, we have

$$
\ddot{k}_{r\theta}=\frac{1}{r}\Big(2\dot{\alpha}\cot\theta+\partial_\theta\dot{\alpha}+\frac{1}{\sin^2\theta}\partial_\varphi\dot{\beta}\Big), \qquad (23)
$$

[b] This spacetime is also applied to describe the evaporation of a black hole by hawking radiation in a quantum mechanical way.

$$\ddot{k}_{r\varphi} = \frac{1}{r}\Big(\dot{\beta}\cot\theta - \partial_\varphi\dot{\alpha} + \partial_\theta\dot{\beta}\Big), \tag{24}$$

$$\frac{dM}{du} = -\frac{\ddot{k}_{\phi\phi} + \sin^2\theta\ddot{k}_{\theta\theta}}{4\sin^2\theta} - \frac{1}{2}r\dot{h}_{uu} - \frac{1}{4}\Big(\dot{\alpha}^2 + \frac{\dot{\beta}^2}{\sin^2\theta}\Big) + \frac{1}{4}\Big(\ddot{\alpha}^2 + \frac{\ddot{\beta}^2}{\sin^2\theta}\Big). \tag{25}$$

Not all the components of $h_{\mu\nu}$ and $k_{\mu\nu}$ are physical, so one needs some extra gauge conditions. Suitable choice of α and β (Choquet-Bruhat uses, for example, $\alpha = 0, \beta = g(u)h(\xi)\sin\theta$), leads to a solution to second order which is in general not axially symmetric. We can integrate these zero order equations with respect to ξ. One obtains then some conditions on the background fields, because terms like $\int \dot{\alpha}d\xi$ disappear. From Eq. (25), we obtain

$$\frac{dM}{du} = -\frac{1}{4\tau}\int_0^\tau \Big(\dot{\alpha}^2 + \frac{\dot{\beta}^2}{\sin^2\theta}\Big)d\xi, \tag{26}$$

which is the back-reaction of the high-frequency disturbances on the mass M. τ is the period of $\dot{h}_{\mu\nu}$. This expression can be substituted back into Eq.(25). However, in the non-vacuum case, the right-hand side will also contain contributions from the matter fields. In order to obtain propagation equations for $h_{\mu\nu}$ and $k_{\mu\nu}$, one proceeds with the next order equation $R^{(1)}_{\mu\nu} = 0$. First of all, Eq.(23) and (24) are consistent with $R^{(1)}_{r\varphi} = 0$ and $R^{(1)}_{r\theta} = 0$. Further, one obtains propagation equations for α and β and for some second order perturbations, such as $k_{\varphi\varphi}$. Moreover, the (φ, θ)-dependent part of the PDE's for α and β (say $A(\theta, \varphi), B(\theta, \varphi)$) can be separated (for the case $k_{\theta\varphi} \neq 0$):

$$\partial_\varphi B + 2\sin\theta\cos\theta A + \sin^2\theta\partial_\theta A = 0, \tag{27}$$

$$\sin^2\theta\partial_{\theta\theta}A + 7\sin\theta\cos\theta\partial_\theta A + 4\cot\theta\partial_\varphi B + 2(5\cos^2\theta - 1)A + 2\partial_{\theta\varphi}B = 0. \tag{28}$$

A non-trivial simple solution is

$$A = \frac{\cos\theta(sin\varphi + \cos\varphi)}{sin^3\theta}, \quad B = \frac{\sin\varphi - \cos\varphi}{\sin^2\theta} + G(\theta), \tag{29}$$

with $G(\theta)$ arbitrary. So the breaking of the spherically and axially symmetry is evident.

4. Data analysis on quasar groups

In our model it is conjectured that the azimuthal dependency expresses itself in the φ alignment of quasar spin vectors in LQG.[7] From the NASA/IPAC extragalactic database and SIMBAD we extract for the three LQG U1.11, U1.27 and U.28 the right ascension, declination, inclination, position angle and eccentricity of the host galaxies. The 3D orientation of the spin vectors can then be calculated by[21–23] by

$$\cos^2 i = \frac{\epsilon^2 - \epsilon_0^2}{1 - \epsilon_0^2}, \tag{30}$$

$$\sin\theta = -\cos i\sin\delta \pm \sin i\sin p\cos\delta, \tag{31}$$

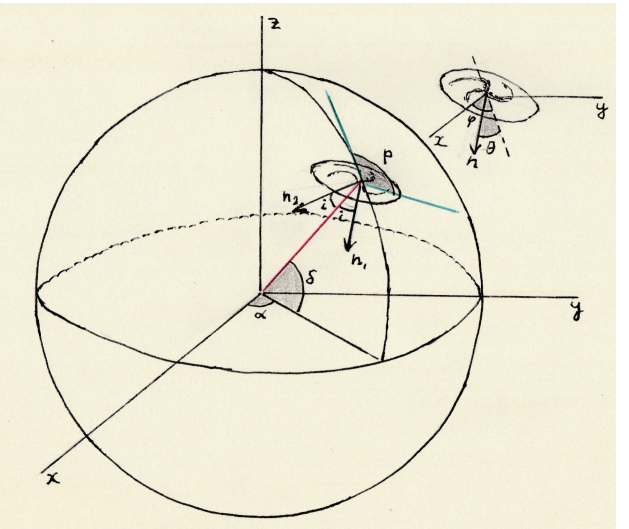

Fig. 4. The two polar coordinates (φ, θ)

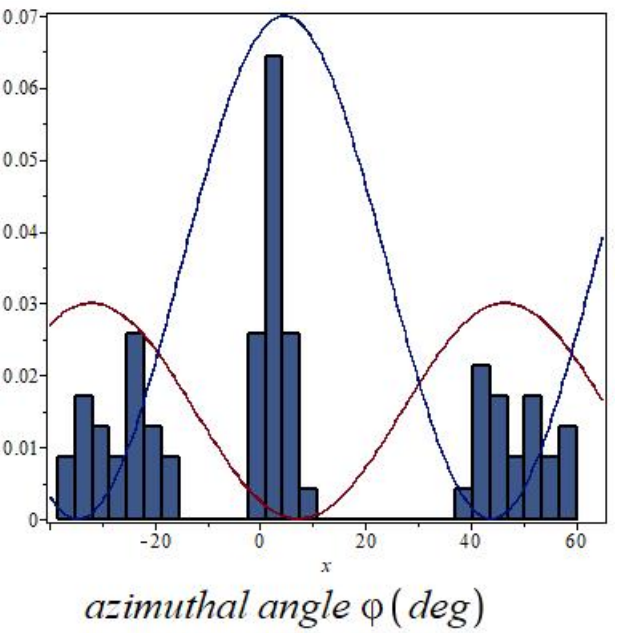

Fig. 5. Plot of the azimuthal angle φ in degrees. This shows the distribution of the azimuthal angle of the spin vectors in the LQG U1.27 (N=71) with a best-fit of two trigonometric functions with a phase shift range of 45°.

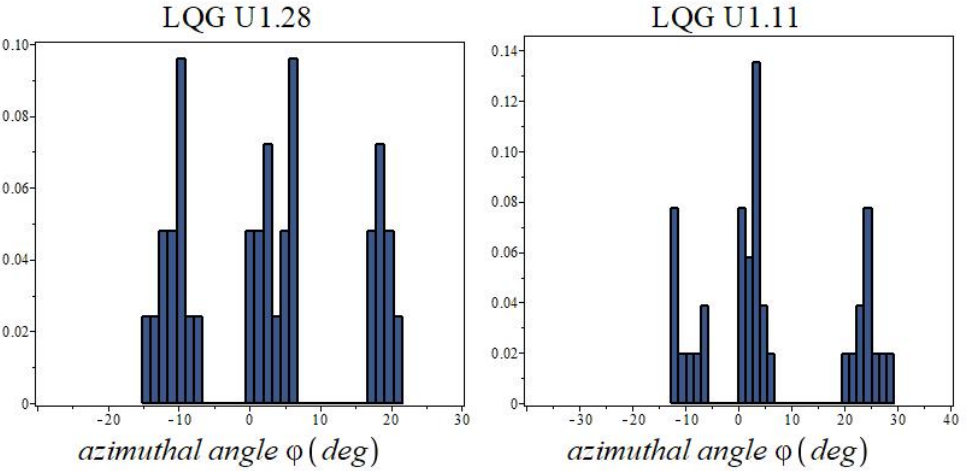

Fig. 6. Plot showing the distribution of the azimuthal angle φ for the LQG U1.28 (N = 34) and U1.11 (N = 38).

$$\sin\varphi = \frac{-\cos i\cos\delta\sin\alpha + \sin i(\mp\sin p\sin\delta\sin\alpha \mp \cos p\cos\alpha}{\cos\theta}. \tag{32}$$

We used for the intrinsic flatness (ϵ_0) the value 0.2, which is the standard value when we have no information about the morphological types of the analyzed galaxies. In figure 5 and 6 we plotted the azimuthal angle. Without statistical analysis one can conclude that the preferred orientations are evident. In the case of LQG U1.27 (see Table 1 for the data), we fitted two trigonometric functions on the distribution, which can theoretically be explained.

5. Conclusion

We find in a nonlinear approximation, an emergent azimuthal-angle dependency of Nielsen-Olesen vortices just after the symmetry breaking at GUT scale. Using a approximation scheme, the azimuthal-angle dependency appears in the first and second order field equations as trigonometrical functions $\sin(n_i - n_j)\varphi$ and $\sin(n_i - n_j)\varphi(i > j)$, with n_i the multiplicities of subsequent perturbation terms of the scalar field. Vortices with high multiplicity decay into a lattice with entangled Abrikosov vortices. The stability of this lattice of correlated flux $n = 1$ vortices with preferred azimuthal-angle is guaranteed by the contribution from the bulk spacetime by means of the warp factor: the cosmic string becomes super-massive for some time during the evolution. These so-called super-massive cosmic strings arise in a natural way in string theory or M-theory., i.e., brane-world models and are produced when the universe underwent phase transitions at energies much higher than the GUT scale, $G\mu > 1$. The imprint on the effective 4D brane spacetime can be

Table 1. Data for the LQG U1.27 (N=71) from NASA/IPAC and SIMBAD. The successive columns represent: right ascension, declination, redshift, inclination, eccentricity, position angle, azimuthal angle and polar angle. We omitted the other two values $\pi - \theta$ in the last column, belonging to the minus sign of φ.

caused by wavelike disturbances triggered by the huge mass of the cosmic strings in the bulk. One conjectures that these disturbances could act as an effective dark energy field. Another possible effect can be the formation of massive KK-modes as the imprint of the 5D gravitational field on the 4D brane. We used the azimuthal-angle correlation for the explanation of the recently observed alignment of polarization axes of quasars in large quasar groups. The detailed behavior of this alignment can be explained with our model. The two different orientations perpendicular to each other in quasars groups of less richness could be a second order effect in our model.

More data of high-redshift quasars will be needed in order to test the second order effect predicted in our model.

6. The Data

The data of LQG U1.27 underlying this article are gathered in Table 1.

Keywords: Cosmic strings.

Cosmic strings (CS's) are topological defects formed at the GUT symmetry breaking scale in the Einstein-U(1) scalar- gauge field model. This model shows a surprising resemblance with superconductivity and the relativistic Nielsen-Olesen quantized magnetic flux vortex solution. In the standard model of particle physics this scalar-gauge field is responsible for the spontaneously broken symmetry (Higgs mechanism). So one could say that this quantum field with the Mexican hat potential has lived up to its reputation. In cosmological context, the confined regions of the false vacuum of the scalar field form a locus of trapped energy, i.e., a CS. The mass and dimension of a CS is largely determined by the energy scale at which the phase transition takes place. It is believed that in the FLRW model a scale-invariant cosmic string-network is formed. Observational bounds, however, predict a negligible contribution of CS's to large-scale inhomogeneities such as the angular distribution in the CMB radiation. A renewed interest occurred when it was realized that CS's could be produced within the framework of superstring theory inspired cosmological models, i.e., brane-world models. Supersymmetric GUT's can even demand the existence of CS. These super-massive CS's could be produced when the universe underwent phase transitions at energies much higher than the GUT scale, so their gravitational impact increases. Although evidence of CS are not yet found, new observational windows are opened by these super-massive CS's.

In this CS1 parallel session one could present cosmic string-related subjects, such as observational results on CS, gravitational waves and CS, vortex solutions and GRT, cosmic strings and higher dimensional models.

Silva evaluates the possibility of the existence of gravitationally bound string-like objects in the framework of the general hybrid metric-Palatini gravity theory,

in which the gravitational action is represented by functions in terms of the Ricci and Palatini scalars, respectively. This theory recognizes equivalent scalar-tensor representations in two independent scalar fields. Assuming cylindrical symmetry and metric invariance, he obtains a gravitational field equation that theoretically describes the structure of the cosmic string. The physical and geometric properties of the cosmic string are determined by two scalar fields, as well as the effective field potential, which functionally depends on two scalar fields. The field equation can be solved exactly for constant and zero potential, respectively, with the corresponding string tensions taking negative and positive values. In addition, for a more general class of potential, which has an additive algebraic structure and multiplication in two scalar fields, the equations of the gravitational field are solved numerically. For each potential, he investigated the effect of changing the parameters of the potential and boundary conditions on the structure of the cosmic string. Thus, he obtains a large class of stable string configurations, the main parameters of which (string tension and radius) substantially depend on the effective field potential and boundary conditions.

Rosa studied 5-dimensional braneworld scenarios in the scalar-tensor representation of the generalized hybrid metric-Palatini gravitational theory. He starts by considering a model for a brane supported purely by the gravitational scalar fields of the theory and then considers other distinct cases where the models are also supported by an additional matter scalar field. He investigates the stability of the gravity sector and shows that the models are all robust against small fluctuations of the metric. In particular, in the presence of the additional scalar field, he finds that the profile of the gravitational zero mode may be controlled by the parameters of the model, being also capable of developing internal structure.

Slagter tried to explain the observational evidence of the correlation of the spin axes of quasars in large quasar groups over hundreds of Mpc. This is seen in the radio spectrum as well as in the optical range. There is not yet a satisfactory explanation of this "spooky" alignment. This alignment cannot be explained by mutual interaction at the time that quasars manifest themselves optically. A cosmological explanation could be possible in the formation of superconducting vortices (cosmic strings) in the early universe, just after the symmetry-breaking phase of the universe. He gathers from the NASA/IPAC and SIMBAD extragalactic databases the right ascension, declination, inclination, position angle and eccentricity of the host galaxies of 3 large quasar groups to obtain the azimuthal and polar angle of the spin vectors. The alignment of the azimuthal angle of the spin vectors of quasars in their host galaxy is confirmed in the large quasar group U1.27 and compared with two other groups in the vicinity, i.e., U1.11 and U1.28, investigated by Clowes (2013). It is well possible that the azimuthal angle alignment fits the predicted azimuthal angle dependency in the theoretical model of the formation of general relativistic superconducting vortices, where the initial axially symmetry is broken just after the symmetry breaking of the scalar-gauge field.

Blasi presented research in gravitational wave astronomy which could open a new window of exploration in fundamental physics. The recent analysis by the NANOGrav collaboration based on the 12.5-year pulsar-timing data set has shown evidence for a common red process which is compatible with a stochastic background of gravitational waves. He discusses the interpretation of this signal in terms of physics beyond the Standard Model with focus on cosmic strings, highly energetic topological defects arising as a consequence of cosmological phase transitions in the early Universe.

Scaling solutions of wiggly cosmic strings

Cosmic string networks form during cosmological phase transitions as a consequence of the Kibble mechanism. The evolution of the simplest networks is accurately described by the canonical Velocity Dependent One-Scale (VOS) model. However, numerical simulations have demonstrated the existence of significant quantities of short-wavelength propagation modes on the strings, known as wiggles, which motivated the recent development of a wiggly string extension of the VOS. Here we summarize recent progress in the physical interpretation of this model through a systematic study of the allowed asymptotic scaling solutions of the model. The modeling mainly relies on three mechanisms: the universe's expansion rate, energy transfer mechanisms (e.g., the production of loops and wiggles), and the choice of the scale in which wiggles are coarse-grained. We consider the various limits in which each mechanism dominates and compare the scaling solutions for each case, in order to gain insight into the role of each mechanism in the overall behavior of the network. Our results show that there are three scaling regimes for the wiggliness, consisting of the well-known Nambu-Goto solution, and non-trivial regimes where the amount of wiggliness can grow as the network evolves or, for specific expansion rates, become a constant. We also demonstrate that full scaling of the network is more likely in the matter era than in the radiation epoch, in agreement with numerical simulations.

Keywords: Cosmology; Topological Defects; Cosmic Strings; Wiggly Strings.

1. Introduction

Cosmic string networks arise in many theories of unification beyond the standard model. In the context of cosmology, they are predicted to have been formed in the early universe as a consequence of the Kibble mechanism.[1] Due to the non-linearity and non-trivial interactions intrinsic to these networks, a complete quantitative description of their evolution, as well as of their observational consequences, proves to be a difficult task.[2]

An accurate description of cosmic strings is accomplished through two complementary approaches: numerical simulations (Nambu-Goto or Abelian-Higgs) and

analytic models. The analytic modeling of string networks relies on the statistical physics of the network so as to derive a description of its thermodynamics. The analytic framework for the simplest Nambu-Goto string networks is the Velocity Dependent One-Scale (VOS) model.[3,4] As the direct comparisons with Nambu-Goto and Abelian-Higgs numerical simulations[5–8] demonstrate, the VOS is able to capture the key large-scales properties of the network extremely well. The VOS is built upon the one-scale assumption embodied in the original model developed by Kibble,[9] which expresses the evolution of the network in terms of a single length scale. This length scale can be the inter-string distance, the correlation length ξ, or the average curvature radius R (note these length scales are expected to be identical in this formalism). Various frameworks attempting to describe the dynamics of string defects have been developed, like the three-scale approach,[10] but it was only with the advent of the VOS that a model capable of making robust predictions in various cosmological epochs emerged. The key difference in the VOS framework lies in an additional macroscopic quantity, a root-mean-square (RMS) velocity, whose evolution is described by an extension of the Newton's Second Law. The equations of the standard Nambu-Goto VOS model are rigorously deduced from the Nambu-Goto effective action.

In spite of the successes of the VOS, the model fails to give an accurate description of realistic networks of strings, whose worldsheets are expected to have additional degrees of freedom. In particular, the aforementioned numerical simulations of cosmic strings in expanding universes have demonstrated the existence of great amounts of short-wavelength propagation modes on the strings, known as wiggles, on scales orders of magnitude below the correlation length. The presence of small-scale structure is simply a byproduct of the energy loss phenomena of the network, and thus, if one aims to have an accurate analytic framework of string networks, it is imperative that these small-scale wiggles are accounted for. This motivated the development of a wiggly extension of the VOS that describes the evolution of both large-scale and small-scale properties of string networks.[11,12]

Here we continue the work recently reported in Ref. 13 studying the properties of wiggly cosmic strings, through an improvement of its physical interpretation and modeling. We carry out a systematic study of the asymptotic scaling solutions of the wiggly generalization of the VOS, so as to explore the allowed scaling regimes, other than the trivial Nambu-Goto solution, where wiggliness grows, disappears, or evolves towards a constant value. One of the open questions in the wiggly model is whether the wiggliness reaches scaling, and if so, under what physical conditions. Numerical studies[6] hint at scaling being reached at least in the matter-dominated era.

Another aim of this mathematical exploration is to determine the role that each mechanism has in the overall behavior of the network, as we know the nature of the scaling solutions is highly dependent on the dominant physical mechanism.[12] We consider the various limits in which each mechanism dominates and compare

the scaling solutions for each case. Finally, this study also aims to pave the way for a future calibration of the wiggly model. Having determined the various possible scaling regimes, and particularly the behavior of the small-scale structure, we can plan future field theory and Nambu-Goto simulations that are optimized for this calibration and able to test the consistency relations of the solutions, as well as to make numerical predictions of the wiggliness on the strings.

This paper is organized as follows. Section 2 gives a brief overview of the wiggly extension of the VOS. In Section 3, we discuss the asymptotic scaling solutions without and with cosmological expansion, followed by a discussion of their physical implications. Finally we present some conclusions and an outlook in Section 4.

2. Wiggly Strings Dynamics

A wiggly extension of the VOS is accomplished by noting that, in direct contrast with Nambu-Goto strings, wiggly strings have their local string tension T differ from the energy density in the string's local rest frame U. In particular, we can define a parameter w that ranges from 0 to 1 (unity being the value of a Nambu-Goto string), such that

$$\frac{T}{\mu_o} = w, \quad \frac{U}{\mu_o} = \frac{1}{w}, \tag{1}$$

where μ_o is the string mass per unit length. The total energy of a piece of string is given by

$$E = a \int \epsilon U d\sigma = \mu_o a \int \frac{\epsilon}{w} d\sigma, \tag{2}$$

which can be decomposed into two contributions: one for the bare string segments E_o,

$$E_o = \mu_o a \int \epsilon d\sigma, \tag{3}$$

and another due to the small-scale wiggles E_w:

$$E_w = \mu_o a \int \frac{1-w}{w} \epsilon d\sigma. \tag{4}$$

Wiggly strings can be conceived as containing a mass current that renormalizes the bare energy per unit length.[14] We define the renormalization factor

$$\mu \equiv \frac{E}{E_o} \geq 1, \tag{5}$$

which is a measure of the energy due to the wiggles of the network, known as the renormalized string mass per unit length. μ is a scale-dependent quantity, that is, it depends on the renormalization scale ℓ at which the wiggliness is being measured. Each energy contribution yields a characteristic length scale

$$\rho \equiv \frac{\mu_o}{L^2} \tag{6}$$

$$\rho_o \equiv \frac{\mu_o}{\xi^2}, \tag{7}$$

which are related by

$$\mu = \left(\frac{\xi}{L}\right)^2. \tag{8}$$

This procedure makes it clear that a quantitative description of small-scale structure implies that the one-scale assumption implicit to the VOS no longer holds. Instead, we have two distinct length scales L and ξ, which will have different dynamics as it will become apparent in their evolution equations. Thus, an averaged model for wiggly cosmic string evolution implies three evolution equations, instead of two, with this additional equation accounting for the evolution of the network's small-scale structure. We note the assumption of $\xi \sim R$ still holds in the wiggly formalism, but it can be tested numerically.[6] It should also be noted that while ξ measures a physical length, L is the length that a Nambu-Goto string with the same total energy would have, and thus should not be interpreted as a physical length.

The equations for the evolution of the network's dynamical quantities are obtained from averaging the microscopic string equations of motion, and so one needs to define the averaging procedure. There are two natural approaches to this. The first consists of averaging over the total energy, so as to give more weight to string segments with larger mass currents. For a generic quantity Q, this is defined as:

$$\langle Q \rangle = \frac{\int Q \frac{\epsilon}{w} d\sigma}{\int \frac{\epsilon}{w} d\sigma}. \tag{9}$$

An alternative approach consists of averaging over the bare string energy

$$\langle Q \rangle_0 = \frac{\int Q \epsilon d\sigma}{\int \epsilon d\sigma} \tag{10}$$

The two procedures are related by:

$$\langle Q \rangle = \frac{\langle QU \rangle_0}{\langle U \rangle_0} = \frac{\langle Q/w \rangle_0}{\mu}. \tag{11}$$

In the wiggly formalism[11,12] the first averaging method is the one adopted (and is the one we adopt in what follows).

The various interactions by which the network loses energy still need to be discussed and included in the evolution equations. In particular, we need to define the phenomenological terms that account for the energy transfers between the bare string and the wiggles. While in the standard VOS model, long string intercommutings had no effect on the evolution of the network, in wiggly strings, they lead to the formation of kinks that increase the energy due to wiggles, and thus, need to be taken into consideration. The energy transfer from the bare string to the wiggles is modeled by:

$$\left(\frac{1}{\rho_o}\frac{d\rho_o}{dt}\right)_{\text{wiggles}} = -cs(\mu)\frac{v}{\xi},, \tag{12}$$

in which s approaches 0 in the Nambu-Goto limit. Besides accounting for the gain in small-scale structure, s should also include the effects of kink decay by gravitational radiation.

Another mechanism by which the network loses energy is the production of loops. In the VOS model, this is encoded in a phenomenological parameter c, the loop chopping efficiency. The loop chopping parameters of the wiggly model are defined in analogy with the VOS definition, but now the energy transferred to the loops may come from the bare string or from the wiggles

$$\left(\frac{1}{\rho_o}\frac{d\rho_o}{dt}\right)_{\text{loops}} = -cf_o(\mu)\frac{v}{\xi}, \tag{13}$$

$$\left(\frac{1}{\rho_w}\frac{d\rho_w}{dt}\right)_{\text{loops}} = -cf_1(\mu)\frac{v}{\xi}, \tag{14}$$

such that

$$\left(\frac{1}{\rho}\frac{d\rho}{dt}\right)_{\text{loops}} = \left(\frac{1}{\rho}\frac{d\rho_0}{dt}\right)_{\text{loops}} + \left(\frac{1}{\rho}\frac{d\rho_w}{dt}\right)_{\text{loops}}. \tag{15}$$

For simplicity, one can define an overall energy loss parameter

$$\left(\frac{1}{\rho}\frac{d\rho}{dt}\right)_{\text{loops}} \equiv -cf(\mu)\frac{v}{\xi}, \tag{16}$$

which using equations (13–15) can be shown to yield:

$$f(\mu) = \frac{f_o(\mu)}{\mu} + \left(1 - \frac{1}{\mu}\right) f_1(\mu). \tag{17}$$

Note that f has an explicit dependence on μ so as to account for the fact that loop production is favored in regions of the long string network with more small-scale structure than average.[6, 15, 16] In what follows we adopt the assumptions introduced in Ref. 12

$$\begin{aligned} f_o(\mu) &= 1 \\ f(\mu) &= 1 + \eta\left(1 - \frac{1}{\sqrt{\mu}}\right) \\ s(\mu) &= D\left(1 - \frac{1}{\mu^2}\right), \end{aligned} \tag{18}$$

where two additional phenomenological parameters η and D were introduced, which should be interpreted as probabilities for small-scale structure loss and gain, respectively.

Finally, we emphasize that the renormalized string mass per unit length is defined at a renormalization scale ℓ that need not be fixed but can be time dependent (e.g., the correlation length). In fact, the choice of scale is equivalent to altering

what defines a wiggle, and consequently, must have a direct influence on the energy distribution between the bare string and the wiggles. One accounts for this by introducing the following scale-drift terms

$$\frac{1}{\mu}\frac{\partial\mu}{\partial\ell}\frac{d\ell}{dt} \sim \frac{d_m - 1}{l}\frac{d\ell}{dt}, \tag{19}$$

$$\frac{\partial v^2}{\partial\ell}\frac{d\ell}{dt} = \frac{1-v^2}{1+\langle w^2\rangle}\frac{\partial\langle w^2\rangle}{\partial\ell}\frac{d\ell}{dt}, \tag{20}$$

where $d_m(\ell)$ is the multifractal dimension of a string segment at scale ℓ. It should be emphasized that while (19) is a mere geometric identity, (20) is a consequence of ensuring energy conservation at all scales. We will also assume the following phenomenological relation

$$d_m(\mu) = 2 - \frac{1}{\mu^b}, \tag{21}$$

where b is a free parameter that imposes the transition limit between two regimes ($d_m = 2$ for Brownian networks, $d_m = 1$ for small scales).

We are now ready to derive the system of equations that compose the wiggly model[11,12]

$$2\frac{dL}{dt} = HL\left[3 + v^2 - \frac{(1-v^2)}{\mu^2}\right] + \frac{cfv}{\sqrt{\mu}} \tag{22}$$

$$2\frac{d\xi}{dt} = H\xi\left[2 + \left(1 + \frac{1}{\mu^2}\right)v^2\right] + v\left[k\left(1 - \frac{1}{\mu^2}\right) + c\left(f_o + s\right)\right] + \left[d_m\left(\ell\right) - 1\right]\frac{\xi}{\ell}\frac{d\ell}{dt} \tag{23}$$

$$\frac{dv}{dt} = \left(1-v^2\right)\left[\frac{k}{\xi\mu^2} - Hv\left(1 + \frac{1}{\mu^2}\right) - \frac{1}{1+\mu^2}\frac{\left[d_m\left(\ell\right) - 1\right]}{v\ell}\frac{d\ell}{dt}\right] \tag{24}$$

$$\frac{1}{\mu}\frac{d\mu}{dt} = \frac{v}{\xi}\left[k\left(1 - \frac{1}{\mu^2}\right) - c\left(f - f_o - s\right)\right] - H\left(1 - \frac{1}{\mu^2}\right) + \frac{\left[d_m\left(\ell\right) - 1\right]}{\ell}\frac{d\ell}{dt}, \tag{25}$$

where $H \equiv \dot{a}/a$ is the Hubble parameter (which we will assume to be of the form $a \propto t^{\lambda}$) and k the momentum parameter already introduced in the VOS formalism. k essentially quantifies the local curvature of strings. It should be noted that equations (22), (23) and (25) are not independent, being related by Eq. (8).

3. Scaling Solutions

We carry out a mathematical exploration of the landscape of scaling solutions of the wiggly model, so as to characterize the behavior of the wiggliness of the network. One important yet unanswered question in the wiggly model is whether the wiggliness is able to scale, i.e, evolve towards a constant value, and if so, what are the underlying physical conditions of the network that lead to this behavior. In spite of current

numerical simulations not giving a definitive answer to this question,[6] they hint at scaling being reached in the matter-dominated era ($\lambda = 2/3$), with the behavior in the radiation era being more complex. This may be indicative of an absence of a scaling solution or of a slower scaling regime (since there is less Hubble damping).

As shown by the system of equations (22)–(25), the evolution of the network is driven by three main mechanisms: the universe's expansion, energy loss by intercommutation, and the choice of the scale in which wiggles are coarse-grained. In what follows, we study the effects of each of them on the possible asymptotic scaling solutions by considering the case where each mechanism dominates and by doing a subsequent comparison of the obtained scaling solutions in each case. This allows us to gain insight into the role that each mechanism has on the evolution of the network.

From a physical point of view, we expect three types of scaling solution regimes. Firstly, we evidently expect the Nambu-Goto solution $\mu = 1$, as the wiggly model reduces to the VOS in the appropriate limit. Secondly, we also expect a regime where the wiggliness scales, $\mu = m_o$. Finally, a regime where small-scale structure grows $\mu \propto t^{\gamma}$ as the network evolves is also expected. In general we will assume

$$\begin{aligned} L &= L_o t^{\alpha} \\ v &= v_o t^{\beta} \\ \mu &= m_o t^{\gamma}, \end{aligned} \tag{26}$$

or alternatively, using Eq. (8):

$$\xi = L_o m_o^{1/2} t^{\alpha+\gamma/2}. \tag{27}$$

It should also be noted that we will discard ultra-relativistic $v = 1$ solutions in our analysis, as well as other branches of solutions that are mathematically allowed but have no physical meaning. This includes solutions in Minkowski space $H = 0$ (expanding universes $H \neq 0$) that hold for non-null values of the momentum parameter $k \neq 0$ (null values of momentum parameter $k = 0$). The reason behind this is we expect the VOS to hold for $k = 0$ in Minkowski space,[6,7,14,17] and in an analogous manner, we expect $k \neq 0$ when $H \neq 0$.[6]

3.1. *Scaling Solutions Without Expansion*

First, we consider the allowed scaling solutions in Minkowski space. We note that linear scaling has been observed in numerical simulations in Minkowski space.[6,18] We also note that a more detailed analysis of some of these solutions has already been published in Ref. 13.

3.1.1. *No dynamical mechanism*

We start by considering the simplest case where no dynamical mechanisms act on the network. In this case we find a trivial solution that depicts a network where all

four dynamical quantities remain constant but undetermined

$$\begin{aligned} L &= L_o \\ v &= v_o \\ \mu &= m_o \\ \xi &= \sqrt{m_o} L_o. \end{aligned} \tag{28}$$

The values of these quantities could be determined by measurement in numerical simulations. The physical interpretation of this solution is clear: the network is in equilibrium due to the absence of energy loss mechanisms, and thus its dynamical quantities have no time evolution.

3.1.2. *With running averaging scale*

In this case we assume the fractal dimension introduced in Eq. (21) with the specific choice $b = 2$, as numerical simulations suggest this value is reasonable.[6] We also assume a generic power-law shaped averaging scale

$$l = l_o t^{\delta}, \quad 0 < \delta \leq 1. \tag{29}$$

In the absence of energy loss mechanisms, we expect that the characteristic length scale of the network remains constant. We find two distinct scaling solutions, the first being the Nambu-Goto limit

$$\begin{aligned} L &= L_o \\ v &= v_o \\ \mu &= 1 \\ \xi &= L_o, \end{aligned} \tag{30}$$

which is analogous to that of Eq.(28), with the difference that μ is no longer arbitrary but restricted to the Nambu-Goto value. This solution gives a clear depiction of how, when there is no small-scale structure, a variation in the coarse-graining scale makes no difference. In other words, this solution exists for any value of δ and has no explicit dependence on its choice.

The second solution yields growing wiggliness

$$\begin{aligned} L &= L_o \\ v &= v_o t^{-\delta} \\ \mu &= m_o t^{\delta} \\ \xi &= \sqrt{m_o} L_o t^{\delta/2}, \end{aligned} \tag{31}$$

subject to the following constraint:

$$v_o^2 m_o^2 = 1. \tag{32}$$

We note that in the fixed scale limit $\delta \longrightarrow 0$ we recover the scaling exponents of Eq. (29). In addition, note that choosing our renormalization scale to be the correlation

length $l \propto \xi$, yields $\delta = \delta/2 = 0$, implying $\gamma = 0$, or in other words, the only possible solution in this case is the Nambu-Goto one. The physical interpretation of this solution is clear. The presence of small-scale structure made this solution explicitly dependent on δ. In particular, we are always able to find small-scale structure for all choices of scale, and a variation in the scale simply modifies the way energy migrates from the bare string to the wiggles, with the total energy of the network staying constant. Moreover, the growth of the wiggliness is compensated by a decrease in the velocity, which suggests that not only is μ scale-dependent, but v also depends on δ. This agrees with the mesoscopic velocity interpretation of the wiggly model, instead of the traditional interpretation of a microscopic RMS one embodied in the VOS.[11,12]

3.1.3. *With energy losses*

We now consider the case where the network is losing energy due the various energy loss mechanisms inherent to the network, as previously described. In particular, we assume the energy loss terms are modeled after Eq. (18). It is clear that the presence of energy losses must lead to a different behavior for the network's characteristic length scales L and ξ, as they are now forced to scale in time. We find two solution regimes. The first solution implies non-trivial wiggliness:

$$\begin{aligned} L &= L_o t \\ v &= v_o \\ \mu &= m_o \\ \xi &= \sqrt{m_o} L_o t, \end{aligned} \tag{33}$$

such that

$$L_o = \frac{c v_o}{2} \frac{(1+\eta) m_o^{1/2} - \eta}{m_o} \tag{34}$$

$$D\left(1 - \frac{1}{m_o^2}\right) = \eta\left(1 - \frac{1}{m_o^{1/2}}\right), \quad \eta \geq D. \tag{35}$$

This allows for a wide range of values of the wiggliness m_o, depending on the values of the small-scale structure parameters D and η. In particular, one retrieves the Nambu-Goto case $m_o = 1$ under the condition $D = \eta$. For realistic values of D and η, Eq. (35) has two real solutions and a pair of complex conjugate solutions. Having in mind that realistic values of the wiggliness imply $m_o \geq 1$, it follows that for values of the parameters such that $D/\eta < 1/4$ the only physically meaningful solution consists of $m_o = 1$, while in the range $D/\eta \in]1/4, 1[$, we find solutions with $m_o > 1$. From a physical point of view, this should be interpreted as: if the amount of wiggliness generated by the network is a small fraction of the amount that is lost, as in the case of $D/\eta < 1/4$, then no wiggliness can asymptotically survive on the string network, resulting in the Nambu-Goto solution. On the other hand, if this

ratio takes up large enough values, then the small-scale structure of the network is able to survive.

In the second regime, we find a solution where small-scale structure builds-up in the network:

$$\begin{aligned} L &= L_o t^{\alpha} \\ v &= v_o \\ \mu &= m_o t^{2-2\alpha} \\ \xi &= \sqrt{m_o} L_o t \end{aligned} \tag{36}$$

with the following constraints and conditions

$$L_o = \frac{c v_o}{2\alpha} \frac{1+\eta}{m_o^{1/2}} \tag{37}$$

$$\alpha = \frac{1+\eta}{1+D} < 1 \tag{38}$$

$$\gamma = 2\frac{D-\eta}{1+D}, \quad D > \eta, \tag{39}$$

which yields Eq. (33) in the limit where the two small-scale structure parameters balance each other $D \longrightarrow \eta$.

The set of solutions (33) (36) allows us to infer the exact physical conditions that dictate the nature of the scaling regime. As seen in Eq. (33), when the amount of small-scale structure removed (e.g., loop production) is greater than its gain (e.g., kink formation upon intercommutation), $\eta > D$, the wiggliness of the network remains constant. On the other hand, as illustrated by Eq. (36), when there is more generation of small-scale structure on the network than loss, $D > \eta$, we find that the long string wiggliness must grow. Moreover, another interesting difference between these two solutions lies in the behavior of μ and L (or equivalently, the total energy density of the network), with ξ scaling linearly ($\xi \propto t$) in both solutions. The fact that ξ maintains its linear scaling independently of the scaling of L just further emphasizes the two scale feature of the wiggly VOS extension.

3.1.4. *With energy losses and a running averaging scale*

If one allows for both energy losses and a varying renormalization scale $\delta \neq 0$, one finds two possible solutions. The first yields constant wiggliness such that:

$$\begin{aligned} L &= \frac{c(1+\eta)v_o}{2} t \\ v &= v_o \\ \mu &= 1 \\ \xi &= L, \end{aligned} \tag{40}$$

which is analogous to that of Eq.(33) with the caveat that m_o is no longer arbitrary but restricted to the Nambu-Goto case. This solution depicts, yet again, that if the network is devoid of small-scale structure a change in the coarse-graining scale makes no difference.

In the second solution, we find that the small-scale structure of the network grows as the network evolves

$$\begin{aligned} L &= L_o t^{\alpha} \\ v &= v_o t^{-\gamma} \\ \mu &= m_o t^{\gamma} \\ \xi &= \sqrt{m_o} L_o t^{\frac{1}{3}+\frac{2}{3}\alpha}, \end{aligned} \tag{41}$$

subject to

$$L_o = \frac{c(1+\eta)v_o}{2\alpha m_o^{1/2}} \tag{42}$$

$$\alpha = \frac{(\frac{2}{3}-\delta)(1+\eta)}{\frac{2}{3}(1+\eta)+2(D-\eta)} < 1, \quad D > \eta \tag{43}$$

$$\gamma = \frac{2}{3} - \frac{2}{3}\alpha = \frac{2(D-\eta)+\delta(1+\eta)}{3(D-\eta)+(1+\eta)} \tag{44}$$

$$\delta = \gamma v_o^2 m_o^2 \in \left]0, \frac{2}{3}\right[\tag{45}$$

Note that if we consider the fixed scale limit $\delta \longrightarrow 0$, we recover Eq. (36) $\gamma \longrightarrow 0$, $\alpha \longrightarrow 1$. We can also take the limit of no energy losses $D, \eta \longrightarrow 0$ on (41) where we partially recover the previous solution of Eq. (31), namely the dynamics for the velocity and wiggliness $\gamma = -\beta = \delta$, but with different behavior of both length scales. Unlike the other solutions so far, δ is restricted because Eq. (45) must always hold. Specifically, the averaging scale is now bounded from above, which can be attributed to the energy losses of the network. In other words, if the scale does not evolve slowly enough, we are unable to find small-scale structure. Furthermore, we note that the total energy of the network, more specifically the exponent α, explicitly depends on δ, hinting at an apparent scale dependence of the total energy of the network. However, one would expect this quantity to be scale-invariant, that is, the way the network loses energy should not depend on the choice of averaging scale choice. Having said this, it is clear that the physics behind this behavior needs to be explored in future studies.

3.2. *Scaling Solutions With Expansion*

We are now concerned with solutions in expanding universes, where we expect $k \neq 0$.[6]

3.2.1. *No dynamical mechanisms*

We start with the case of no energy losses and a fixed scale. In this case, we find the three expansion regimes. Firstly, we find the canonical Nambu-Goto VOS solution

$$\begin{aligned} L &= \left(\frac{k^2}{4\lambda(1-\lambda)}\right)^{1/2} t \\ v &= \left(\frac{1-\lambda}{\lambda}\right)^{1/2} \\ \mu &= 1 \\ \xi &= \left(\frac{k^2}{4\lambda(1-\lambda)}\right)^{1/2} t\,. \end{aligned} \tag{46}$$

The range of expansion rates of this solution depends on the physical interpretation of the velocity. Interpreted as a microscopic velocity, we require $v_o^2 < 1$ and we find that the radiation epoch is the limiting case $\lambda > 1/2$. This implies that scaling can be achieved in the matter-dominated era, but not in the radiation epoch, since in the latter the network does not lose enough energy by Hubble damping. Alternatively, one can also interpret this velocity as an average one, with now the physical constraint being $v_o^2 \leq 1/2$ (corresponding to the average velocity of loops in Minkowski space), leading to the matter era becoming the limiting case $\lambda \geq 2/3$.

Secondly, we find a solution of non-trivial constant wiggliness, only viable in the matter era

$$\begin{aligned} L &= L_o t \\ v &= v_o \\ \mu &= m_o \\ \xi &= \sqrt{m_o} L \\ \lambda &= \frac{2}{3} \end{aligned} \tag{47}$$

$$L_o = \frac{3k}{2(m_o^3 + m_o)^{1/2}}, \quad v_o = \frac{1}{(1+m_o^2)^{1/2}}, \tag{48}$$

which in principle holds for any value of the wiggliness m_o. We note that by choosing $m_o = 1$, we retrieve the previous solution (46). This solution also demonstrates that scaling is more easily reached in the matter era than in the radiation era, in agreement with Nambu-Goto numerical simulations.[6] In addition, the behavior depicted by this solution is analogous to the one previously identified for chiral superconducting strings.[19]

Thirdly, a regime of growing wiggliness is also allowed, which implies decreasing velocities $\beta < 0$, and $\alpha = 3/2\lambda$, as well as the consistency relations $3/2\lambda + \gamma/2 - \beta = 1$, and $\beta + \gamma \geq 0$. This narrows the range of allowed expansion rates to slower rates

than the matter era one $\lambda < 2/3$. There are two solution regimes, depending on the value of the expansion rate. For very slow expansion rates we have

$$\begin{aligned} L &= L_o t^{3/2\lambda} \\ v &= v_o t^{-\lambda} \\ \mu &= m_o t^{2-5\lambda} \\ \xi &= \frac{v_o k}{2-4\lambda} t^{1-\lambda}, \end{aligned} \tag{49}$$

subject to the following constraints:

$$m_o = \left(\frac{v_o k}{L_o (2-4\lambda)} \right)^2 \tag{50}$$

$$\lambda \leq \frac{1}{3}. \tag{51}$$

Conversely, in the intermediate expansion rate regime, we find

$$\begin{aligned} L &= L_o t^{3/2\lambda} \\ v &= v_o t^{-\gamma} \\ \mu &= m_o t^{\gamma} \\ \xi &= \sqrt{m_o} L_o t^{\lambda+\frac{1}{3}} \\ \gamma &= \frac{2}{3} - \lambda, \end{aligned} \tag{52}$$

with the following constraints:

$$v_o = \frac{2}{3} \left(\frac{L_o}{(\frac{4}{3}\lambda - \frac{4}{9})^{1/4} k} \right)^{2/3}, \quad m_o = \left(\frac{k}{(\frac{4}{3}\lambda - \frac{4}{9})^{1/2} L_o} \right)^{2/3} \tag{53}$$

$$\lambda \in \left] \frac{1}{3}, \frac{2}{3} \right[. \tag{54}$$

We note that in the limit $\lambda \longrightarrow 1/3$ this solution matches the scaling solution obtained in the slow regime. In addition, we also recover the full scaling solution (47) in the limit $\lambda \longrightarrow 2/3$, apart from differences in the coefficients for the velocity.

It is instructive to consider the particular case of the radiation epoch ($\lambda = 1/2$), where we find

$$L \propto t^{3/4}, \quad v \propto t^{-1/6} \quad \mu \propto t^{1/6} \quad \xi \propto \sqrt{m_o} L_o t^{5/6}, \tag{55}$$

These relations provide an opportunity for testing with Nambu-Goto simulations where energy loss terms can be switched off on demand.

3.2.2. *With a running averaging scale*

We consider the averaging scale previously introduced in Eq. (29). In this case we still find the Nambu-Goto solution

$$\begin{aligned} L &= L_o t \\ v &= v_o \\ \mu &= 1 \\ \xi &= \sqrt{m_o} L_o t \\ \lambda &> \frac{1}{2}, \end{aligned} \tag{56}$$

$$L_o = \left(\frac{k^2}{4\lambda(1-\lambda)} \right)^{1/2}, \quad v = \left(\frac{1-\lambda}{\lambda} \right)^{1/2}. \tag{57}$$

We observe that the introduction of a running averaging scale neither affected the scaling behavior of the previous obtained solution (46) nor did it impose any restriction on δ.

We also find a full scaling solution

$$\begin{aligned} L &= L_o t \\ v &= v_o \\ \mu &= m_o \\ \xi &= \sqrt{m_o} L_o t \\ \lambda &< \frac{2}{3} \end{aligned} \tag{58}$$

$$v_o = \left(\frac{1 + m_o^2 (2\lambda^{-1} - 3)}{1 + m_o^2} \right)^{1/2} \tag{59}$$

$$\delta = \left(1 - \frac{3}{2}\lambda \right) m_o^2 (1 + m_o^2). \tag{60}$$

This solution demonstrates how the inclusion of a renormalization scale decreased the value of the expansion rate for which full scaling can occur: this is now achieved for expansion rates lower than the matter era one.

Lastly, we find two possible solutions with growing wiggliness, which entail the same dynamics for the characteristic length scale and velocity as found for the expansion case, namely $\alpha = 3\lambda/2$, $\beta < 0$, $3/2\lambda + \gamma/2 - \beta = 1$, and $\beta + \gamma \geq 0$. For very slow expansion rates we have

$$\begin{aligned} L &= L_o t^{3/2\lambda} \\ v &= v_o t^{-\lambda} \\ \mu &= m_o t^{2-5\lambda} \\ \xi &= \sqrt{m_o} L_o t^{1-\lambda} \\ \lambda &\leq \frac{1}{3}, \end{aligned} \tag{61}$$

where the scaling coefficients are related by:

$$m_o = \left(\frac{kv_o}{L_o(2-4\lambda+\delta)}\right)^2, \tag{62}$$

while in the intermediate expansion regime we determine:

$$\begin{aligned} L &= L_o t^{3/2\lambda} \\ v &= v_o t^{-\gamma} \\ \mu &= m_o t^{\gamma} \\ \xi &= \sqrt{m_o} L_o t^{1/3+\lambda} \\ \frac{1}{3} &< \lambda < \frac{2}{3}, \end{aligned} \tag{63}$$

such that

$$v_o = \left(\frac{1}{(3\lambda-1)m_o^2}\right)^{1/2}, \quad m_o = \left(\frac{kv_o}{L_o(\frac{2}{3}+\delta)}\right)^2 \tag{64}$$

$$\gamma = \frac{2}{3} - \lambda. \tag{65}$$

Note that the two regimes match for an expansion rate $\lambda = \frac{1}{3}$.

3.2.3. *With energy losses*

We finally consider the most realistic case, where the network is losing energy in the context of an expanding universe. Firstly, we recover the canonical VOS Nambu-Goto solution

$$\begin{aligned} L &= L_o t \\ v &= v_o \\ \mu &= 1 \\ \xi &= L_o t, \end{aligned} \tag{66}$$

$$L_o = \left(\frac{k(k+c)}{4\lambda(1-\lambda)}\right)^{1/2}, \quad v = \left(\frac{k(1-\lambda)}{\lambda(k+c)}\right)^{1/2}. \tag{67}$$

We note that Eq. (46) is a particular case of Eq. (66) for which $c = 0$, which can be physically interpreted as the network's intrinsic energy losses being unnecessary for the network to reach linear scaling because Hubble damping is enough to ensure this.

Secondly, there is also a non-trivial wiggliness solution

$$\begin{aligned} L &= L_o t \\ v &= v_o \\ \mu &= m_o \\ \xi &= \frac{k}{\lambda v_o(1+m_o^2)} t, \end{aligned} \tag{68}$$

subject to the following constraints:

$$L_o^2 = \frac{k}{\lambda}\frac{k + c(1+\eta)m_o^2 - c\eta m_o^{3/2}}{m_o(1+m_o^2)(\lambda + (2-3\lambda)m_o^2)} \tag{69}$$

$$v_o^2 = \frac{k}{\lambda}\frac{\lambda + (2-3\lambda)m_o^2}{(1+m_o^2)(k + c(1+\eta)m_o^2 - c\eta m_o^{3/2})} \tag{70}$$

$$\begin{aligned}\left(\lambda + m_o^2(2-3\lambda)\right)\left((k+cD)\left(1-\frac{1}{m_o^2}\right) - c\eta\left(1-\frac{1}{m_o^{1/2}}\right)\right)\\ = \lambda\left(1-\frac{1}{m_o^2}\right)\left(k + (1+\eta-\eta m_o^{-1/2})m_o^2 c\right).\end{aligned} \tag{71}$$

We note that the previous solution (47) is recovered by direct substitution of $\lambda = 2/3$, and $c = 0$ on this solution. So as to understand more about its physical implications, we consider the case study of large amounts of wiggliness. Before proceeding to this analysis, we define new parameters

$$\begin{aligned} k_{eff} &\equiv k + c(D-\eta)\\ c_{eff} &\equiv c(1+\eta).\end{aligned} \tag{72}$$

This is not only convenient, but also makes sense from a physical point of view: it is known that the presence of small-scale structure on the long strings modifies its typical curvature, as well as enhances energy losses.[12] The large wiggliness limit $m_o \gg 1$ yields:

$$\begin{aligned} L_o &= \left(\frac{k c_{eff}}{\lambda m_o^3(2-3\lambda)}\right)^{1/2}\\ v_o &= \left(\frac{k(2-3\lambda)}{c\lambda m_o^2(1+\eta)}\right)^{1/2}\\ \lambda &= \frac{2k_{eff}}{c_{eff}+3k_{eff}}.\end{aligned} \tag{73}$$

This solution clearly illustrates that when there are great amounts of wiggliness on the network, the overall energy density increases while the velocity decreases, as expected. In addition, it is interesting to note that in the radiation era, the effective parameters balance one another

$$k_{eff} = c_{eff}. \tag{74}$$

This relation constitutes an opportunity for testing with Nambu-Goto numerical simulations.

Thirdly, there also exists a growing wiggliness regime. This has the same implications as found for the expanding case, namely a decreasing velocity $\beta < 0$, although $\alpha = 3\lambda/2$ no longer holds, and instead we have $\alpha > 3\lambda/2$. Physically, this

makes sense as the energy loss terms enable faster energy loss. We again distinguish two regimes according to their expansion rates. For slow expansion rates,

$$\begin{aligned} L &= L_o t^{\alpha} \\ v &= v_o t^{-\lambda} \\ \mu &= m_o t^{\gamma} \\ \xi &= \sqrt{m_o} L_o t^{1-\lambda}, \end{aligned} \tag{75}$$

$$\alpha = \frac{1}{2} \frac{2c_{eff} + \lambda(3k_{eff} - c_{eff})}{k_{eff} + c_{eff}} \tag{76}$$

$$\gamma = 2(1 - \lambda - \alpha) = \frac{2k_{eff} - \lambda(c_{eff} + 5k_{eff})}{k_{eff} + c_{eff}} \tag{77}$$

$$\gamma \in]0, 2 - 5\lambda[\tag{78}$$

$$\lambda \leq \frac{k_{eff}}{3k_{eff} + c_{eff}}. \tag{79}$$

It is worthy of note that one recovers the previous slow expansion solution (49) in the limit $c \longrightarrow 0$.

As far as the intermediate expansion rate regime is concerned, we find

$$\begin{aligned} L &= L_o t^{\alpha} \\ v &= v_o t^{-\gamma} \\ \mu &= m_o t^{\gamma} \\ \xi &= \sqrt{m_o} L_o t^{\frac{1}{3} + \frac{2}{3}\alpha} \end{aligned} \tag{80}$$

$$L_o^2 = \frac{k c_{eff}}{(2\alpha - 3\lambda)(\lambda + \frac{2}{3}\alpha - \frac{2}{3}) m_o^3} \tag{81}$$

$$v_o^2 = \frac{k(2\alpha - 3\lambda)}{c_{eff}(\lambda + \frac{2}{3}\alpha - \frac{2}{3}) m_o^2} \tag{82}$$

$$\alpha = \frac{\frac{2}{3}c_{eff} + \lambda(3k_{eff} + c_{eff})}{\frac{2}{3}c_{eff} + 2k_{eff}} \tag{83}$$

$$\gamma = \frac{2}{3} - \frac{2}{3}\alpha = \frac{2k_{eff} - \lambda(3k_{eff} + c_{eff})}{c_{eff} + 3k_{eff}} \tag{84}$$

$$\lambda \in \left] \frac{k_{eff}}{3k_{eff} + c_{eff}}, \frac{2k_{eff}}{3k_{eff} + c_{eff}} \right[, \tag{85}$$

where one is also able to retrieve the previous solution Eq. (52) in the limit $c \longrightarrow 0$. It should be emphasized that the domain of the expansion rate is now broader, when in comparison to Eq. (52), which is due to the two energy loss mechanisms acting on the network (not just Hubble damping).

Note that the two regimes match for the expansion rate

$$\lambda = \frac{k_{eff}}{3k_{eff} + c_{eff}}, \tag{86}$$

which is half of the expansion rate of Eq. (73). We also note that in the no energy losses limit $c \longrightarrow 0$, the expansion rate approaches $\lambda = 1/3$.

Finally, it is also instructive to consider a particular case study where the two effective parameter balance each other $k_{eff} = c_{eff}$ which yields in the slow regime

$$\alpha_{slow} = \frac{1+\lambda}{2}, \quad \gamma_{slow} = 1 - 3\lambda, \quad \lambda \leq \frac{1}{4}, \tag{87}$$

while in the intermediate regime we find:

$$\alpha_{int} = \frac{1}{4} + \frac{3}{2}\lambda, \quad \gamma_{int} = \frac{1}{2} - \lambda, \quad \lambda \in \left]\frac{1}{4}, \frac{1}{2}\right[. \tag{88}$$

This solution leads to full scaling in the radiation epoch and growing wiggliness regimes for slower expansion rates than the radiation one. The transition between slow and intermediate regimes takes place at $\lambda = 1/4$.

4. Conclusions and Further Work

We have improved the physical interpretation of the wiggly generalization of the VOS model,[11,12] building upon a mathematical exploration of the landscape of possible scaling solutions. Not only did we successfully characterize the behavior of the wiggliness in various regimes, but we also have managed to determine the effect that each dynamical mechanism has on the scaling solutions.

In Minkowski space, we find that the network is in a trivial equilibrium solution in the absence of energy loss mechanisms. Allowing the network to lose energy, we find that the network's correlation length always maintains its linear scaling, while the behavior of the characteristic length scale depends on the dynamics of the wiggliness. If the wiggliness is constant, L scales linearly, while if the wiggliness grows in time, L exhibits slower growth specified by the energy loss parameters. These results agree with linear scaling observed in Minkowski space simulations.[6,18] Moreover, the inclusion of a renormalization scale led to a possible regime where small-scale structure grows in time, but is compensated by a decreasing velocity, with the network's total energy density remaining constant and the domain of the scale remaining unrestricted due to energy conservation. Lastly, when the network is subject to both mechanisms, we determined that the averaging scale becomes bounded from above, as a consequence of the network losing energy.

In power-law expanding universes, we determined that the three scaling regimes were possible, primarily depending on the expansion rate. For slow and intermediate expansion rates one has growing wiggliness solutions, while in fast expansion regimes one has the Nambu-Goto regime. For a specific value of expansion rate, one finds a full scaling solution. In the absence of energy losses, this expansion rate coincides with the matter era one, whereas the inclusion of energy loss mechanisms decreases this value, possibly reaching the radiation era for an appropriate value of the energy losses. Our results also demonstrate that scaling is more easily achieved in the matter era rather than the radiation epoch, in agreement with numerical simulations[6 16].[15] It is also interesting to note that the three scaling behaviors here determined have also been found for the case of chiral superconducting strings[19] and other current-carrying strings.[20] The case where all three mechanisms act on the network was not included in this work for reasons of space. Lastly, one aspect that remains unclear and should be subject to future studies, is the role of the coarse-graining scale, and in particular, the apparent scale dependence of the total energy of the network.

These analytic results pave the way for a future calibration of the wiggly model. While our results show qualitative agreement with previous Nambu-Goto numerical simulations, the current available data does not allow for a detailed comparison. Our work therefore motivates additional, higher resolution simulations that cover a broad range of expansion rates and that are able to extract accurate numerical diagnostics for the wiggliness.

The canonical velocity-dependent one-scale (VOS) model for cosmic string evolution contains a number of free parameters which cannot be obtained ab initio. Therefore it must be calibrated using high resolution numerical simulations. We exploit our state of the art graphically accelerated implementation of the evolution of local Abelian-Higgs string networks to provide a statistically robust calibration of this model. In order to do so, we will make use of the largest set of high resolution simulations carried out to date, for a variety of cosmological expansion rates, and explore the impact of key numerical choices on model calibration, including the dynamic range, lattice spacing, and the choice of numerical estimators for the mean string velocity. This sensitivity exploration shows that certain numerical choices will indeed have consequences for observationally crucial parameters, such as the loop chopping parameter. To conclude, we will also briefly illustrate how our results impact observational constraints on cosmic strings.

Keywords: Cosmic strings; Velocity-dependent One-Scale model; Abelian-Higgs string simulations; Observational consequences

1. Introduction

Topological defects are expected consequences of phase transitions in the early Universe, formed via means of the Kibble mechanism.[1] Depending on the symmetry broken different defects, with different dimension, can appear. The most studied defects are the filament-like cosmic strings. These are generically predicted in many candidates of Grand Unified Theories[2] and superstring theory,[3] and are cosmologically safe, in the sense that they are not expected to overclose the Universe.

Due to their ubiquitous nature they have become a primary target for observational facilities, both current[4,5] and forthcoming.[6,7] Analytical and observational studies of defect networks (strings included) often rely on a combination of semi-analytical modelling and simulations.

Here we present an up-to-date model calibration using high-resolution simulations, that ran in one of Europe's largest supercomputers, Piz Daint, using up to

4096 GPUs. In order to ensure robustness, we will also explore how sensitive the model calibration is to certain numerical choices. We will also discuss our recently developed visualization strategy and avenues it might open in the study of defects. Some of this work has been published in Ref. 8.

2. Simulation Setup

We begin with a brief description of our simulations. Take a Lagrangian density which, while originally invariant under $U(1)_L$ transformations, is already in the broken symmetry phase,

$$\mathcal{L} = |D_\mu \phi|^2 - \frac{\lambda}{4}(|\phi|^2 - 1)^2 - \frac{1}{4e^2} F^{\mu\nu} F_{\mu\nu} \,, \tag{1}$$

where ϕ is a complex scalar field, $D_\mu \phi = \partial\phi - ieA_\mu$ are the covariant derivatives, A_μ is a gauge field, $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$ is a gauge field strength and the scalar and gauge couplings are λ and e, respectively. The defect network that will form corresponds to homotopically stable solutions of the equations of motion of this Lagrangian. In fact a cosmic a string is the result of a specific solution of the equations of motion, which maps ϕ to the symmetry breaking scale (here set to u; minima of potential) infinitely away from the string, and to zero at its core (maxima of potential). The equations of motion in Friedmann-Lemaitre-Robertson-Walker Universes and under the assumption of the temporal gauge ($A_0 = 0$) are

$$\ddot{\phi} + 2\frac{\dot{a}}{a}\dot{\phi} = D^j D_j \phi - \frac{a^2 \lambda}{2}(|\phi|^2 - 1)\phi \tag{2}$$

$$\dot{F}_{0j} = \partial_j F_{ij} - 2a^2 e^2 Im[\phi^* D_j \phi] \,. \tag{3}$$

Abelian-Higgs field theory simulations of cosmic strings[9,10] merely use the discretization procedure of lattice gauge theory[8]—which places scalar fields on lattice points distanced by $\Delta = 0.5$, and gauge fields on lattice links—to provide a discretized set of equations to update fields every conformal timestep. Due to the existence of Hubble damping and due to the topological nature of the potential, the initial conditions eventually relax into a configuration with multiple string networks. For simplicity, and to mimic what the fields are post-phase-transition, the initial conditions are set as follows: null on every field, except ϕ which is set to have a random phase and unit magnitude.

We will additionally set scalar and gauge couplings to $\lambda = 2$ and $e = 1$, respectively, which sets the Bogmolnyi ratio to $\frac{\lambda}{2e^2} = 1$ (a usual choice in the literature) and force the gauge and scalar core to have the same width. Given that the string radius varies as $r \propto \frac{1}{\sqrt{\lambda} a}$ and this could cause strings to "slip" through the lattice, we will make each coupling vary as

$$\lambda = \lambda_0 a^{2(1-\beta)} \qquad\qquad e = e_0 e a^{(1-\beta)} \tag{4}$$

where β is set to zero. This unphysical constant comoving width trick was first proposed in Ref. 11 and has been used throughout the literature to avoid resolution

problems. We note that while previous work has suggested that $\beta = 0$ and $\beta = 1$ dynamics seem to agree, it is unknown presently if changing the value of β would somehow pose a systematic error source in model calibration. This particular effect will be studied in a future publication and is beyond the scope of the present work.

In order to characterize the defect network that forms and its evolution throughout cosmic time, we also need to characterize the mean comoving distance between strings, ξ, and the mean squared velocity, $\langle v^2 \rangle$. For velocity estimators we will use two different forms, one first proposed in Ref. 12 and the other in Ref. 10. The first one is based on a boosted static string (detailed derivation in Ref. 10) and will be referred to as the scalar field velocity estimator. It has the following form

$$< v^2 >_{\phi} = \frac{2R}{1+R}, \qquad R = \frac{\int |\Pi|^2 \mathcal{W} dx^3}{\int (\sum_i |D_i^+ \phi|^2) \mathcal{W} dx^3}\,. \tag{5}$$

where $\mathcal{W}$ is weight function, chosen to localize the estimator on strings. We will use the Lagrangian density $\mathcal{L}$ to this end. Additionally, we will use the equation of state based velocity estimator,

$$< v^2 >_{\omega} = \frac{1}{2}\left(1 + 3\frac{\int p \mathcal{W} dx^3}{\int \rho \mathcal{W} dx^3}\right). \tag{6}$$

We remark that the work of Reef. 10 showed the second estimator to perform better in Minkowski space than the scalar based estimator, i.e. it is in better agreement with the analytical expectation for the velocity of an oscillating string in flat space. Such disagreement is lattice space dependent, and indeed an exploration of this feature in the opposite low velocity limit is published in Ref. 13.

One way to characterize the typical distance between strings is by counting the total amount of string in the box, L,

$$\xi_W = \sqrt{\frac{\mathcal{V}}{L}}\,, \tag{7}$$

where $\mathcal{V}$ is box volume, and L as mentioned the total amount of string. L can be counted in multiple ways, but we will use an integer called winding. To explain it, remember one can think of a string as a magnetic flux tube, where the flux is quantized around the string,

$$\Phi = \oint dx^{\mu} A_{\mu} = \frac{2\pi}{e} \tag{8}$$

and the integer n is the winding. If a cell face is pierced by a string, then the lattice version of the winding[14] will be non-zero (1 for the choices of λ and e made above), and therefore we can say that a segment of length Δx pierced the plaquette. Summing all the segments (taking care not to double-count) we then obtain the total length of string in the box, L.

Note that output of cells pierced by windings forms the basis of our visualization strategy. Given that this novel aspect of our simulation has thus far not been described elsewhere, we will now describe the strategy itself and what avenues it opens for the study of defect networks.

2.1. *Visualization strategy I — In-situ windings*

One of the most stringent and common bottlenecks for many High-Performance Computing simulations is related to Input/Output. Not only does computational throughput grow much faster than the typical read/write speeds of most storage solutions, but also, very often, the amount of data required to do science exceeds the amount of storage available. It is thus no surprise that in recent years there has been a push towards techniques of in-situ visualization, where the output data is heavily reduced beforehand and a smaller subset is used afterwards. There are many literature examples of successful application of such techniques.[15–19] In this section we will detail how this technique is applied in our multiGPU cosmic string simulations[20] and the resulting performance gains.

In order to use an in-situ approach to outputting string positions in the lattice, we use ParaView Catalyst version 5.8.0. There are then two relevant components: the Adaptor code (written in C++) and a Python script which applies three filters to the data and then outputs an Unstructured grid (in *.pvtu format).

In the case of the Adaptor, it begins (if necessary) by creating a vtkMultiBlock-Dataset, where each rank contains then a vtkImageData with the correct information about block extent (in number of points), lattice spacing and origin of each block or sub-domain of the grid. Afterwards a series of vtkFloatArray are either created or updated by copying the contents of 7 different arrays pinned host memory buffers updated by GPUs before-hand. Six of these arrays (one for each cell face) contain only ± 1 in case a string pierces a cell face and 0 otherwise. The last array is merely an OR of the previous six, and will be used to determine which cells are pierced by strings and should therefore be outputted.

This determination is done in the Python script, which applies a Threshold filter to the data, selecting only cells wherein the last array is non-zero. In other words, from this point on we already have a reduced dataset. The Merge Block filter is then applied to collect pieces of strings spread throughout several sub-domain. To finalize the Parallel Unstructured Grid writer is used to output data in the *.pvtu format (alongside multiple block files *.vtu).

Table 1. A summary of typical output sizes for a timestep either with Raw output of all cells (HDF5) or using only the unstructured grid outputs from our in-situ approach.

Lattice size	Output data size (MB)		Time taken (s)	
	HDF5 estimated	In-situ measured	HDF5 estimated	In-situ measured
512^3	5296	$[8.7, 25.0]$	0.9	$[2.6, 3.5]$
1024^3	42368	$[11.0, 126.0]$	0.9	$[2.7, 3.2]$
2048^3	338944	$[33.0, 199.0]$	3.0	$[2.9, 5.6]$
4096^3	2711552	$[99.0, 144.0]$	23.9	$[4.1, 8.2]$

Note: Given that the in-situ approach size depends on the number of cells that are part of a string, we indicate the range of sizes obtained over the conformal time ranges where we output.

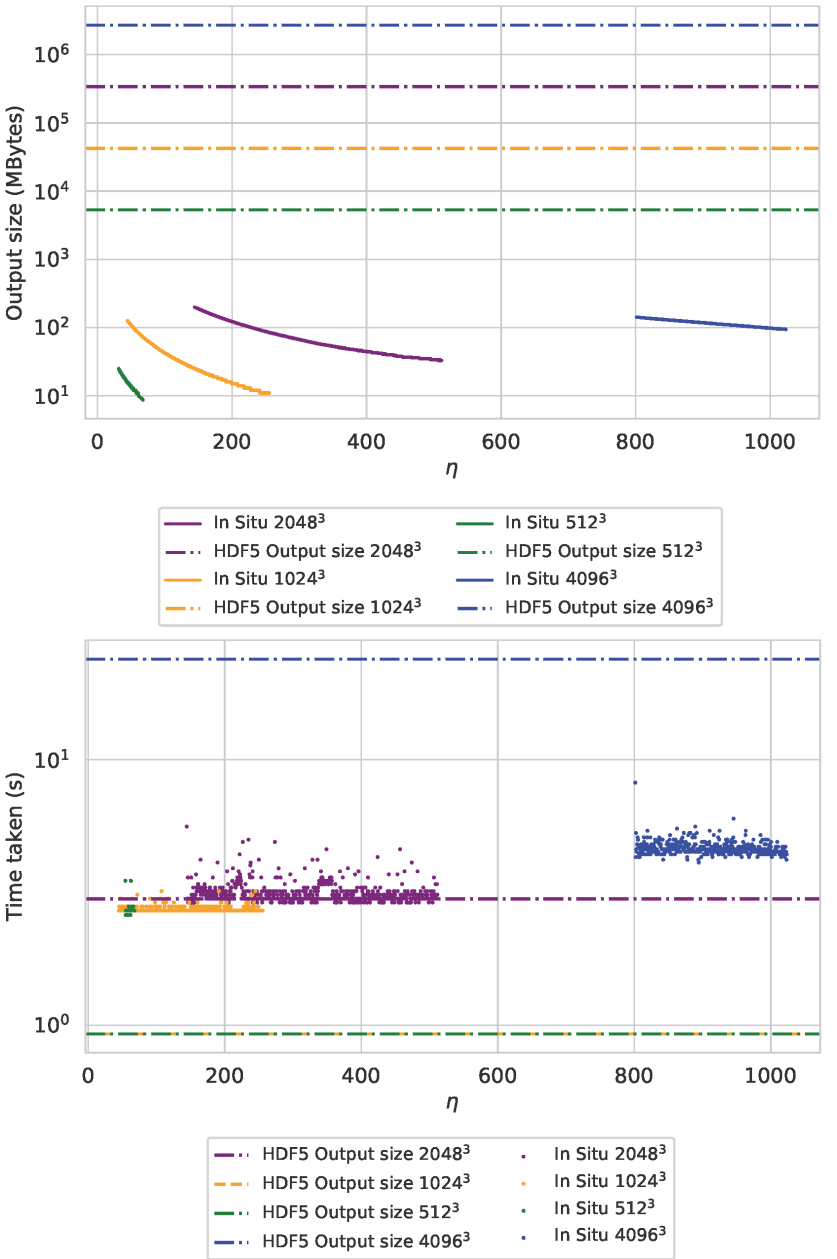

Fig. 1. Top: Size of raw HDF5 data output (windings for six cell faces, dashed lines) and of that for the In-Situ approach, where Unstructured grids are output (full lines), for lattice sizes: 4096^3 (blue), 2048^3 (purple), 1024^3 (orange) and 512^3 (green). Bottom: corresponding output times.

Note that no rendering is done so far: the in-situ aspect outputs heavily reduced data, but it does not produce a string centerline. The next section will describe how to create such a centerline by connecting each cell of each individual string and applying an averaging to string positions, such that the effect of taxicab geometry is greatly reduced.

Before we move on, we must detail the gains obtained from using this particular approach to data output, by comparing to the previous method of output of the simulation, which was to output all cells throughout the domain in HDF5 files (file-per-process approach). All benchmarks were conducted at Piz Daint, the Swiss National Supercomputer, the $4th$ most powerful supercomputer in Europe at the time of writing.[21] This machine features 5704 nodes, each equipped with an Nvidia Tesla P100, together with a *scratch* partition which is a Cray Sonexion 3000 Lustre filesystem with 8.8PB capacity. The system contains 40 object storage targets, and can handle a file per process approach well as long as there are not thousands of files in a single folder (this can be circumvented by grouping files according to rank for instance).

The first, more obvious consequence is how this results in less data being output. The smallest size of single HDF5 file with 7 single precision floating point datasets of dimension $(256, 256, 256)$ is around 662 MB in our test set. In order to determine the total typical output size for the benchmarks we are about to describe, we need to multiply the number by the number of ranks used. Keeping the problem size per process fixed. We will then run the benchmarks for in-situ with the following lattice sizes 512^3, 1024^3, 2048^3 and 4096^3 with domain decomposition of $(2, 2, 2)$, $(4, 4, 4)$, $(8, 8, 8)$ and $(16, 16, 16)$. In all benchmarks we output data every five timesteps. The obtained total timestep output sizes are shown in Table 1 and in Figure 1. We note that as the networks evolve, and the strings interact, the energy density of strings decreases which has an immediate and obvious effect on the number of cells output: they decrease with conformal time. This is translated in the total timestep size, which decreases with conformal time for every lattice size. The other important conclusion is that there is a vast reduction in total storage space required, at worst two orders of magnitude, at best four. This not only allows us to output data at a larger temporal rate (more timesteps), but also allows the possibility of adding more data to the outputs, if necessary.

We must also ask if there a performance (wall-clock time) speed-up or a performance penalty, or if, even including a costly filter like Merge Blocks, we can output data at similar rates as in the previous case. In order to do so, we will use the maximum measured writing bandwidth of our file per process approach with HDF5 files with 8, 64 and 512 writers for 512^3, 1024^3 and for both 2048^3 and 4096^3. The three maximum bandwidth are, respectively 5712, 45640 and 113300 MB/s. Note that we will use the maximum measured bandwidth of 512 writers for 4096 as it is already very close to the estimated peak bandwidth of the Lustre filesystem on Piz Daint.

Using these maximum bandwidths and the estimated storage needed for each file allows us to calculate a typical time taken. For in-situ we measure the time taken to output each timestep where data is written out. Our results, shown in table 1 and in figure 1, indicate that in-situ is definitely worth it if the file size becomes extremely large and the bandwidth is already saturated (close to the theoretical maximum bandwidth of the filesystem). This is evident when comparing the 2048^3 and 4096^3 cases where the amount of time taken is roughly comparable for 2048^3 but in the 4096^3 the amount of time taken for in-situ is roughly an order of magnitude below.

In conclusion, the technique described herein makes studying small-scale structure of strings possible with large lattices, not only reducing the amount of storage required by the simulation towards feasible amounts, but also permitting a significant speed-up, circumventing the limitation imposed by the maximum bandwidth of the filesystem.

2.2. *Visualization of string networks II — post-processing*

After the simulation runs, we can use the Unstructured grid output to construct string centerlines. The first step is to group neighboring cells via the Connectivity filter, and then use the PassArrays filter to pass all the data arrays to the input of the custom filter. The centerline script loops over each region identified by the connectivity filter and by each cell. The problem of trying to connect cells based on the order of the cellId in the Unstructured grid is that they are ordered by index (i,j,k) and not by the order they should be in a string.

The way to solve this issue is to begin in a cell in the string, ask for the neighbors according to the connectivity filter and then use the information contained in each of the winding arrays to understand if the connectivity established via cell faces is physically valid, i.e. if magnetic flux passes through that cell face. Note that we choose the positive, +1 direction for the magnetic flux but the script would work if working in the opposite direction too. Once a valid neighbor is identified, the vortexBounds for the specific cell and the next one are used to find cell center coordinates. These coordinates used to trace a vtkLine connecting one cell to the next, passing in the middle of a cell face. Cell by cell and segment by segment, the string centerline begins taking shape, as a collection of vtkLines (hence the output is of vtkPolyDataCollection type).

There are however some special cases to be mentioned as they can cause issues in the correct visualization and analysis.These are merely a consequence of the phenomenology of a string network. When two strings meet at one point (forming an X-shaped region), they can exchange ends, i.e. intercommute, and two new strings emerge immediately afterwards. On the other hand, if strings are to either meet in two points or to self-intersect, it is very likely that a closed loop forms. Loops are

Fig. 2. String cells colored by region in two close-up screenshots of 2048^3 radiation era simulation. We show in addition the output of the centerlines custom filter with smoothing via a Hanning window. A Loop (in blue) is shown at the center of the top panel screenshot. An intercomutation event (in red) is shown on the left-hand side of the bottom panel.

extremely important for observational consequences, as they shrink and dissipate energy[a] therefore generating some observational fingerprints.

Intercommutation events (or X-regions) can cause the string centerline to stop at the boundary of the box but not go through all the cells of the entire region. In effect the initial version of the custom filter would draw a single string (corresponding to two legs of the X-region, so to say). This can be avoided by comparing the number of cells used for the creation of the centerline so far and the total number of cells in the region. If one is much smaller, then the centerline drawing must restart at a cell not used previously and create the other two legs. Loops require us to close the path of the centerline, in other words, to connect the last cell and the first. Identifying

[a]Here lies a disagreement between two types of cosmic string simulation in the literature: in what type of energy do loops decay? Gravitational waves, massive radiation? This can alter the overall energy loss of the network, subsequent evolution of the network, and observational imprints. The scientific goal of the numerical techniques developed in the present work is to address this issue.

whether a loop is present can be done using the number of points and the number of cells. Should they differ by one, it is necessary to close this path.

After dealing with these two problematic cases we now have the string positions along every stair-case-like segment.This staircase behavior is no more, no less a consequence of the discrete nature of the lattice and of not having complete information about where exactly in each cell face a string lies (one assumes perfectly in the middle but this is not entirely realistic either). There is therefore some small-scale structure on the resulting strings in a scale roughly of the lattice size. Given that this is not a physical effect, we wish to remove it. In Ref. 12 the smoothed string was obtained by averaging string positions along the string path. Here we convolve each string with a window function in order to remove such artificial structure. The specific window function and the window size can be chosen in the filter. Given that numpy and scipy are used for this procedure, possible window functions by default include Hanning, Haming, Bartlett, Blackman. Figure 2 shows a collection of cells in two long strings and one loop either in cells as the resulting output of the Connectivity filter or as string centerlines (in white) smoothed over with the Hanning window function. Qualitatively this is more representative of a natural string. An example of the completed centerlines for a 4096^3 lattice simulation, with $\Delta x = 0.5$ aand $\Delta\eta = 0.1$ in radiation epoch is shown in Fig. 3.

3. Extended Velocity-dependent One-Scale model

The canonical semi-analytic model for string network evolution is the so-called Velocity dependent One-Scale model of Refs. 22, 23. It can be thought of as thermodynamic model in the sense that it describes the time evolution of two network averaged quantities, the mean string separation L, and the root mean squared velocity v. The cosmological history of these quantities is described in terms of relevant physical effects. For instance, the expansion of the Universe tends to act as a friction force on the strings (thereby affecting velocities) and also acts to dilute the network (affecting the mean separation). The model takes the following form, in comoving coordinates,

$$\frac{d\xi}{d\eta} = \frac{m\xi}{(1-m)\eta}v^2 + F(v) \tag{9}$$

$$\frac{dv}{d\eta} = (1-v^2)\left[\frac{k(v)}{\xi} - \frac{2mv}{(1-m)\eta}\right], \tag{10}$$

where $\xi = La$ is the comoving mean string separation, η is the conformal time, related to t by means of $d\eta = adt$, $\mathcal{H}$ is the conformal Hubble parameter, m is an expansion rate such that the scale factor $a \propto t^m$, and $k(v)$ and $F(v)$ are two phenomenological functions, related to the curvature of strings and to energy loss processes, respectively. In the original VOS, $k(v)$ can be analytically determined by comparison with the helicoidal string ansatz. However, for the present work, we will

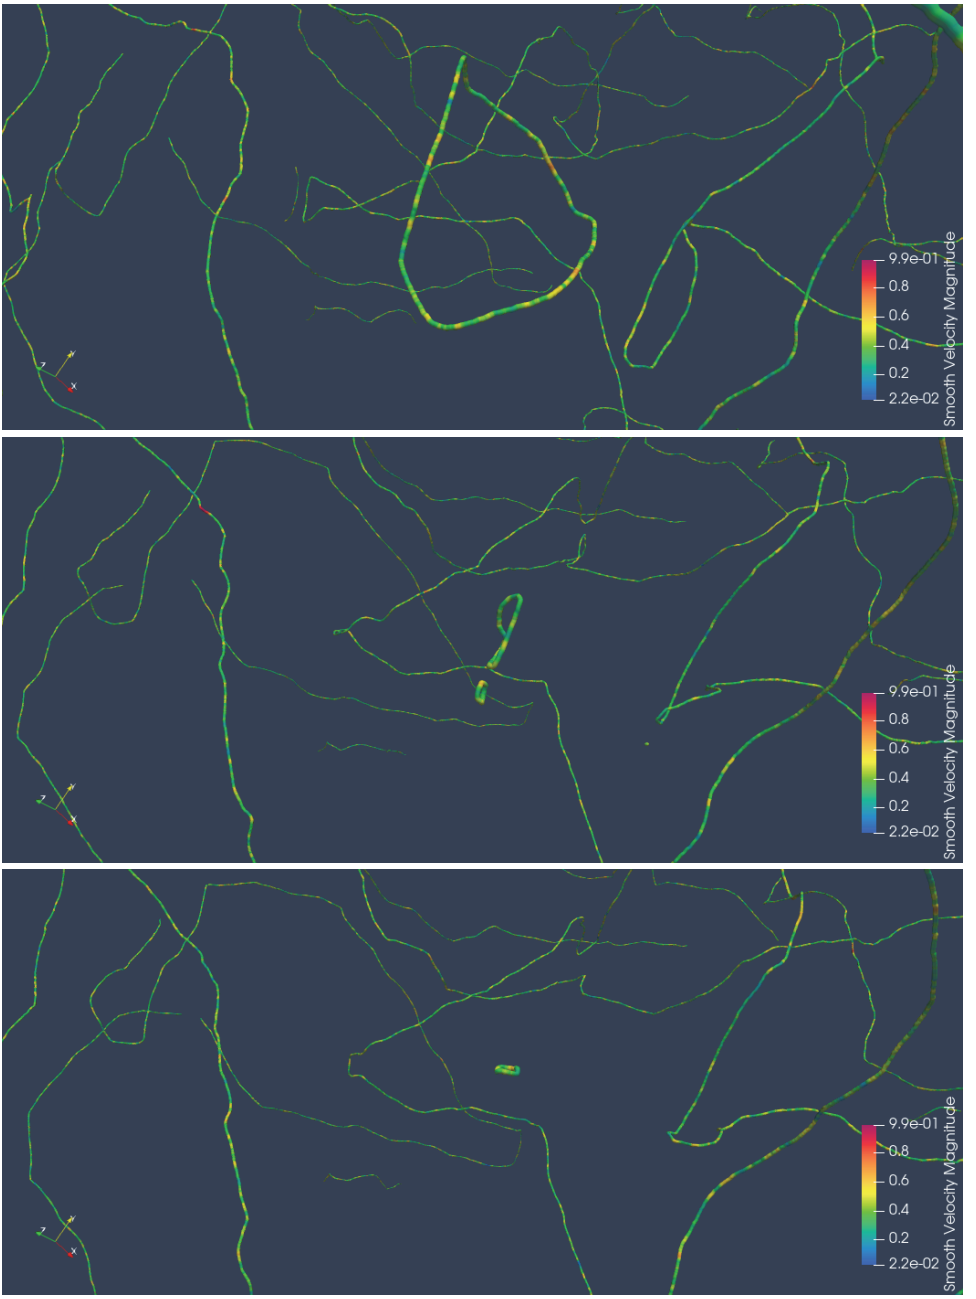

Fig. 3. Comparison of the mean rate of change of correlation length ξ/η (top left) and the mean velocity $\langle v \rangle$ (top right) with the solid lines corresponding to the calibration and the shaded regions to the uncertainty of the measurements of each estimator for three different box sizes. The bottom plots show how these differences impact the momentum parameter $k(v)$ (bottom left) and in the energy loss parameter $F(v)$ (bottom right).

allow a more general form,

$$k(v) = k_0 \frac{1-(qv^2)^\beta}{1+(qv^2)^\beta}. \tag{11}$$

where q, k_0 andβ are free parameters, which in the case of q and k_0 have a clear physical meaning. The former corresponds to the inverse of the maximum defect velocity squared $q \approx 1/v^2$ and the latter to the maximal value of $k(v)$, obtained in the low velocity limit. Note that the helicoidal ansatz corresponds to setting $q = 2$, $k_0 = \frac{\sqrt{2}\pi}{2}$ and $\beta = 3$. Letting these parameters free allows us to verify if small-scale structure on strings deviates from the Nambu-Goto expectation significantly, as this would be reflected on parameters q, k_0 and β taking different values from the analytical expectation.

The energy loss function $F(v)$ was originally devised to only include a term linearly proportional to the velocity to model energy loss via loop chopping. However, recent work on radiation on Abelian-Higgs strings,[10] then prompted the authors of Ref. 24 to introduce a radiative loss term when studying domain wall evolution. Such a term is described by a power law of curvature,

$$F(v) = cv + d[k_0 - k]^r \,, \tag{12}$$

where c, d and r are free parameters which express the loop chopping parameter and the energy loss normalization and exponent, respectively. Although the original VOS, with the helicoidal ansatz and no explicit energy loss, had only one parameter, the extended version has 6. This is not a problem per se, as long as one can extract the correct velocity dependencies of each function $k(v)$ and $F(v)$. It is for this reason we will simulate string networks in Universes where with a power law scale factor, $a \propto m$ and with expansion rates m in the range $m \in [0.5, 0.95]$ (i.e. not only matter and radiation epoch are simulated).

We note that since string networks, under any Universe with a power law scale factor ($a \propto t^m \propto \eta^{m/(1-m)}$), are expected to evolve according to the so-called linear scaling regime where,

$$\xi \propto \eta \propto d_H \qquad v = const \,, \tag{13}$$

we can easily use the measured $\dot{\xi} \sim \frac{\xi}{\eta}$ and v to extract the proper velocity dependencies of $k(v)$ and $F(v)$, and also calibrate model parameters. To this end, we will use the same Markov Chain Monte Carlo pipeline of Ref. 25 to assess posterior distributions on all model parameters, and thus unveil possible correlations, and predict likelihood maxima and uncertainties. All model parameters are sampled from uniform distributions, with the range of these distributions adapted to each dataset as necessary. The logarithm of the likelihood is to be given by the χ^2 statistic. We will use 32 walkers and a minimum of 10000 steps.

4. Dynamic range and lattice size

String simulations have a problem of separation of scales, as it is often necessary to resolve scales all the way from the size of the horizon, down to scales comparable to

the radius of the strings. When it comes to better resolving small-scale structure, there are two possible ways to do so, either by decreasing lattice spacing or by increasing lattice size, which in turn increases dynamic range. The latter follows because the lattice size directly determines the final simulation time: half-a-light crossing time or when the horizon size is half the box size. If a larger horizon can be reached by the end of the simulation, then for the same lattice spacing we can better resolve scales of a fraction of the horizon.

We now explore the effects of increasing lattice size, while keeping spacing constant throughout ($\Delta x = 0.5$). To this end, we calibrate the VOS with 1024^3, 2048^3 and 4096^3 lattices, with expansion rates $m \in [0.45, 0.95]$, 10 simulation runs each. For now we will use the equation of state velocity estimator. The resulting calibrations are summarized in table 2 and the corresponding posterior plots are found in figure 3 of Ref. 13, remade in Fig. 4.

Table 2. Calibrated VOS model parameters for our three different lattice sizes, 1024^3, 2048^3 and 4096^3, all with the same lattice spacing $\Delta x = 0.5$, and two different choices of velocity estimators, $\langle v_\omega^2 \rangle$ and $\langle v_\phi^2 \rangle$ (in the top and bottom parts of the table, respectively),

Lattice size	Δx	Velocity estimator	d	r	β	k_0	q	c
1024^3	0.5	$\langle v_\omega^2 \rangle$	$0.32^{+0.04}_{-0.04}$	$1.51^{+0.48}_{-0.37}$	$1.82^{+0.34}_{-0.30}$	$1.27^{+0.08}_{-0.06}$	$2.41^{+0.13}_{-0.13}$	$0.15^{+0.05}_{-0.07}$
2048^3			$0.37^{+0.02}_{-0.02}$	$1.27^{+0.17}_{-0.15}$	$2.33^{+0.21}_{-0.20}$	$1.21^{+0.03}_{-0.03}$	$2.57^{+0.06}_{-0.06}$	$0.03^{+0.02}_{-0.03}$
4096^3			$0.39^{+0.02}_{-0.02}$	$1.36^{+0.15}_{-0.13}$	$2.32^{+0.20}_{-0.18}$	$1.18^{+0.03}_{-0.03}$	$2.59^{+0.05}_{-0.05}$	$0.00^{+0.01}_{-0.01}$
1024^3	0.5	$\langle v_\phi^2 \rangle$	$0.35^{+0.23}_{-0.10}$	$2.39^{+1.58}_{-0.94}$	$2.79^{+0.73}_{-0.56}$	$1.06^{+0.05}_{-0.05}$	$2.95^{+0.18}_{-0.19}$	$0.44^{+0.04}_{-0.05}$
2048^3			$0.33^{+0.05}_{-0.04}$	$1.86^{+0.39}_{-0.32}$	$2.65^{+0.28}_{-0.26}$	$1.05^{+0.03}_{-0.03}$	$2.84^{+0.08}_{-0.08}$	$0.31^{+0.02}_{-0.02}$
4096^3			$0.36^{+0.03}_{-0.03}$	$1.72^{+0.26}_{-0.23}$	$2.50^{+0.21}_{-0.20}$	$1.06^{+0.02}_{-0.02}$	$2.83^{+0.06}_{-0.06}$	$0.23^{+0.01}_{-0.01}$

Note: Displayed values correspond to 16th, 50th, 84th percentiles of the posterior distributions.

We see that most parameters remain relatively unchanged by increasing the lattice size, being subject only to a reduction of uncertainties (smaller contours in Fig. 4). The only exceptions are parameters c and (to a lesser extent) d. We remark as well that these differences are qualitatively larger when comparing 1024^3 with 2048^3, than if comparing 2048^3 to 4096^3, which might hint that there is a minimum lattice size/dynamic range for model calibration. Gradually, c is even reduced to zero at 4096^3 which seems to suggest that as lattice resolution increases, loop-chopping is eventually replaced by radiative losses, bu this is at odds with information from visually seeing the network evolve—as loops are formed at various instants and at various sizes—as can be inferred from Fig. 3.

In Ref.[13] we found, by comparing asymptotic quantities at all expansion rates, that the main culprit for the changes we discussed in the previous paragraph was the behavior of ξ/η. In fact, while the velocities remain mostly unchanged, ξ/η is

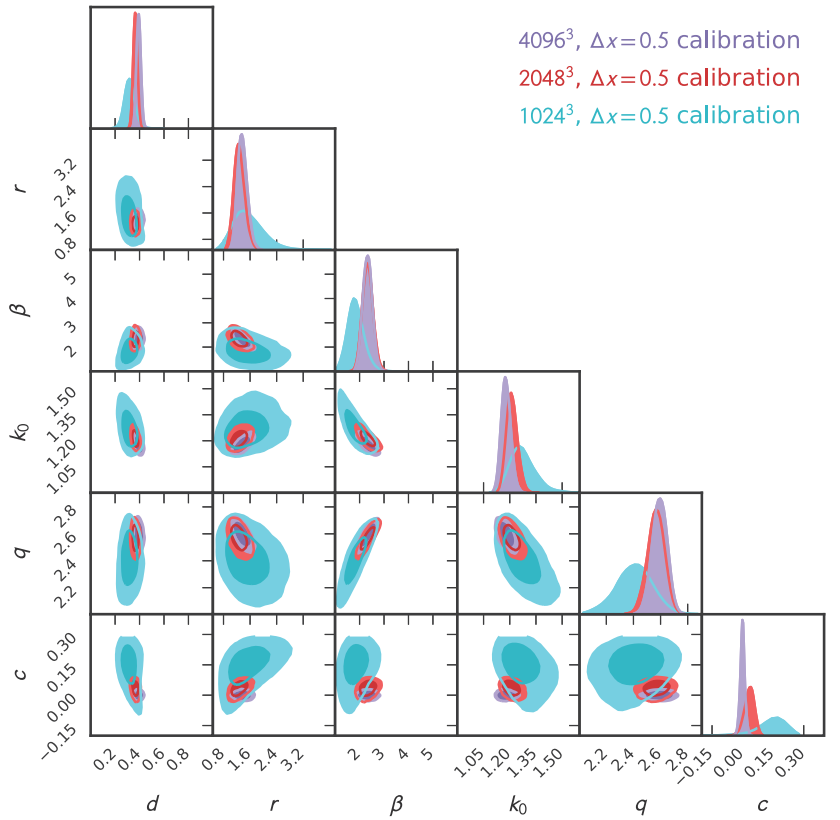

Fig. 4. Corner plots for the MCMC calibration of the VOS model, obtained with the velocity estimator $\langle v_\omega \rangle$, lattice spacing $\Delta x = 0.5$, box sizes 4096^3, 2048^3 and 1024^3. Remake of figure 3 of Ref. 13.

decreases (this is present in the literature too[9, 12]) with lattice size, as does it uncertainty. The reduction of the uncertainties is responsible for the narrower posterior distributions, and the lower mean value translates itself in change in a downwards shift of $F(v)$. This is reflected in the parameters that control the normalization of $F(v)$, i.e. in c and (to a lesser extent), via anti-correlation d. Again the differences are larger when going from 1024^3 to 2048^3 than from 2048^3 to 4096^3.

Going back to our previous discussion of c, it appears the calibration suggested the loop-chopping parameter would eventually go to zero, however the visualization strategy showed loops being produced at different sizes and different size. Perhaps, as a cross-check, we should also repeat this analysis using the scalar field velocity estimator. The resulting parameters are summarized in the bottom half of Table 2 and in figure 4 of Ref. 13. This now leads to a surprisingly different calibration, with very different model parameters, namely c is statistically non-zero. This prompts an investigation on the biases of each velocity estimator and on possible solutions.

5. Lattice spacing and velocity estimators

Here we investigate why both velocity estimators give vastly different calibrations and suggest one possible solution. From the point-of-view of the extended VOS, the high expansion rates can be some of the most important (statistically) for two reasons. First, in the low-velocity limit, both velocity functions are reduced to one parameter each,

$$\lim_{v\to 0} F(v) = cv \qquad \lim_{v\to 0} k(v) = k_0\,, \tag{14}$$

and this means that overall the model becomes reduced to only two parameters. Uncertainties on observed asymptotic quantities also decrease with decreasing velocity (increasing expansion rate). Statistically this will mean that the high expansion rate limit will be important in determining c and k_0, which will in turn affect all variables correlated with them, and that the lower uncertainties give a larger statistical weight to higher expansion rates. This leads us to suspect that the high expansion rate behavior of both velocity estimators might be the cause, as the difference between them increases with expansion rate.[10]

If we compare velocity estimators in the range $m \in [0.5, 0.95]$ (see figure 3 of Ref. 26) the difference is maximal at $m = 0.95$, and of about $\sim 10\%$. For even larger expansion rates, in the range $m \in [0.95, 0.997]$ (left panel of figure 5 of Ref. 13), the velocity estimators can disagree up to 60% in the worst case scenario for lattice spacing $\Delta x = 0.5$, In the work of Ref. 10, which explored the differences between the two estimators in Minkowski space (the opposite limit), it was shown that lattice spacing could reduce this disagreement. But even at high expansion rate this remains true: the disagreement is heavily reduced when we halve lattice spacing $\Delta x = 0.25$ as can be seen on the right panel of the aforementioned Figure 5. There is however one interesting difference between two opposite limits of high expansion rate and Minkowski: in the first the equation of state estimator approximates the scalar field, in the latter the opposite occurs. There is no a priori reason as to why both should behave the same way under lattice spacing reductions, therefore this is not in contradiction with previous results.

As expected, the differences and their reduction under lattice spacing, are also reflected in the velocity functions $k(v)$ and $F(v)$. This as can be seen in Figure 6 of Ref. 13, where two conclusions can be drawn. First, the equation of state velocity estimator yields unphysical $F(v)$ at lattice spacing $\Delta x = 0.5$, leading one to question its validity at the low velocity limit. Second, as the lattice is made finer, this brings both estimators in better agreement, namely by approximating $F(v)$ and $k(v)$ obtained via the equation of state estimator to the scalar field estimator. Note that this doesn't solve the problem of unphysical $F(v)$ completely, although for our intents and purposes it brings agreement for expansion rates $m \in [0.93, 0.95]$.

Now we compare the resulting model parameters for the two choices of lattice spacing. The results are summarized in Table 3 and in the corresponding posterior contours of figures Figures 7 and 8 of Ref. 13. We also showcase the contours of the

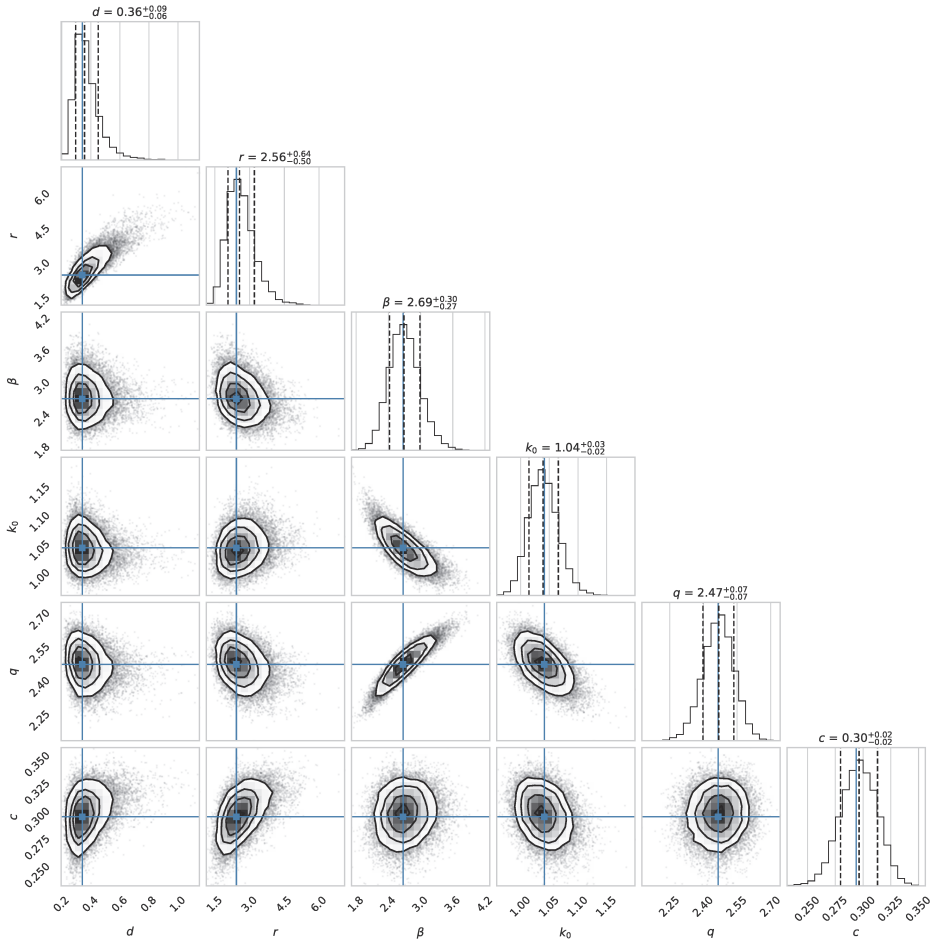

Fig. 5. Corner plots for the MCMC calibration of the VOS model, obtained with the velocity estimator $\langle v_\phi \rangle$, lattice spacing $\Delta x = 0.25$, box size 4096^3.

4096^3, $\Delta x = 0.25$, $\langle v_\phi^2 \rangle$ calibration in Fig. 5. Since the equation of state velocity estimator is highly sensitive to lattice spacing at large expansion rate, it is no surprise that the calibration drastically changes for all model parameters under a reduction of spacing, as can be seen both in the table and in the first aforementioned figure of Ref.[13] With the finer calibration, it is also obvious the value of c is no longer consistent with zero, that indeed loop-chopping is still a viable energy loss mechanism.

The calibrations performed with the scalar field velocity estimator mostly reduce uncertainties (with one exception) as the lattice spacing is reduced, as can be inferred from the lower half of Table 3 and from the contours of Figure 8 from

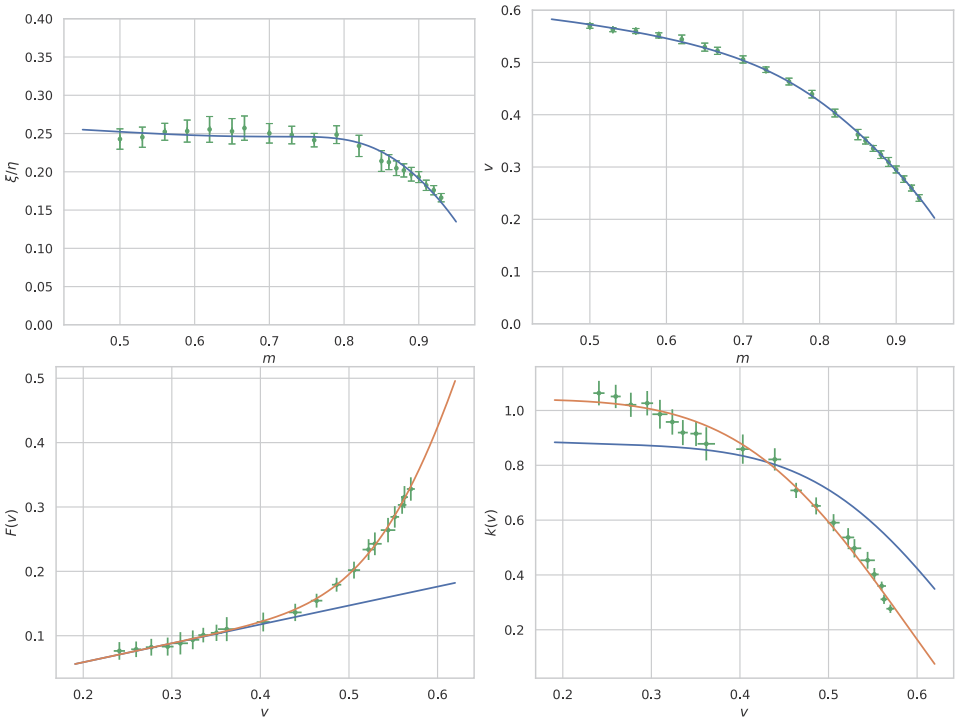

Fig. 6. A showcase of the VOS predictions for the mean rate of change of correlation length ξ/η (top left) and the mean velocity $\langle v \rangle$ (top right) with the solid blue lines corresponding to the calibration and the green points to the measured quantities with statistical $1-\sigma$ uncertainties. The bottom plots show the functions $F(v)$ and $k(v)$ with green points showing measured values and the blue lines showing the standard VOS prediction with the extended VOS prediction in orange.

Ref. 13. The only exception to this is the parameter q which is again expected, as it is related to the maximal defect velocity and the estimator changes mostly in the high velocity limit.

Thus lowering lattice spacing brings both calibrations, with different velocity estimators, into better agreement with the only different parameter being c. Overall this means one of the most important parameters from an observational point of view, c, is the most sensitive in the model, being somewhat affected by resolution effects and choice of velocity estimator.

To conclude we present the VOS predictions of the best-case scenario calibration, with lattice 4096^3, spacing, $\Delta x = 0.25$ and velocity estimator $\langle v_\phi^2 \rangle$ in Fig. 6. The VOS model predicts reasonably well, for all expansion rates, the values of ξ/η and v. We can see the measured value of $k(v)$ and $F(v)$ seem to be well described by the generalized forms, while the standard forms fail to predict the proper velocity dependency.

Table 3. Calibrated VOS model parameters for our two choices of lattice spacing Δx and corresponding lattice sizes, for the two different choices of velocity estimators, $\langle v_\omega^2 \rangle$ and $\langle v_\phi^2 \rangle$, further described in the main text.

Lattice size	Δx	Velocity estimator	d	r	β	k_0	q	c
2048^3	0.5	$\langle v_\omega^2 \rangle$	$0.37^{+0.02}_{-0.02}$	$1.27^{+0.17}_{-0.15}$	$2.33^{+0.21}_{-0.20}$	$1.21^{+0.03}_{-0.03}$	$2.57^{+0.06}_{-0.06}$	$0.03^{+0.02}_{-0.03}$
4096^3	0.25		$0.34^{+0.07}_{-0.05}$	$2.32^{+0.52}_{-0.40}$	$2.62^{+0.29}_{-0.26}$	$1.06^{+0.03}_{-0.02}$	$2.37^{+0.06}_{-0.07}$	$0.25^{+0.02}_{-0.02}$
2048^3	0.5	$\langle v_\phi^2 \rangle$	$0.33^{+0.05}_{-0.04}$	$1.86^{+0.39}_{-0.32}$	$2.65^{+0.28}_{-0.26}$	$1.05^{+0.03}_{-0.03}$	$2.84^{+0.08}_{-0.08}$	$0.31^{+0.02}_{-0.02}$
4096^3	0.25		$0.36^{+0.09}_{-0.06}$	$2.56^{+0.64}_{-0.50}$	$2.69^{+0.30}_{-0.27}$	$1.04^{+0.03}_{-0.02}$	$2.47^{+0.07}_{-0.07}$	$0.30^{+0.02}_{-0.02}$

Note: Displayed values correspond to 16th, 50th, 84th percentiles of the posterior distributions.

6. Observational Impact

We will now a highlight the impact of different calibrations on observational footprints of cosmic string networks. Note that a detailed study is beyond the scope of this manuscript, and this is merely illustrative of the need for an accurate calibration.[13]

We can use the CMBACT4 code[27,28] to compute the Cosmic Microwave Background anisotropies generated by a string network, assuming different VOS calibrations. This code assumes the Unconnected Segment Model,[27] where ensembles of straight, randomly oriented segments with separations and velocities given by the VOS model are used to compute power spectra.

We cancompare four different calibrations: standard VOS compatible with Nambu-Goto, standard VOS calibrated for Abelian-Higgs and two extended VOS calibrations present in the previous section, a worst (1024^3, $\Delta x = 0.5$, $\langle v_\omega^2 \rangle$) and best ($4096^3$, $\Delta x = 0.25$, $\langle v_\phi^2 \rangle$) case scenario. The resulting TT, TE, EE and BB can be found in figure 9 of Ref. 13, all normalized to a string tension $G\mu = 1.0 \times 10^{-7}$. It is clear that the Abelian-Higgs spectra are in better agreement between each other, than the Nambu-Goto one, which is expected.[29–34]

However, there are still some noticeable differences between Abelian-Higgs calibrations. The most discrepant overall is the 1024^3 calibration—the worst-case scenario. The 4096^3 calibration and the standard VOS one are in better agreement, although it should be noted there still exist some scale-dependent differences. To exemplify, at $l = 10$, the relative difference between the two TT spectra is around 16%, 30% and 11% for scalar, vector, tensor C_l, respectively.

The exact quantifying of how much of these differences are uniquely due to the calibrations or due to the USM requires a more in-depth, detailed study. Nevertheless, this illustrative comparison highlights the need for accurate VOS calibrations.

7. Conclusion

In this work we used our recently developed multiGPU Abelian-Higgs code and high-end computational resources of Piz Daint to obtain a robust calibration of the canonical semi-analytical model of string evolution. Using high-resolution simulations from lattice sizes ranging from 1024^3 to 4096^3 and various choices of expansion rate. We explored the impact of two different numerical choices on the obtained calibrations. This allowed us to not only reduce statistical uncertainties but also to correct for systematic error sources. Since we tested the sensitivity of model parameters to each of these choices we uncovered that the loop-chopping parameter is highly sensitive to both resolution effects and also to choice of velocity estimator. We showed that a minimum dynamic range of about 512.0 conformal time units and a minimum lattice spacing of $\Delta x = 0.25$ are necessary to minimize the impacts of these systematic error sources.

We then illustrated one of the main motivations to pursue an accurate, high-resolution calibration of the VOS: observational consequences. We specifically showed that different calibrations can give rise to scale-dependent differences on the computed CMB anisotropy power spectra. Although one cannot (at least without a more in-depth study) exclude that these differences are caused by the various approximations of the Unconnected Segment Model, it is still clear that precise and accurate calibrations are necessary to for both current and future constraints.

Radiation from Global Cosmic Strings using adaptive mesh refinement

Amelia Drew* and E. P. S. Shellard

We present results from adaptive mesh refinement (AMR) simulations of global cosmic strings. Using the public code, GRChombo, we perform a quantitative investigation of the dynamics of single sinusoidally displaced string configurations. We study a wide range of string energy densities $\mu \propto \ln \lambda$, defined by the string width parameter λ over two orders of magnitude. We investigate the resulting massless (Goldstone boson or axion) and massive (Higgs) radiation signals, using quantitative diagnostic tools to determine the eigenmode decomposition. Given analytic radiation predictions for global Nambu-Goto strings, we compare the oscillating string decay with a backreaction model accounting for radiation energy losses, finding excellent agreement. We establish that backreaction decay is accurately characterised by the inverse square of the amplitude being proportional to the inverse tension μ for $3 \lesssim \lambda \lesssim 100$. The investigation of massive radiation at small to intermediate amplitudes finds evidence that it is suppressed exponentially relative to the preferred massless channel with a $\sqrt{\lambda}$ dependence in the exponent. We conclude that analytic radiation modelling in the thin-string (Nambu-Goto) limit provides the appropriate cosmological limit for global strings.

Keywords: Cosmic strings; adaptive mesh refinement.

1. Introduction

Cosmic strings are a fundamental prediction of many physically motivated field theories with symmetry-breaking phase transitions. They are a potential source of dark matter axions,[1] as well as gravitational waves.[2] However, their complex non-linear evolution means that significant uncertainties in their observational signatures and other properties persist in the literature.

The simplest example of cosmic string defects are 'global strings' formed from the breaking of a $U(1)$ symmetry with a single complex scalar field φ, given by

$$\mathcal{L} = (\partial_\mu \bar{\varphi})(\partial^\mu \varphi) - \frac{\lambda}{4}(\bar{\varphi}\varphi - \eta^2)^2 \,. \tag{1}$$

The symmetry breaking scale with this potential is set by the constant λ, which also determines the width of the string core $\delta \approx (\sqrt{\lambda}\,\eta)^{-1}$, where η is also a constant. Massive ϕ and massless (Goldstone) ϑ radiative modes are generated when these global strings oscillate, which can be analysed respectively using the following

diagnostics:

$$\Pi_\phi \equiv \frac{\phi_1\dot{\phi}_1 + \phi_2\dot{\phi}_2}{\phi}, \qquad \mathcal{D}_i\phi \equiv \frac{\phi_1\nabla_i\phi_1 + \phi_2\nabla_i\phi_2}{\phi},$$
$$\Pi_\vartheta \equiv \frac{\phi_1\dot{\phi}_2 - \phi_2\dot{\phi}_1}{\phi}, \qquad \mathcal{D}_i\vartheta \equiv \frac{\phi_1\nabla_i\phi_2 - \phi_2\nabla_i\phi_1}{\phi}. \tag{2}$$

Despite their apparent simplicity, the study of cosmic strings using large-scale numerical simulations poses a very significant computational challenge. This is due to the vast difference in scale between the typical string width δ and the string curvature scale (set by the Hubble radius $R \lesssim H^{-1}$, where H is the Hubble scale). This is characterised by the ratios $\ln R/\delta \sim 70$ and $\ln R/\delta \sim 100$ for QCD axion and GUT scale strings respectively. This challenge is typically addressed by using the Nambu-Goto action (e.g. Ref. 3), or field theory simulations with a fixed (comoving) core width (e.g. Ref. 4). This work addresses some of the uncertainties introduced by these methods by implementing field theory simulations of individual string configurations using adaptive mesh refinement.

2. Simulations

In this work, we perform adaptive mesh simulations of single, sinusoidally displaced strings with $0.3 \leq \lambda \leq 100$ and spatial periodicity (wavelength) $L = 32$. After an initial period of dissipative damping, strings are subsequently evolved from a desired initial amplitude A_0, with both linear and nonlinear evolution regimes investigated. The oscillation amplitude is measured by calculating the position of the string core i.e. where there is non-zero winding, and the massive and massless diagnostics Π_ϕ and $\mathcal{D}_i\vartheta$ are extracted on a cylinder far from the string core. Our simulations are performed using the adaptive mesh refinement code, GRChombo.[5]

In this study, we measure the string radiation damping rate for a range of $1 \leq \lambda \leq 100$, and investigate the massless radiation spectrum for $\lambda = 1$ and $\lambda = 10$ at linear and nonlinear oscillation amplitudes.[6] We also investigate the massive radiation in detail for strings with $\lambda \leq 2.5$.[7]

3. Results

It has been previously shown[8] that for a sinusoidally displaced string, the massless quadrupole radiation rate can be described using a simple analytic backreaction model, derived from the Kalb-Ramond string action. The effect of radiation energy losses on the string oscillation amplitude A is given by

$$\frac{1}{\varepsilon^2} - \frac{1}{\varepsilon_0^2} = \frac{\beta\, t}{\bar{\mu}L} \quad \Rightarrow \quad \varepsilon = \varepsilon_0 \left(1 + \frac{\beta\varepsilon_0^2 t}{\bar{\mu}L}\right)^{-1/2}. \tag{3}$$

Here, $\varepsilon = 2\pi A/T$ is the amplitude relative to the oscillation time period T of the string, where ε_0 is measured at time $t = 0$. The normalised energy per unit length

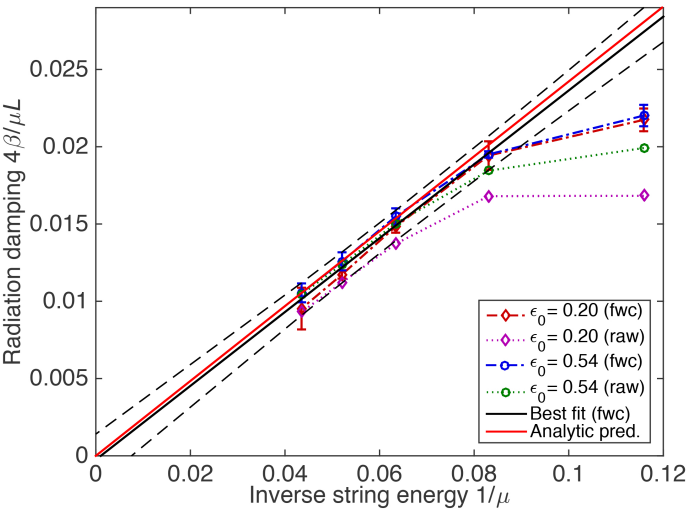

Fig. 1. Radiative damping rate measured using the inverse square model, plotted as a function of inverse string density μ^{-1}. We apply a finite size correction (fwc) to the data and exclude the result at $\lambda = 1$ from the best fit, due to string width effects which limit radiative damping at small λ. The analytic prediction in red uses an effective string radius cutoff $R = 3.5$. The dashed black lines show the error in the extrapolated slope. We observe that the damping rate tends to zero as $\mu \to \infty$ ($\lambda \to \infty$).

$\bar{\mu} = \mu/\eta^2 \approx 2\pi \ln(\sqrt{\lambda}\,\eta\, R)$, where the cutoff R is related to the radius of curvature of the string, $\beta = \pi^3/4 \approx 7.75$ is a constant and L is the spatial period of the string.

Figure 1 shows the main result of the work: the damping rate of a string measured using the inverse square model (3) depends linearly on the inverse of the string tension. We find that the model provides a good fit to the decay rate using the parameters $\beta = 7.6 \pm 1.6$ and $\ln R = 1.3 \pm 0.3$ ($R \approx 3.6$) (after applying a modest finite width correction of $\sim 8\%$ to account for internal oscillations within the string core). These values are consistent with the analytic damping coefficient β, and indicate an effective radial cutoff $R \approx L/8$, about half the string radius of curvature $L/4$. Hence, the inverse square radiation model provides an accurate picture of an oscillating and radiating global string, predicting both the correct power law dependence $\varepsilon^{-2} \propto \mu^{-1}$ and magnitude of the radiation damping.

We also investigate the spectrum of the massless eigenmodes emitted by oscillating strings for $\lambda = 1$ and $\lambda = 10$. Figure 2 gives an example of the massless radiation emitted from a $\lambda = 1$ string with intermediate initial amplitude $A_0 = 4$, showing an apparent dominant quadrupole signal. Figure 3 shows the dominant massless radiative modes for a $\lambda = 1$ string with initial amplitude $A_0 = 1$. We observe the $\{mn\} = \{2\,0\}$ quadrupole mode is dominant (where m and n denote the θ and z eigenvalues respectively), with a $\{1\,1\}$ self-field mode present from the start of the simulation and higher modes present at $\lesssim 100\times$ magnitude. We observe similar results for higher initial amplitudes in the nonlinear regime, $A_0 = 4$ and $A_0 = 8$,

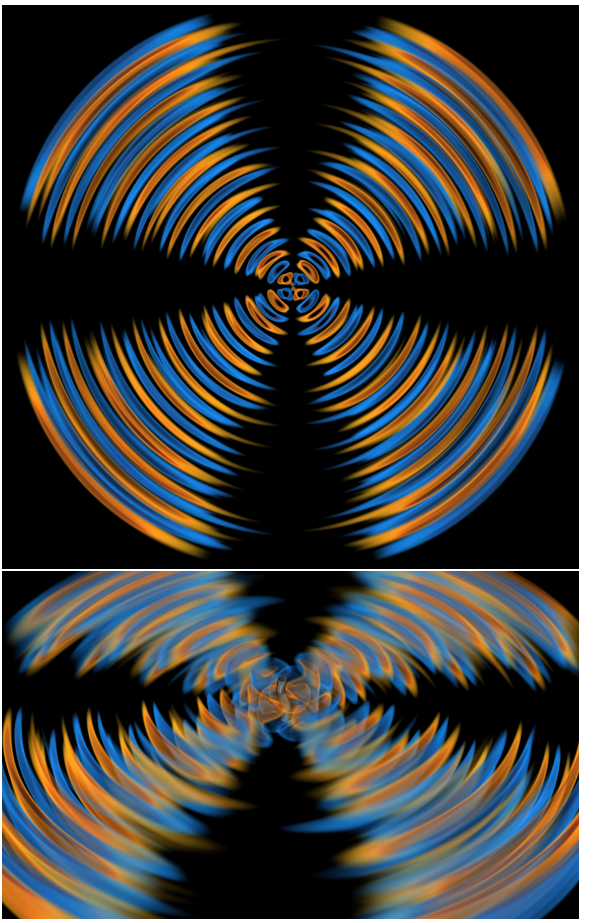

Fig. 2. Volume rendering in 3D space (x, y, z) of the massless radiation $\mathcal{D}\vartheta \cdot \hat{\mathbf{r}}$ from a $\lambda = 1$ string with initial amplitude $A_0 = 4$. The radiation is emitted from a string at the centre of the grid, with the quadrupole mode $\{mn\} = \{2\,0\}$ clearly dominant.

but with higher total magnitude and higher relative amplitude of the subdominant modes as A_0 increases. The amplitudes and spectra are similar for the more massive $\lambda = 10$ with some subtle differences discernible, including a higher initial radiation amplitude and a slightly slower amplitude decay rate. The former arises because, for $\lambda = 1$, finite size effects become important as the string core $\phi < 1$ extends into the radiation zone, causing some suppression of the quadrupole amplitude. The latter is a consequence of the $\lambda = 1$ string being lighter, so there is a larger relative effect from radiation backreaction.

Finally, we briefly present results from an investigation into the massive radiation from light strings with $\lambda \lesssim 3$. Overall, radiation via massive modes is subdominant; even for quasinonlinear intermediate amplitude regimes with $A_0 = 4$ ($\varepsilon \approx 0.7$),

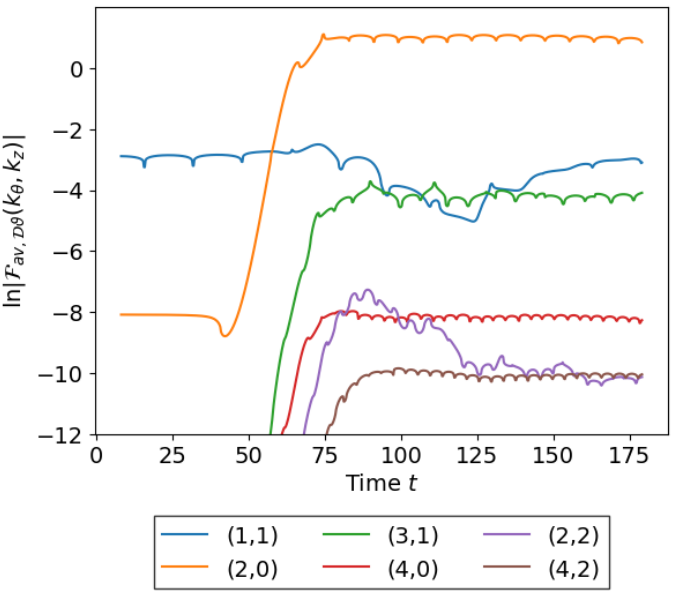

Fig. 3. Dominant 2D Fourier modes of the massless radiation $\mathcal{D}\vartheta \cdot \hat{\mathbf{r}}$ from a $\lambda = 1$ string with an initial amplitude $A_0 = 1$, measured on a cylinder at $R = 64$ and time averaged over approximate half-period $\Delta t = 33/2$.

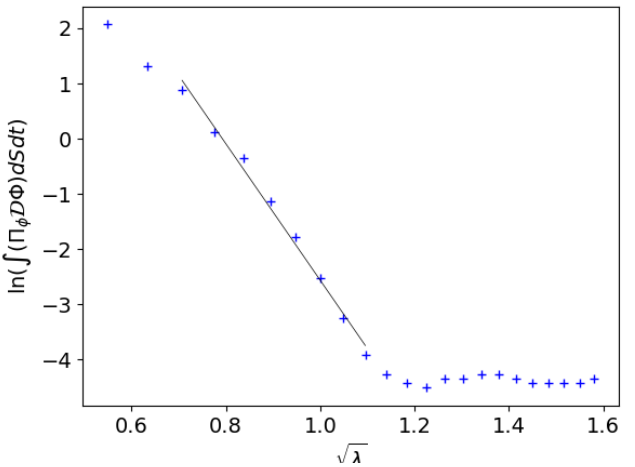

Fig. 4. Log-linear plot of the massive radiation diagnostic $\Pi_\phi \mathcal{D}\phi$ integrated over a diagnostic cylinder S at $R = 64$ from $90 \leq t \leq 228$ for $\varepsilon = 0.5$ and a range of $0.3 \leq \lambda \leq 2.5$. The black line indicates an exponential fit to the data for $0.5 \leq \lambda \leq 1.2$.

the magnitude of the massive signal is $\sim 10^3\times$ smaller than the massless emission. We propose a simple phenomenological model adapted from Ref. 9 to obtain an expression for the energy loss per period via massive radiation,

$$E(L, A_{\rm rel}, \lambda) = \sqrt{L A_{\rm rel}} \exp\left[-\gamma\sqrt{\lambda}\frac{L}{A_{\rm rel}}\right], \tag{4}$$

where $A_{\rm rel} = 4\,A/L$ and γ is a constant to be determined. Figure 4 shows the extracted massive signal $\Pi_\phi \mathcal{D}\phi$ for $A_0 = 4$ ($A_{\rm rel} = 0.5$), integrated over time from $90 \leq t \leq 228$ to give a quantitative estimate for the energy loss through this channel. We observe a clear exponential decay from $0.7 \lesssim \sqrt{\lambda} \lesssim 1.1$ ($0.5 \lesssim \lambda \lesssim 1.2$), consistent with the prediction in (4). We measure

$$\gamma = 0.193\ (\pm\ 0.007) \tag{5}$$

and the intercept $\ln\sqrt{L A_{\rm rel}} = 9.80\ (\pm\ 0.41)$. The first two points are excluded due to finite width effects that appear to suppress radiation, as are $\sqrt{\lambda} \gtrsim 1.1$ ($\lambda \gtrsim 1.3$) where numerical resonance effects become significant. The latter appears to be due to limited grid resolution (despite the use of AMR simulations), but we note that in the small and intermediate amplitude regimes studied the massive radiation always remains subdominant relative to massless modes for all λ.

4. Conclusions

We have presented results from adaptive mesh refinement simulations of global cosmic strings with a range of widths given by $0.3 \leq \lambda \leq 100$. By accurately fitting the oscillation amplitude to an inverse square decay model, we have demonstrated that dual radiation predictions from the Kalb-Ramond action are accurate as we asymptotically approach the small width regime. This lends weight to the Nambu-Goto approach as an accurate method to approximate strings in a cosmological context. We further conclude that the primary radiation channel for sinusoidal string configurations is the massless quadrupole eigenmode $\{mn\} = \{2\,0\}$, strongly dominating other radiation modes even at high amplitude. Finally, we conclude that massive radiation is subdominant in quasilinear regimes and decays exponentially with $\sqrt{\lambda}$ as expected.

Analysing the scaling density of axion strings

A. Lopez-Eiguren

Institute of Cosmology, Department of Physics and Astronomy, Tufts University, Medford, MA 02155, USA
E-mail: asier.lopez_eiguren@tufts.edu

In the QCD axion dark matter scenario with post-inflationary Peccei-Quinn symmetry breaking, the number density of axions, and hence the dark matter density, depends on the length of string per unit volume at cosmic time t, by convention written ζ/t^2. The expectation has been that the dimensionless parameter ζ tends to a constant ζ_0, a feature of a string network known as scaling. It has recently been claimed that in larger numerical simulations ζ shows a logarithmic increase with time. This case would result in a large enhancement of the string density at the QCD transition, and a substantial revision to the axion mass required for the axion to constitute all of the dark matter. With a set of new simulations of global strings we compare the standard scaling (constant-ζ) model to the logarithmic growth. We also study the approach to scaling, through measuring the root-mean-square velocity v as well as the scaled mean string separation x. We find good evidence for a fixed point in the phase-space analysis in the variables (x, v), providing a strong indication that standard scaling is taking place. We show that the approach to scaling can be well described by a two parameter velocity-one-scale (VOS) model, and show that the values of the parameters are insensitive to the initial state of the network. We conclude that the apparent corrections to ζ are artifacts of the initial conditions, rather than a property of the scaling network.

Keywords: Axionic Dark Matter, Topological Defects, Strings, Field Theory Simulations

1. Introduction

Axions[1, 2] were proposed to solve the strong-CP problem, a puzzling question of why QCD does not seem to break Charge Parity (CP) symmetry in strong interactions, but these models also inevitably produce dark matter by releasing their initial potential energy density. However, the analysis of the axions would not only provide us with the information about the dark matter nature or the solution to the strong-CP problem; axion dark matter searches and cosmic microwave background experiments would provide complementary evidences of inflation, a measurement of the axion mass would also immediately determine or constrain the energy scale of cosmic inflation and recent phenomenological analysis has also indicated a possible rich interplay between QCD axions and the electroweak hierarchy problem. Therefore, the analysis of the QCD axions will provide important information about unsolved problems in physics.

The axion particles can be produced in two different scenarios in the non-thermal case. One of these scenarios is described by the so-called misalignment mechanism.[3] In this scenario, the nonperturbative effects at the QCD phase transition generate a mass and the axion field relaxes to its minimum, oscillating around it. The axions

created in this process have zero momentum. The other scenario is based on the formation of topological strings after the spontaneous symmetry breaking of the Peccei-Quinn symmetry.[4] These strings show scaling behaviour and therefore emit axion particles in order to reduce their energy. After the QCD phase transition, the network of strings vanishes due to the presence of domain walls. The misalignment mechanism produces a dominant axion contribution when the axions are created before the end of inflation, otherwise axionic string radiation would produce the bulk of the axion population.

As we have mentioned, the axion[1,2] is a particle, the angular excitation of the "Peccei-Quinn" (PQ) field,[5,6] proposed to solve the strong-CP problem. The axion model has one undetermined parameter, the vacuum value of the field, f_a. The mass of the axion, m_a, can be written by using this parameter: $m_a = (\chi(T)/f_a)^{1/2}$. In this expression $\chi(T)$ is the temperature-dependent topological susceptibility of QCD. The value of f_a also determines the amount of axion dark matter that would have been produced in the early Universe, which means that it should be possible to predict the axion mass using the dark matter densities measured by the recent experiments such as Planck.[7] But to do so, we need to understand the efficiency of axion production in cosmology.

Thus, the vacuum value of the axion field, f_a, is an important energy scale to determine the axion mass. However, there is also another important energy scale to analyse the cosmological behaviour of the axion field. This energy scale is the QCD symmetry breaking scale. In the cosmological evolution of the axion field the first important event is the PQ phase transition, which is broken at a high temperature $T \sim f_a > 109$ GeV. In this phase transition a network of axionic strings are formed. These strings decay gradually emitting axion particles. At lower temperatures, temperatures similar to the QCD symmetry breaking, domain walls are formed between strings and the complex hybrid network annihilates into axions in about one Hubble time.

As we have shown the axion production analysis is complicated because topological defect, axionic strings, appear in the axionic field[8] and because the only reliable way to analyse their dynamics is through field simulations. However, numerical simulations cannot cover the whole string evolution and they must be extrapolated. The prediction of the axion density depends on having an accurate description of axion string evolution.

A physical basis is very important for the extrapolation of the simulation results. In the case of strings, the one-scale model[9] and its velocity-dependent improvement[10–12] can give the appropriate basis. These models predict that the system will acquire a scaling regime, where the mean string separation grows in proportion to cosmic time t, and the RMS velocity of the strings is constant. By scaling we mean that at distances much larger than the string width, network length-scales such as the mean string separation are proportional to the cosmic time t.

In the following, we will analyse if the axionic strings follow the standard scaling picture,[13–15] where the dynamical evolution of the network is independent of the

string width and tension. Or on the contrary, the system follows the model recently put forward,[16–21] which suggest a logarithmic correction to scaling based on the logarithmic growth in the effective string tension of a global string with their mean separation.

2. Model and Network Parameters

2.1. *Field dynamics*

The simplest axion model can be constructed using a singlet scalar field with a U(1) symmetry, Φ, with action

$$S = \int d^4x\sqrt{-g}\Big(\frac{1}{2}\partial_\mu\Phi\partial^\mu\Phi - \frac{1}{4}\lambda(\Phi^2-\eta^2)^2\Big), \tag{1}$$

where we have written the field as a two-component vector, and the U(1) symmetry is realised as a rotation on the vector.

In a FLRW metric, and when the field is coupled to a thermal bath of weakly-coupled particles, the equations of motion take the form

$$\Phi'' + 2\frac{a'}{a}\Phi' - \nabla^2\Phi = -a^2\lambda(\Phi^2-\eta^2(T))\Phi, \tag{2}$$

where a is the scale factor, a prime denotes differentiation with respect to conformal time τ, and in the radiation era $a \propto \tau$. The free energy of the system is minimised at the field magnitude $\eta(T)$, where $\eta^2(T) = d(T_{\rm c}^2 - T^2)$, $T_{\rm c} \simeq \eta$ is the critical temperature of the PQ phase transition, and d is a constant computable in perturbation theory. For $T \gg T_{\rm c}$, it is energetically favourable for the field to fluctuate around $\Phi = 0$. Well below the critical temperature it is energetically favourable for the magnitude of the field to take the value η, with a massless pseudoscalar fluctuation mode (the axion) and a scalar mode of mass $m_{\rm sca} = \sqrt{2\lambda}\eta$. During the phase transition, the direction in field space is chosen at random in uncorrelated regions of the universe, with the result that the field is forced to stay zero along lines.[22] These lines form the cores of the axion strings.[8] The size of the core is approximately $w_0 = m_{\rm sca}^{-1}$.

2.2. *Network parameters from field averages*

The evolution of the network of strings produced after the symmetry breaking can be analysed using the string length ℓ and the RMS velocity v of the strings.

In order to compute the string length we can use a couple of estimators. On the one hand we can use the number of plaquettes pierced by strings. This estimator is known as the winding length $\ell_{\rm w}$. The length of the strings is obtained by multiplying the number of plaquettes pierced by strings by the physical lattice spacing $a\delta x$ and then correcting the value by factor of 2/3 to compensate for the Manhattan effect.[23] The plaquettes pierced by strings are identified by working out the "winding" phase of the field around each plaquette of the lattice.[24] This is an estimate of the length

of string measured in the "universe frame", that is, observers comoving with the expansion of the universe.

One can obtain other measures of length taking into account that the energy of a string configuration is proportional to its length. In this case the estimators are constructed using local functions of the fields. Neglecting the expansion of the universe and considering the energy components to be weighted, we can write the rest-frame length $\ell_{\rm r}$ and the mean square velocity as

$$\ell_{\rm r} = \frac{E + f_V L}{\mu(1 - f_V)}, \tag{3}$$

$$v_L^2 = \frac{E + L}{E + f_V L}, \tag{4}$$

where the subscript L denotes the use of the Lagrangian to obtain the estimate. The energy, E, and the lagrangian, L, are defined as:

$$E = E_\pi + E_D + E_V, \tag{5}$$

$$L = E_\pi - E_D - E_V, \tag{6}$$

where E_π is the weighted kinetic energy, E_D is the weighted gradient energy and E_V is the weighted potential energy. Likewise, μ is the weighted mass per unit length of a static string and f_V is the fraction contributed by the potential energy density. In this case their values are $\mu = 0.892\eta^2$ and $f_V = 0.368$. For more information about the weighting procedure and computation of the values of μ and f_V we refer the reader to.[15]

An alternative way of estimating the string velocity comes from the pressure,

$$p\mathcal{V} = E_\pi - \frac{1}{3}E_D - E_V, \tag{7}$$

giving another mean square velocity estimator

$$v_\omega^2 = \frac{1 + 3\omega + 2f_V}{2 + f_V(1 + 3\omega)}, \tag{8}$$

where $\omega = p\mathcal{V}/E$ is the equation of state parameter of the strings. A third estimate for the string velocity can be constructed from the ratio of the kinetic to gradient energies,[25]

$$R_{\rm s} = \frac{E_\pi}{E_D}, \tag{9}$$

which can be rearranged to give

$$v_{\rm s}^2 = \frac{2R_{\rm s}}{1 + R_{\rm s}}. \tag{10}$$

Following the analysis performed in,[15] the estimators that we are going to use in this paper will be the rest frame length, $\ell_{\rm r}$, and the velocity estimator derived from the kinetic and gradient energies, v_s.

In a cosmological simulations one can express the string length in terms of Hubble lengths per Hubble volume, or

$$\zeta_{\rm r} = \frac{\ell_{\rm r} t^2}{\mathcal{V}}. \tag{11}$$

When investigating scaling in string networks, it is more transparent to parametrise the string density by the mean string separation, which is obtained from measures of the string length via

$$\xi_{\rm r} = \sqrt{\frac{\mathcal{V}}{\ell_{\rm r}}}. \tag{12}$$

The above estimators were derived for a Minkowski space-time. In an expanding background, one can view the space-time coordinates as representing comoving position and conformal time, from which physical lengths follow by multiplication by the scale factor a.

3. Simulations

In order to perform simulations of axionic string we discretise the equations of motion (2) and evolve them on a cubic lattice with periodic boundary conditions. The system is evolved in conformal time τ. The simulations analysed in this paper are the same set of simulations used in,[14,15] where we analyzed lattices with 1024, 2048 and 4096 sites per dimension with spatial resolution of $\delta x \eta = 0.5$ and conformal time steps of $\delta\tau\eta = 0.1$. We will give a short summary of the procedure and we refer the reader interested in more details to.[14,15]

The field configuration is initiated at conformal time $\tau_{\rm start}$ by setting the canonical momentum to zero and the scalar field to be a Gaussian random field with power spectrum $P_\Phi(k) = A\left[1 + (k l_\phi)^2\right]^{-1}$, were A is chosen so that $\langle\Phi^2\rangle = \eta^2$ and l_ϕ is the field correlation length in comoving coordinates. We use different values of l_ϕ in order to cover a range of string separations in the initial conditions. The values used are $l_\phi = 5, 10, 20, 40$, where $l_\phi = 40$ case have been used only for $s = 1$ case. In order to allow the strings to form, and to remove the energy excess in the field fluctuations around the string configurations, we evolve this configuration with a diffusion equation with unit diffusion constant until conformal time $\tau_{\rm diff}$. We then apply the second-order time evolution equation (2).

Similarly to our previous paper, we extract data from simulations with both fixed comoving string width and fixed physical string width. We promote the scalar self-coupling constant to be a time dependent parameter $\lambda = \lambda_0/a^{2(1-s)}$ following the PRS method.[26] This makes the comoving string width decrease with conformal time as:

$$w(\tau) = \frac{w_0}{a^s(\tau)}\,. \tag{13}$$

The physical equation of motion, where the physical string width remains constant at $w_0 = 1/\sqrt{2\lambda_0}\eta$, and the comoving width decreases with time, corresponds to $s = 1$. With $s = 0$ the comoving width is constant at w_0 and the physical string width increases in time.

For the $s = 1$ case, it is difficult to avoid the string width being larger than the Hubble length at early times, which also means that the relaxation of the field to its equilibrium value is longer than a Hubble time. In order to speed up the string formation, we arrange the time-dependence of the coupling so that strings are formed and diffused with a constant comoving width, equal to their final comoving width. At the end of the diffusion period, the string width is much smaller than its physical value w_0. The string width is then allowed to grow by setting $s = -1$ until $\tau_{\rm cg}$, which is when the string core has expanded to its correct physical width w_0. After conformal time $\tau_{\rm cg}$, the physical evolution with $s = 1$ starts. We call this procedure core growth. Simulations end at conformal time $\tau_{\rm end}$.

Table 1 contains all simulation parameter choices that have been considered in the procedures described above. Four simulations with different random number seeds were carried out at each parameter choice. The data are analysed in cosmic time $t = (\tau/\tau_{\rm end})^2\tau_{\rm end}/2$.

Table 1. Run parameters used in simulations. See text for explanation.

Model	$s = 1$	$s = 0$
$l_\phi\eta$	(5,10,20,40)	(5,10,20)
$\tau_{\rm start}\eta$	50	50

4. Results

In Fig. 1 we show the evolution of the mean string separation (12) and the RMS velocities for all the simulations performed with size 4096. In these figures the solid line represents the mean obtained by averaging over realisations and the shaded regions the 1σ standard deviations. In both estimators the uncertainties are worked out by propagating the fluctuations in the weighted energies E_π, E_D and E_V.The color code is as follows: black for $l_\phi\eta = 5$, red for $l_\phi\eta = 10$, blue for $l_\phi\eta = 20$, and green for $l_\phi\eta = 40$. Note that we only have $l_\phi\eta = 40$ simulations in the $s = 1$ case. The end of the core growth period is shown as a vertical green dashed line.

Figure 1 show that, independently of the initial field correlation length, all simulations are compatible, *i.e.* all of them give separation and velocity data which are within 1σ of each other. Moreover, the behaviour of both estimators (ξ and v) qualitatively agrees with the standard scaling, showing a tendency towards linear growth in ξ and a constant RMS velocity.

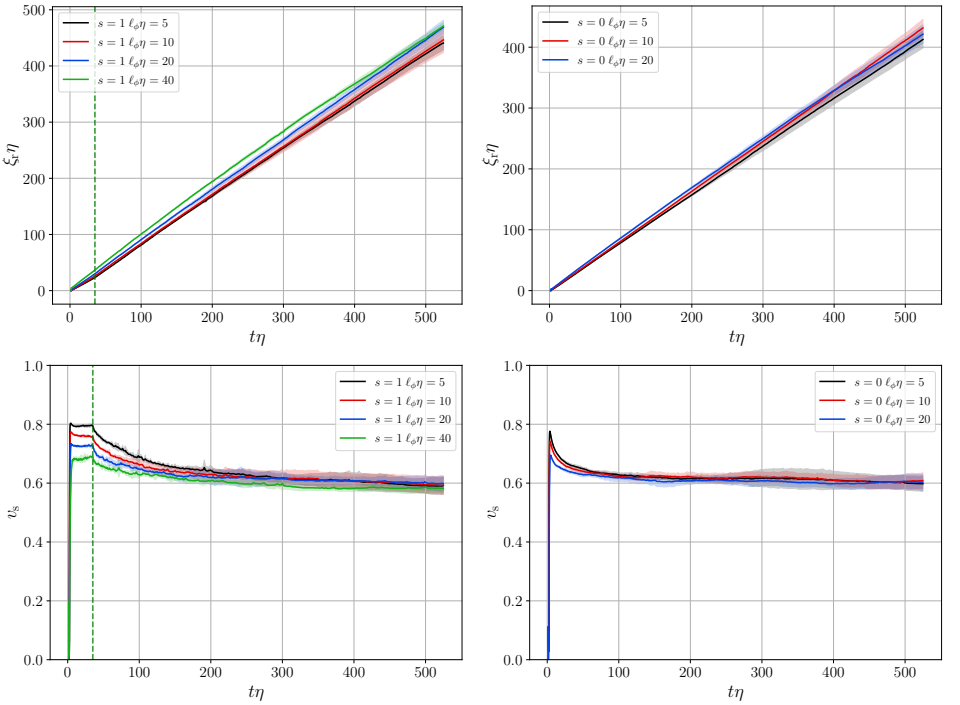

Fig. 1. Mean string separation ξ_r and velocity v_s evolution for $s = 1$ (right) and $s = 0$ (left).

Now we are going to analyse more in detail the scaling behavior of the system. First we will analyse the Length estimator and compare the different behaviors proposed in the literature for the scaling regime. Afterwards using the both length and velocity estimators we will analyse the approach to the scaling phase.

4.1. *Length Estimator*

As we have previously mentioned after a relatively short period of relaxation, the mean string separation ξ tends to a line that can be well fitted with

$$\xi = 2\beta(t - t_0). \tag{14}$$

where β and t_0 are parameters to be fitted. β is predicted to be a universal parameter, while t_0 is a phenomenological fit parameter to reduce the effect on estimates of β of the initial conditions and evolution of the RMS velocity. This model is known as the standard scaling and in this case the scaling value of the string length in terms of Hubble lengths per Hubble volume, ζ, is $\zeta_0 = 1/4\beta^2$.

We measure the parameters β and t_0 for each one of the individual runs we performed with a linear fit over the ranges in conformal time defined by the boundary

times $\tau_{\rm b} = [6, 10]\tau_s$, and $\tau_s\eta = [25, 50, 100]$ for $N = [1k, 2k, 4k]$. That is, in the $1k$ case the fitting range is $\tau_{\rm b} = [150, 250]$. The times are chosen in the last half of the conformal time range to minimise the biases coming from the initial conditions.

The values obtained are shown in Fig 2. The color code in this figure is the same as in Fig. 1 and the style of each point represent the size of the simulation box, circles represent $1k$ simulations, triangles pointing downwards represent $2k$ simulations and triangles pointing upwards represent $4k$ simulations. The parameter t_f is taken to be as the end of the fitting period.

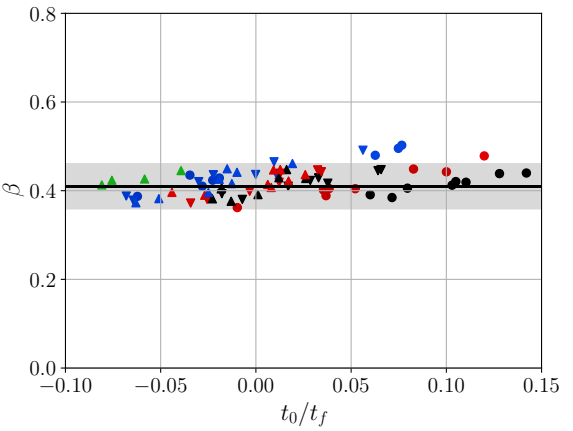

Fig. 2. Parameters β and t_0 for each one of the individual runs.

In Fig. 2 we have also added the mean value for β and its 1σ standard deviation obtained in.[15] As we can see all the points agree with the average value within 2σ and there is no correlation between the value of t_0 and β, showing that the initial conditions are not affecting the value obtained for β.

We now turn to the alternative model recently put forward: logarithmic[16–19,21] correction to scaling

$$\zeta(t) = \zeta_0^* + \alpha^* \log(\eta t) \tag{15}$$

where ζ_0^* and α^* are the fitting parameters. We performed fits over the ranges used previously and we show the values in Fig. 3, where we use the value of t_0 computed previously.

In Fig. 3 we have also added the mean value for β and its 1σ standard deviation obtained in,[15] but in this case translated to ζ_0. One can see that there is a clear correlation between the values of ζ_0^* and α^* with respect to t_0, showing that the initial conditions are affecting the values. Moreover, in the case that $t_0 = 0$ the value of α^* is zero and ζ_0^* agrees with the value obtained in.[15]

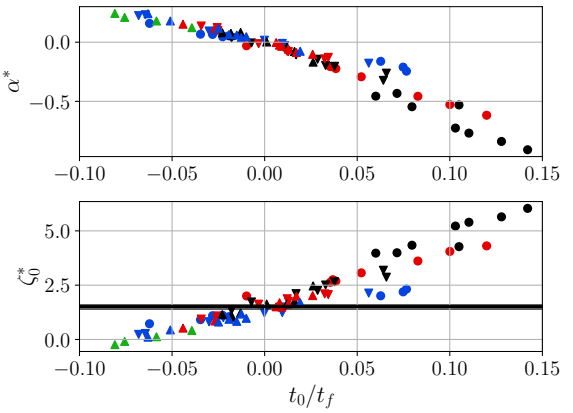

Fig. 3. Parameters ζ_0^* and α^* for each one of the individual runs.

4.2. *Length and Velocity Estimators*

As we have seen in the previous section, there is a small departure from standard scaling in the earlier phases of the simulations. It is necessary to understand this departure to improve the estimates of the asymptotic behavior of v and ξ, or more precisely the asymptotic values of the *scaled mean string separation*,

$$x = \xi/t. \tag{16}$$

In the previous Section, we have studied scaling using ξ only. Now we will also use the RMS velocity data, which gives extra information about the approach to scaling, and we will avoid the use of t_0. We will see that in doing so we will improve the accuracy of the estimate of β, while remaining consistent with our previous estimate. The analysis of this Section will be performed in simulations with size 4096.

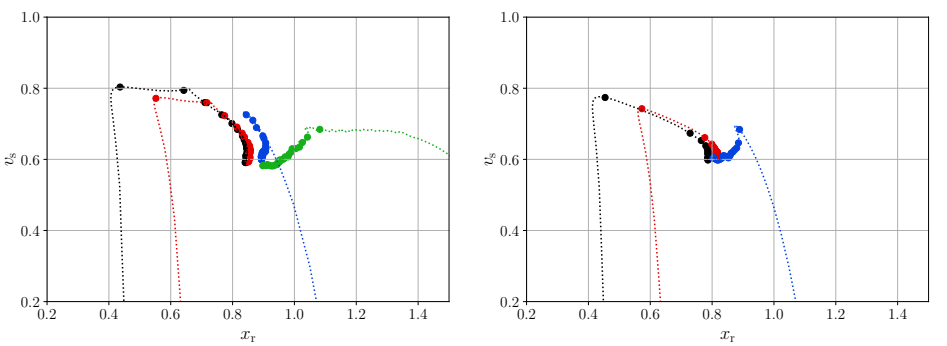

Fig. 4. The evolution of the network in the phase space (x, v).

In Fig. 4 we show the evolution of the network in the phase space (x, v). The phase space representation shows clearly the different regimes in which the network evolves. A rapid increase in the RMS velocity, while the inter-string distance remains nearly constant, happens after the end of the diffusion period, when strings are accelerated under their curvature. In the case of $s = 1$, after the diffusion period we impose a core growth period as part of the preparation of the initial conditions, where the velocities remain approximately constant but the scaled mean string separation changes. This change is different for different initial conditions. For correlation lengths $l_\phi \eta = 5,\ 10$, the scaled mean string separation grows, whereas for correlation lengths $l_\phi \eta = 20,\ 40$ it decreases. Finally, when the physical equations of motion (2) are being solved, the system starts to spiral towards an apparent common fixed point for all simulations.

The evolution of the scaled mean string separation and the RMS velocity can be modeled by the velocity-dependent one-scale (VOS) model.[9–12] Assuming that the statistical distribution of string configurations and velocities has a universal form the model parametrised it by the string separation ξ and the RMS velocity v.

The model uses the following equations to describe the dynamical system,

$$\frac{d\xi}{dt} = H\xi(1 + v^2) + \frac{1}{2}cv, \tag{17}$$

$$\frac{dv}{dt} = (1 - v^2)\left(\frac{k}{\xi} - 2Hv\right), \tag{18}$$

where H is the Hubble parameter. There are two phenomenological parameters, k and c. The parameter c describes the efficiency of the energy loss mechanism, while the parameter k describes the correlation between the string curvature and the velocity.

Using the dimensionless mean string separation variable x (16), and $H = 1/2t$ since we are considerning a radiation-dominated universe, we have,

$$t\dot{x} = \frac{1}{2}x\left(v^2 - 1\right) + \frac{c}{2}v \tag{19}$$

$$t\dot{v} = \left(1 - v^2\right)\left(\frac{k}{x} - v\right) \tag{20}$$

This dynamical system has a fixed point in the relevant region $0 \leq x$, $0 \leq v < 1$,

$$x_* = \sqrt{k(c + k)} \qquad v_* = \sqrt{\frac{k}{(c + k)}}. \tag{21}$$

The fixed point is a stable spiral. We plot flows in the phase diagram predicted by the VOS model in Fig. 5 for the global best fit (x_*, v_*) (computed from a χ^2 analysis; for more details see[15]), along with the mean values of selected (x, v) from the simulations. The stable spiral form is clearly visible in the streamlines.

To show in a more quantitative way how well the VOS model describe the evolution of the system, we show in Fig. 6 the relative difference between the simulation

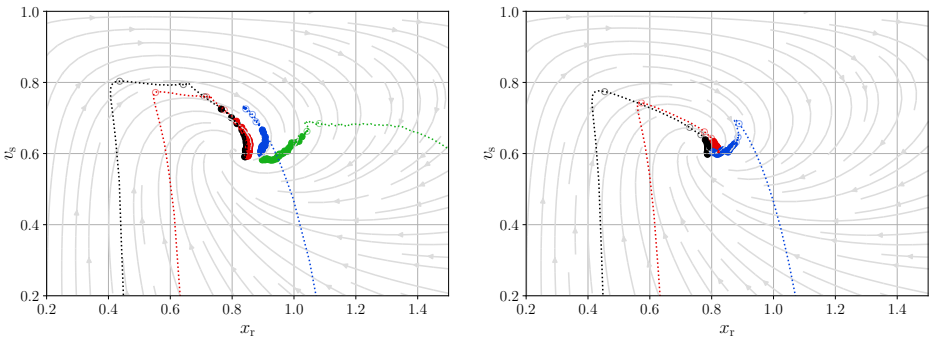

Fig. 5. The evolution of the network in the phase space (x, v) with stream lines.

time series data and the VOS best-fit model for each (s, l_ϕ), where the VOS model is initialized at $t_{\rm fit}$, which is the same as in the previous Section. Shaded regions correspond to the uncertainties propagated from simulation estimators. It can be observed that the mean relative difference always lies below 5% level of deviation, with zero deviation always within the errors.

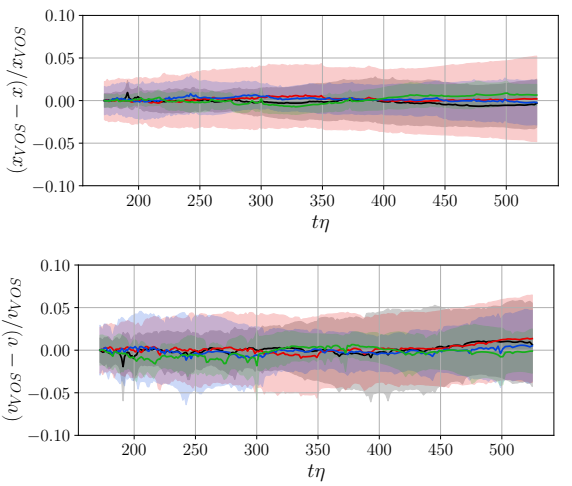

Fig. 6. Relative errors.

To understand better how the network evolves it is fundamental to analyse it in terms of the length density parameter ζ (11). In Fig. 7 we show ζ plottted against the logarithm of time, in order to emphasise the earlier times when the network is further away from scaling. The case that we are showing is this plot is $s = 1$, where we have also added the best-fit VOS models for each correlation length, and their extrapolation to larger values of time. The asymptotic values obtained in[15]

($\zeta_{r,*} = 1.50 \pm 0.11$) is also shown in the figure. The solid line represents the central value and the shaded region represents the 1σ error. In the figure we can see that the simulations approach the asymptotic value of ζ from below and that at the end of the simulations they are still slowly increasing, but within 20% of its asymptotic value. This increase is more visible in the simulations that start very underdense and therefore have much more to evolve until they reach scaling. The extrapolated values of the VOS model show that the system will reach the asymptotic value and become constant.

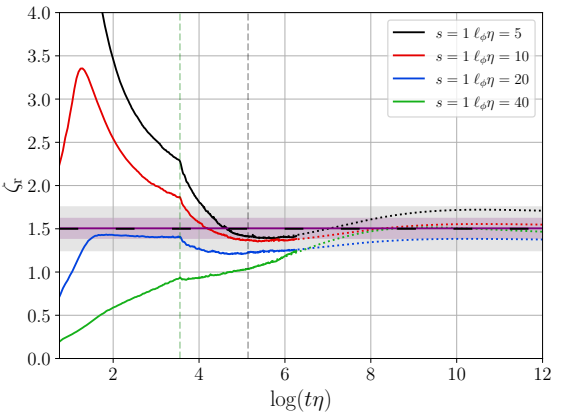

Fig. 7. ζ evolution.

5. Conclusions

In this paper we have analysed the evolution of the mean string separation ξ and the RMS velocity for an axion string network in the radiation era. The axion model has been constructed using a singlet scalar field with a U(1) symmetry, where the field has been considered as a two-component vector and the U(1) symmetry has been realised as a rotation on the vector.

Firstly, we have fitted the mean string separation (12) from the simulations we have performed with two two-parameter models: the standard scaling model with the usual time offset t_0 to account for the initial string evolution and a constant parameter β, and a model with a logarithmically increasing ζ (11). Using linear fits to obtain the values for β we have seen that the value does not depend on the initial conditions, or on the value of t_0. The coefficients of the logarithmically increasing model can be understood in terms of the dependence of ζ on the initial string evolution parameter t_0, and describe a disguised approach to scaling for non-zero values of t_0. We find that the value of the parameter describing the logarithmic increase is consistent with zero when $t_0/t_f \to 0$, where t_f is the final fitting time. In this case the constant term of the model is consistent with the standard scaling values.

Secondly, we have fitted the results of our set of numerical simulations to a two-parameter VOS model (18). We find that the evolution of the network is well described, qualitatively and quantitatively, by the VOS model. Qualitatively, we see that after the effects of the initial conditions are gone the systems turns into a curved approach to the fixed point in the (x, v) plane. A deeper analysis of the spiral behavior of the system showed that the apparent logarithmic growth in ζ is a transient epoch of the system, and that the length of this transient epoch depends on how far the initial conditions are from the fix point. After the transient epoch the system tends to a constant ζ evolution.

We study axion strings with the electroweak gauge flux in the DFSZ axion model and show that these strings, called electroweak axions, exhibit superconductivity without fermionic zero modes. We also show that the primordial magnetic field in the early universe can induce a large electric current along the string. A pair of the strings carrying such a large current feels a net attractive force between them and can form a Y-shaped junction in the early universe, whose formation probability is roughly estimated to be 1/2.

Keywords: Axion; Cosmic string; Soliton; Higgs

1. Introduction

The strong CP problem is one of the mysteries in the Standard Model (SM) of particle physics. The problem can be naturally solved by the Peccei-Quinn mechanism, in which a global symmetry denoted by $U(1)_{\rm PQ}$ is assumed to be spontaneously broken and provides a (pseudo) Nambu-Goldstone particle, the axion.[1–4] The axion can also play a role of cold dark matter.

The DFSZ model[5,6] is a popular model providing the axion as well as the KSVZ model.[7,8] In the DFSZ model, the scalar sector of the SM is extended to have two Higgs doublets and one SM-singlet complex scalar. The scalar fields and the SM fermions are assumed to be charged under the $U(1)_{\rm PQ}$ symmetry, which is spontaneously broken by a vacuum expectation value (VEV) of the complex scalar. The axion is a linear combination of imaginary components of the doublets and the complex scalar.

It is known that if the $U(1)_{\rm PQ}$ symmetry is broken after the cosmological inflation, the axion strings, which are global cosmic strings, are created by the Kibble-Zurek mechanism.[9,10] To avoid dominating the energy of the universe, the strings should lose their energy by reconnection. When the probability of the reconnection is sufficiently close to unity, the number density of the strings approach $\mathcal{O}(1)$ values per Hubble length, called the scaling regime.

Table 1. Quantum charges of scalar fields.

	H_1	H_2	S
$SU(2)_W$	**2**	**2**	**1**
$U(1)_Y$	1	1	0
$U(1)_{\rm PQ}$	1	-1	1

It has been believed that axion strings almost always reconnect when they collide. This is because the interaction between the strings is thought to be dominated by exchange of the (massless) axion as a long-range force. This is analogous to the case of the magnetic flux tube in the type-II superconductor. However, when there is a strong attractive force between them, they can form a bound state called Y-junction.[11,12] When the Y-junction is formed, the reconnection does not work successfully, making the evolution of the string network non-trivial. Is such an attractive force realized for axion strings?

Sometimes, cosmic strings can be superconducting when $U(1)_{\rm EM}$ is broken inside them. This is called the superconducting string.[13] Electric current flows along the string without dissipation and can induce magnetic attractive interaction between the strings. This enables them to form Y-junctions!

In this work,[14] we show that the axion string in the DFSZ model can become a superconducting string after the breaking of the electroweak (EW) symmetry.[a] This is because the charged fields, the charged Higgs and W bosons, acquire nonzero values inside the string and the $U(1)_{\rm EM}$ symmetry is spontaneously broken there. This is a similar situation to superconductivity of non-Abelian vortices[21,22] and of the $U(1) \times \tilde{U}(1)$ model considered by Witten.[13] Remarkably, the amount of the supercurrent can be of order of the $U(1)_{\rm PQ}$ breaking scale resulting in large magnetic energy. As a consequence, the strings feel a large magnetic interaction, which can overcome the one from the axion exchange. The formation probability of the Y-junctions is roughly estimated to be 1/2.

2. DFSZ axion model

Throughout this article, we concentrate on the bosonic sector of the DFSZ model. The particle contents and the charge assignments under the SM gauge group and the $U(1)_{\rm PQ}$ are shown in Tab. 1. We introduce a SM-singlet complex scalar S and two $SU(2)_W$ doublets, H_1 and H_2, both with the hypercharge $Y = 1$. The Lagrangian which describes the EW and scalar sectors is written as

$$\mathcal{L} = -\frac{1}{4}\left(Y_{\mu\nu}\right)^2 - \frac{1}{4}\left(W^a_{\mu\nu}\right)^2 + \sum_{i=1,2} |D_\mu H_i|^2 + |\partial_\mu S|^2 - V(H_1, H_2, S). \qquad (1)$$

[a] Our mechanism of superconductivity is different from one using fermionic zeromodes.[15–20] In the DFSZ model, the fermionic zeromodes should be irrelevant for the dynamics of the strings because the mass scale of the SM fermions are much lighter than the $U(1)_{\rm PQ}$ breaking scale.

Here, $Y_{\mu\nu}$ and $W^a_{\mu\nu}$ describe field strength tensors of the hypercharge and weak gauge interactions, respectively, with μ (ν) and a being Lorentz and weak iso-spin indices, respectively. D_μ represents the covariant derivative acting on the Higgs fields, and the index i runs $i = 1, 2$. The scalar potential $V(H_1, H_2, S)$ being invariant under the charge assignments of Tab. 1 is

$$V(H_1, H_2, S) = V_H + V_S + V_{\rm mix}, \tag{2}$$

where each part is given by

$$\begin{aligned} V_H =& m_{11}^2 H_1^\dagger H_1 + m_{22}^2 H_2^\dagger H_2 + \frac{\beta_1}{2}\left(H_1^\dagger H_1\right)^2 + \frac{\beta_2}{2}\left(H_2^\dagger H_2\right)^2 \\ &+ \beta_3\left(H_1^\dagger H_1\right)\left(H_2^\dagger H_2\right) + \beta_4\left(H_1^\dagger H_2\right)\left(H_2^\dagger H_1\right), \end{aligned} \tag{3}$$

$$V_S = - m_S^2|S|^2 + \lambda_S|S|^4, \tag{4}$$

$$V_{\rm mix} = \left(\kappa S^2 H_1^\dagger H_2 + {\rm h.c.}\right) + \kappa_{1S}|S|^2|H_1|^2 + \kappa_{2S}|S|^2|H_2|^2, \tag{5}$$

with $m_S^2 > 0$ which admits S to acquire a non-zero VEV: $\langle S\rangle = v_s$. From astrophysical constraints, v_s is supposed to be $\mathcal{O}(10^{8-12})$ GeV. Without loss of generality, we can suppose that the Higgs fields develop VEVs as $\langle H_1\rangle = (0, v_1)^{\rm T}$, $\langle H_2\rangle = (0, v_2)^{\rm T}$ with $v_1, v_2 \in \mathbb{R}$. For simplicity, we take $v_1 = v_2 \equiv v$ in this article. Then the electroweak scale, $v_{\rm EW}$ ($\simeq 246$ GeV), can be expressed by these VEVs as $v_{\rm EW}^2 = 4v^2$.

3. Electroweak axion strings

Similarly to other axion models, the DFSZ axion model provides a vortex string solution known as the axion string corresponding to the breaking of $U(1)_{\rm PQ}$. On the other hand, after the electroweak phase transition, the axion string can contain flux tubes of the $SU(2)_W \times U(1)_Y$ gauge fields like the Abrikosov-Nielsen-Olesen vortex[23,24] since the two Higgs doublets also acquire the VEVs. We call such vortex strings the EW axion strings.

3.1. *Axion string in DFSZ model*

We first review the conventional axion string in this subsection. Let us consider a case that the $U(1)_{\rm PQ}$ symmetry is spontaneously broken by $\langle S\rangle \neq 0$ but the EW symmetry remains unbroken, $\langle H_1\rangle = \langle H_2\rangle = (0, 0)^{\rm T}$. This situation is realized in the early universe when the temperature of the thermal bath T_{th} satisfies $v_{EW} \ll T_{th} \ll v_s$. In this case, as is well-known, a vortex-string configuration associated with the global $U(1)_{\rm PQ}$ symmetry exists as a solution to the equation of motion (EOM), which is called the axion string in the literature. The configuration located on the z-axis is described by the following ansatz

$$S = v_s e^{i\theta}\phi(r), \qquad H_1 = H_2 = \begin{pmatrix} 0 \\ 0 \end{pmatrix}, \tag{6}$$

where r and θ are the distance from the z-axis and the rotational angle, respectively, *i.e.*, $x + iy = re^{i\theta}$. The profile function $\phi(r)$ satisfies the boundary conditions

$$\phi(0) = 0, \qquad \phi(\infty) = 1. \tag{7}$$

The detailed form of $\phi(r)$ is determined by solving the EOM. This string has a winding number associated with the $U(1)_{\rm PQ}$ symmetry, and hence is topologically stable. The $U(1)_{\rm PQ}$ symmetry is restored at the string core because of $\phi(0) = 0$.

After these axion strings are produced in the early universe, their string network evolves to the scaling regime. This is because the interaction between the strings is dominated by exchange of massless axion particles, resulting in the long-range repulsive force for two parallel axion strings with the same topological charge. The potential of the interaction $V_{\rm st.}$ is approximately given as $V_{\rm st.} \sim -v_s^2 \log R$ with R being the distance between the pair.

3.2. *Electroweak axion string with W-flux*

Next, we discuss the EW axion strings. Let us consider a string configuration after the EW phase transition $T_{th} \lesssim v_{\rm EW}$. The two doublets also acquire the VEVs and can have winding phases.[14] There are three patterns of the winding phases, only one of which (called type-C EW axion string in Ref. 14) is studied in the following.

We consider a configuration that has winding phases in $U(1)_{\rm PQ}$ and in the $U(1)_{W^1}$ subgroup of the $SU(2)_W$ gauge group. Its asymptotic form is given as

$$S \sim v_s e^{i\theta}\,, \tag{8}$$

$$H_1 \sim \frac{1}{2} v e^{i\theta} e^{i\theta\sigma_1} \begin{pmatrix} 0 \\ 1 \end{pmatrix}, \quad H_2 \sim \frac{1}{2} v e^{-i\theta} e^{i\theta\sigma_1} \begin{pmatrix} 0 \\ 1 \end{pmatrix}, \tag{9}$$

at $r \to \infty$. The exponential factor with σ_1 means a rotation in the direction of $U(1)_{W^1}$. Since these configuration are singular at $r = 0$, they must be smeared by introducing profile functions as follows:

$$\begin{cases} S = v_s e^{i\theta} \phi(r) \\ H_1 = \frac{1}{2} v_1 e^{i\theta} \begin{pmatrix} f(r) e^{i\theta} - h(r) e^{-i\theta} \\ f(r) e^{i\theta} + h(r) e^{-i\theta} \end{pmatrix} \\ H_2 = \frac{1}{2} v_2 e^{-i\theta} \begin{pmatrix} h(r) e^{i\theta} - f(r) e^{-i\theta} \\ h(r) e^{i\theta} + f(r) e^{-i\theta} \end{pmatrix} \end{cases} \tag{10}$$

The profile functions $f(r), h(r)$ and $\phi(r)$ satisfy the following boundary conditions,

$$f(0) = \phi(0) = 0, \quad \partial_r h|_{r=0} = 0, \quad f(\infty) = h(\infty) = \phi(\infty) = 1. \tag{11}$$

Note that $h(r)$ does not necessarily vanish at the center of the string. Due to the non-zero value of $h(0)$, the EW symmetry is not restored inside the string.

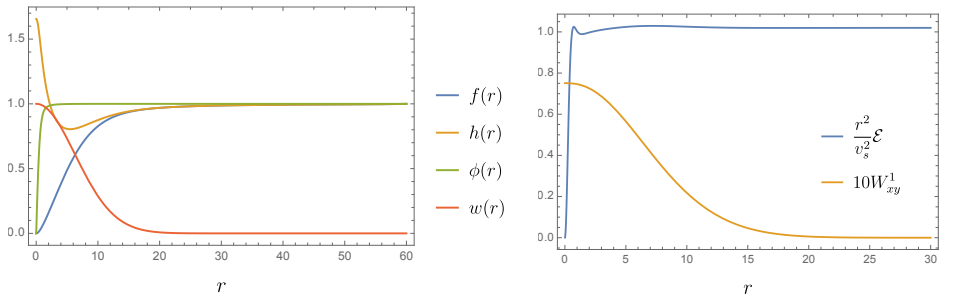

Fig. 1. Numerical solution for the EW axion string. Also we adopt a length unit as $v_s^{-1} = 0.5$. (left): Plots of profile functions. The profile function of the W^1 field, $w(r)$, approaches to zero as $r \to \infty$ starting from unity at $r = 0$. (right): Plots of energy density divided by v_s^2/r^2 and the W^1-flux density multiplied by 10. The tension integrated over $0 \le r \le 120\, v_s^{-1}$ is 140.604. The total value of the W^1-flux is calculated to 19.3208, which is consistent with Eq. (14).

To cancel the gradient energy from the windings for $U(1)_{W^1}$ at infinity, the W^1 gauge field is induced as

$$W_i^1 = \frac{-2}{g}\frac{\epsilon_{ij}x_j}{r^2}(1 - w(r)), \tag{12}$$

and $A_i = Z_i = 0$. The profile function $w(r)$ satisfies

$$w(0) = 1, \quad w(\infty) = 0. \tag{13}$$

This string has the confined W^1-flux

$$\Phi_{W^1} = \oint_{r=\infty} dx_i\, W_i^1 = \frac{4\pi}{g}. \tag{14}$$

This feature is similar to the electroweak strings[25,26] in the SM and its extended models. The detailed behavior of the profile functions, ϕ, f, h, and w are obtained by solving the EOMs numerically. The obtained numerical solutions are shown in Fig. 1.

The most important feature of this string is that the $U(1)_{\rm EM}$ symmetry is spontaneously broken inside the string core because the W^1 boson acquires a non-zero value Eqs. (12) and (14). (The charged component of the Higgs doublets also acquires a non-zero value, see Ref. 14). Actually, that is generally inevitable for a configuration with a non-vanishing winding number for charged components,[21,22] i.e., a configuration whose asymptotic form is $\exp[i\hat{T}(\theta)]H_i(\theta = 0)$ with a non-Abelian generator $\hat{T}(\theta)$ satisfying $[\hat{T}(\theta), \hat{Q}] \neq 0$, where $\hat{Q}$ is the generator of $U(1)_{\rm EM}$. ($\hat{T} = \sigma_1\theta$ in our case.) Due to this breaking of $U(1)_{\rm EM}$, the string is a superconducting string. We discuss its consequence in the next section.

In Ref. 14, other two types of the EW axion strings are studied. Since they do not break $U(1)_{\rm EM}$ inside it and are not superconducting ones, we do not consider them in this article.

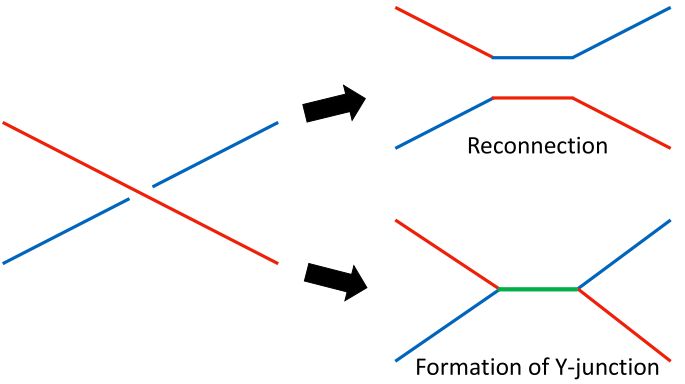

Fig. 2. Reconnection process and formation of a Y-junction.

4. Superconductivity and Y-junction formation

In the EW axion string presented above, the W^1-flux is confined, and the $U(1)_{\rm EM}$ symmetry is broken by the charged Higgs components and the W^1 gauge field, which means that there exists a zero mode (massless excitation) propagating on the string with the speed of light. It can carry an electric current without resistance, resulting in a superconducting current. We will show that such a current changes the interaction between the strings and can lead to formations of the Y-junctions in the early universe.

Firstly, let us assume the presence of a primordial magnetic field (PMF) in the universe after the electroweak phase transition. There are the observational lower and upper bounds on the present strength of intergalactic magnetic fields for a coherent length $\lambda \gtrsim 0.1\,\mathrm{Mpc}$ as $3 \times 10^{-16}\,\mathrm{G} \lesssim B_0 \lesssim 10^{-11}\,\mathrm{G}$, given by Refs. 27, 28. For simplicity, we further assume that the power spectrum of PMF is scale invariant and almost coherent over the entire Hubble horizon.

We then show that PMF can induce large superconducting currents on the strings. Such large currents are sufficient to form the Y-junctions. The scale invariant PMF evolves as

$$B(t) \propto a(t)^{-2}\,, \tag{15}$$

where $B(t)$ and $a(t)$ are the magnetic field strength and the scale factor at the cosmological time t, respectively. It is convenient to define a ratio of the energy density of PMF (ρ_B) to that of photon (ρ_γ),

$$\epsilon \equiv \frac{\rho_B}{\rho_\gamma} \sim B(t)^2 G_N t^2, \tag{16}$$

with G_N being the Newton constant. The ratio ϵ is a constant as the universe expands. If we take the upper limit on B_0, we have $\epsilon \sim 10^{-11}$.

In the early universe, the superconducting strings move with velocity $v_{\rm str}$ ($\sim \mathcal{O}(1)$) in the presence of PMF, and hence feel the electric fields $E \sim B(t) v_{\rm str}$, which

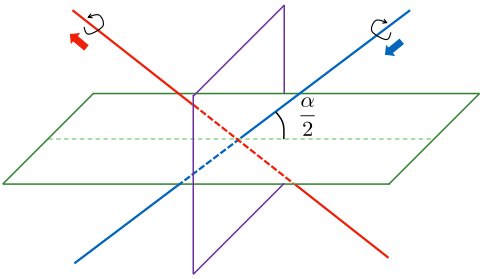

Fig. 3. Two strings (red and blue lines) collide with the crossing angle α. The black arrows indicate the directions of the topological winding number of $U(1)_{\rm PQ}$. The red and blue arrows indicate the directions of the flowing electric currents, which are parallel for $\alpha = 0$. The green and purple planes are orthogonal and include the collision point.

induce the superconducting current,

$$J_{\rm PMF} \sim e^2 B(t) \xi v_{\rm str}\,, \tag{17}$$

with ξ being a string typical length. Since there are no superconducting strings before the electroweak phase transition, we can assume that the scaling property $\xi \sim t$ holds at least just after the phase transition, and obtain

$$J_{\rm PMF} \sim 10^{12} \left(\frac{\epsilon}{10^{-11}}\right)^{1/2} {\rm GeV} \sim 10^{12} \left(\frac{B_0}{10^{-11}\,{\rm G}}\right) {\rm GeV}\,. \tag{18}$$

Note that this is independent of t. For the upper limit of B_0, yielding $\epsilon \sim 10^{-11}$, the induced current Eq. (18) is $\sim 10^{12}\,{\rm GeV}$. On the other hand, it is shown[14] that the EW axion string can carry an electric current at most $J_{\rm max} \simeq v_s/e$ with e the $U(1)_{\rm EM}$ coupling constant. Thus the current saturates at this value for $v_s \simeq 10^{9-12}\,{\rm GeV}$. In the following argument, we use this maximum current as those the strings carry in the early universe.

Let us discuss the formation of Y-junctions. They can be formed by collisions of two superconducting strings when they feel an attractive force and are trapped in the potential. We suppose that the two strings collide with the crossing angle α and that they are identical and parallel for $\alpha = 0$. The superconducting currents are assumed to flow in the same direction for $\alpha = 0$ (the opposite case will be considered later). The three-dimensional dynamics of the collision event is rather complicated and difficult to analyze. However a qualitative picture can be understood by reducing it on two orthogonal planes including the colliding point[29–31] (see Fig. 3). On one of them (purple plane in Fig. 3), the situation is regarded as a collision (scattering) event of two point-like vortices in two dimensions while, on the other plane (green plane in Fig. 3), as a vortex-antivortex collision resulting in the annihilation in two dimensions. Note that this picture reproduces the reconnection process shown in the upper-right picture in Fig. 2 when the strings have no superconducting current; two scattered vortices on the purple plane and nothing on the green one.

We concentrate on the two-dimensional analysis of the superconducting vortex-vortex collision since the current does not change the annihilation. Unlike the non-superconducting case leading to the 90° scattering, the long-range magnetic interaction plays a crucial role in our case. On the reduced plane, the vortex-vortex pair feel a net interaction potential,

$$V \sim \frac{v_s^2}{e^2} \cos\frac{\alpha}{2} \log r \,, \tag{19}$$

where r is the distance between the two vortices and we have ignored the axion-mediated repulsive interaction, which should be subleading by a factor e^2 compared to Eq. (19). If the vortices do not have sufficient kinetic energy to escape to infinity, they become trapped by the potential. Thus we obtain a condition to form a bound state,

$$\frac{v_s^2}{e^2} \cos\frac{\alpha}{2} \log\frac{L}{\delta} \geq (\gamma - 1)\mu \,, \tag{20}$$

where γ and μ are the Lorentz factor and the tension of the colliding vortices. L and δ are the IR and UV cutoff for the potential, which we take as the Hubble radius and the width of the strings, respectively. As considering just after the electroweak phase transition, the logarithmic factor gives $\log(10^{17} \times v_s/v_{\rm EW}) \sim 50$. In addition, we take a mildly relativistic velocity ~ 0.6 for the vortices, yielding $\gamma \sim 1.25$, and thus Eq. (20) gives

$$\cos\frac{\alpha}{2} \geq 10^{-3} \,, \tag{21}$$

which means that they *almost always* form the bound state except for $\alpha \simeq \pi$.

On the other hand, they cannot form such a bound state in the case that the currents flow in the opposite directions (anti-parallel) on the vortex-vortex plane because they always feel a repulsive force. Therefore, we obtain a rough estimation for the formation probability of the bound state,

$$\begin{cases} \text{Y-junction formed for current in the same directions} \\ \text{not formed for current in the opposite directions} \end{cases}$$
$$\Rightarrow \text{probability} \simeq \frac{1}{2} \,. \tag{22}$$

Note that this is based on the two-dimensional analysis focusing on the collision point. This picture may break down for the case that the dynamics after colliding is dominated by other parts of the strings than the collision point. Furthermore, the formed Y-junction could be peeled off, depending on the velocities and the crossing angle of the strings. For a more detailed study including these effects, it is necessary to perform a three-dimensional simulation, which is beyond the scope of the present paper.

Finally, we discuss a consequence of the formation of Y-junctions. When a superconducting string intersects with itself, it forms the Y-junction with probability 1/2,

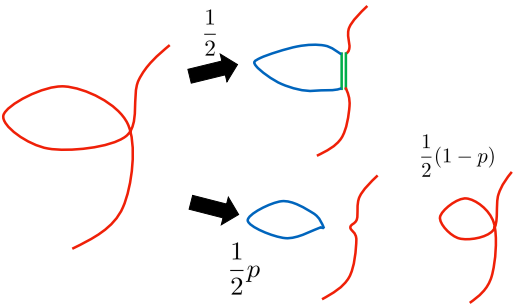

Fig. 4. Self-intersection of a superconducting string. The Y-junction (green doubled line) is formed with probability $\frac{1}{2}$. Otherwise, it reconnects producing a small loop (blue line) or passes through. The reconnection probability is $p \sim 1$.

produces a small loop with probability $p/2$, or passes through with probability $(1-p)/2$ (see Fig. 4), where p is the reconnection probability without the current ($p \sim 1$). If such a Y-junction-connected loop (upper one in Fig. 4) is produced, it is not obvious whether the strings sufficiently loose their energy, and the scaling behavior of the energy density of strings is not ensured. Once the energy density of the universe is dominated by such superconducting strings, it causes large impacts on cosmology, and hence some parameter region in the DFSZ axion model may be constrained.

5. Conclusion

We have studied the axion strings with the electroweak gauge flux, and their superconductivity in the DFSZ model. The superconducting current is induced by PMF in the early universe, and a large electric current can flow along the string. This large current may realize a net attractive force between the axion strings, which could form the so-called Y-junctions in the early universe. By considering the string collision reduced onto two-dimensional planes, the probability of the formation of the Y-junctions is estimated to be $\sim 1/2$.

Once such Y-junctions are formed, they can affect the evolution of the string network and make non-trivial whether the network evolves to the scaling solution. If no obeying the scaling behavior, the string network could dominate the energy density of the the universe and the model is severely constrained. To conclude whether this is true or not, we need detailed numerical simulations on the time evolution of the network taking into account both the axionic and magnetic interactions.

Hints for the $H_0 - r_d$ tension in uncorrelated Baryon Acoustic Oscillations dataset

Denitsa Staicova

Institute for Nuclear Research and Nuclear Energy, Bulgarian Academy of Sciences, Sofia, Bulgaria
E-mail: dstaicova@inrne.bas.bg

Baryon Acoustic Oscillations (BAO) datasets use very precise measurements of the spatial distribution of large-scale structures as a distance ladder to help constrain cosmological parameters. In a recent article,[1] we combined 17 uncorrelated BAO measurements in the effective redshift range $0.106 \leq z \leq 2.36$ with the Cosmic Chronometers data, the Pantheon Type Ia supernova and the Hubble Diagram of Gamma Ray Bursts and Quasars to obtain that the ΛCDM model fit infers for the Hubble constant: $69.85 \pm 1.27 km/sec/Mpc$ and for the sound horizon distance: $146.1 \pm 2.15 Mpc$. Beyond the ΛCDM model we test Ω_kCDM and wCDM and we get $\Omega_k = -0.076 \pm 0.012$, $w = -0.989 \pm 0.049$ accordingly. In this proceeding we present elaborate on our findings and we compare them to other recent results in the literature.

Keywords: Baryon Acoustic Oscillations, Dark Energy, Dark Matter, Large Scale Structure, Hubble Tension

1. Introduction

The $\sim 4\sigma$ tension between the Hubble parameter measured by late universe observations by the SH0ES collaboration[2] and the one measured from the cosmic microwave background (CMB) by the Planck Collaboration[3] is one of the major stumbling block in front of modern cosmology and the theories aiming to explain the evolution of the Universe.[4–22] The default ΛCDM model which uses a combination between cold dark matter and dark energy components has been shown to fit remarkably well current astronomical observations yet it fails to explain not only the beginning of the universe (the inflationary epoch) but also the Hubble tension and the related σ_8 tension.

In a recent article[1] we selected 17 uncorrelated BAO points from the largest collection of BAO data points (333 points). We then combined them with the Cosmic Chronometers data, the Pantheon Type Ia supernova, and the Hubble Diagram of Gamma-Ray Bursts and Quasars. From this combination of datasets, referred in the article sometimes as the *full* dataset, we found: the Hubble constant yields $69.85 \pm 1.27 km/sec/Mpc$, the sound horizon distance is $146.1 \pm 2.15 Mpc$ and the matter energy density – $\Omega_m = 0.271 \pm 0.016$. If one uses the so called *Riess prior* (denoted here as R19) to constrain H_0 by the model-independent local universe measurement,[2] one gets: $H_0 = 71.40 \pm 0.89$, $r_d = 143.5 \pm 2.0$ and $\Omega_m = 0.267 \pm 0.017$. Beyond the ΛCDM model we test Ω_KCDM and wCDM. The spatial curvature is

$\Omega_k = -0.076 \pm 0.012$ and the dark energy equation of states is $w = -0.989 \pm 0.049$. In this proceeding we discuss how our results are situated regarding other published results by emphasizing on the need to consider the H_0-tension in the context of the $H_0 - r_d$ plane or even of the $H_0 - r_d - \Omega_m$ plane.

2. Overview of the used datasets

The Baryon acoustic oscillations (BAO) are fluctuations in the photon-baryonic plasma that froze at recombination at the so called drag sound horizon. Because the sound horizon can be calculated rather simply from basic assumptions of the pre-recombination plasma, they provide a standard ruler which can be seen in the clustering of large scale structures. This provides an independent way to probe cosmological parameters, complimentary to this of the Supernova and the CMB surveys, see.[23–25] The BAO peak can be measured from objects with different nature and using different methods. For example: the BOSS experiment measures the clustering of different galaxies: emission-line galaxies (ELGs), luminous red galaxies (LRGs), and quasars, and also from the correlation function of the Lyman-alpha (Lyα) absorption lines in the spectra of distant quasars etc. The peak can be seen on different redshifts, providing us with a standard ruler evolving with the Universe since the recombination epoch.[26,27]

The final dataset we use is a set of uncorrelated data points from different **BAO** measurements: the Sloan Digital Sky Survey (SDSS), the WiggleZ Dark Energy Survey, Dark Energy Camera Legacy Survey (DECaLS), the Dark Energy Survey (DES), the 6dF Galaxy Survey (6dFGS).[28–43] To this dataset, we add **cosmic chronometers (CCs)** (30 uncorrelated CC measurements of $H(z)$[44–47]), and **standard candles (SCs)** (the Pantheon Type Ia supernova dataset[48–51]), and quasars[52] and gamma-ray bursts[53] (186 points).

3. Theoretical background

We use the following theoretical setup. If one assumes a Friedmann-Lemaître-Robertson-Walker metric with the scale parameter $a = 1/(1+z)$, where z is the redshift, one gets for the Friedmann equation for the ΛCDM model:

$$E(z)^2 = \Omega_r(1+z)^4 + \Omega_m(1+z)^3 + \Omega_k(1+z)^2 + \Omega_\Lambda, \tag{1}$$

where Ω_r, Ω_m, Ω_Λ, and Ω_k are respectively the fractional densities of radiation, matter, dark energy, and the spatial curvature at redshift $z = 0$. Here $E(z) = H(z)/H_0$, and $H(z) = \dot{a}/a$ is the Hubble parameter at z, while H_0 is the Hubble parameter today. The radiation density can be computed as $\Omega_r = 1 - \Omega_m - \Omega_\Lambda - \Omega_k$. For wCDM the Friedmann equation is generalized to $\Omega_\Lambda \to \Omega^0_{DE}(1+z)^{-3(1+w)}$, while $\Omega_k = 0$ represents a flat universe.

Since in cosmology one deals with the measurements of angles and redshifts, it is needed to connect the different cosmological distances with the observational

quantities. The comoving angular diameter distance:[54,55]

$$D_M = \frac{c}{H_0} S_k \left(\int_0^z \frac{dz'}{E(z')} \right), \tag{2}$$

where one accounts for non-zero spatial curvature with:

$$S_k(x) = \begin{cases} \frac{1}{\sqrt{\Omega_k}} \sinh\left(\sqrt{\Omega_k} x\right) & \text{if} \quad \Omega_k > 0 \\ x & \text{if} \quad \Omega_k = 0 \\ \frac{1}{\sqrt{-\Omega_k}} \sin\left(\sqrt{-\Omega_k} x\right) & \text{if} \quad \Omega_k < 0 \end{cases}. \tag{3}$$

The other distances we use are the Hubble distance $D_H(z) = c/H(z)$, the angular diameter distance $D_A = D_M/(1+z)$ and the volume averaged distance:

$$D_V(z) \equiv [z D_H(z) D_M^2(z)]^{1/3}. \tag{4}$$

As said before the BAO use as a standard ruler depends only on the sound horizon r_d at the drag epoch ($z_d \approx 1060$) when photons and baryons decouple:

$$r_d = \int_{z_d}^{\infty} \frac{c_s(z)}{H(z)} dz, \tag{5}$$

where $c_s \approx c\,(3 + 9\rho_b/(4\rho_\gamma))^{-0.5}$ is the speed of sound in the baryon-photon fluid with the baryon $\rho_b(z)$ and the photon $\rho_\gamma(z)$ densities, respectively.[56] One needs to acknowledge that since the actual measured quantities are the projections $\Delta z = r_d H/c$ and $\Delta\theta = r_d/(1+z)D_A(z)$, where Δz and $\Delta\theta$ are the redshift and the angular separation, from BAO one can get information only about the quantity $r_d \times H$. Thus in order to decouple these quantities, one needs some kind of independent measurement of H_0 or an assumption for r_d. Here we take r_d as an independent parameter but use the additional datasets (CC+SC) to decouple the two variables. In a recent paper,[57] we instead use the combination $r_d \times H_0$ as a parameter to break the degeneracy.

4. Numerical methods

To deal with the possible correlations in the BAO dataset, we perform a covariance analysis based on the one proposed in Ref.[58]. We transform the standard covariance matrix for uncorrelated points C_{ii} into C_{ij} as follows:

$$C_{ii} = \sigma_i^2 \quad \longrightarrow \quad C_{ij} = \sigma_i^2 + 0.5\sigma_i\sigma_j \tag{6}$$

by adding randomly certain number of nondiagonal elements while keeping it symmetric. Here $\sigma_i\sigma_j$ are the published 1σ errors of the data points i, j. With this approach we show that the effect of up to 25% random correlations with this magnitude results in less than 10% deviation in the final results, thus it is minimal and the points can be considered uncorrelated.

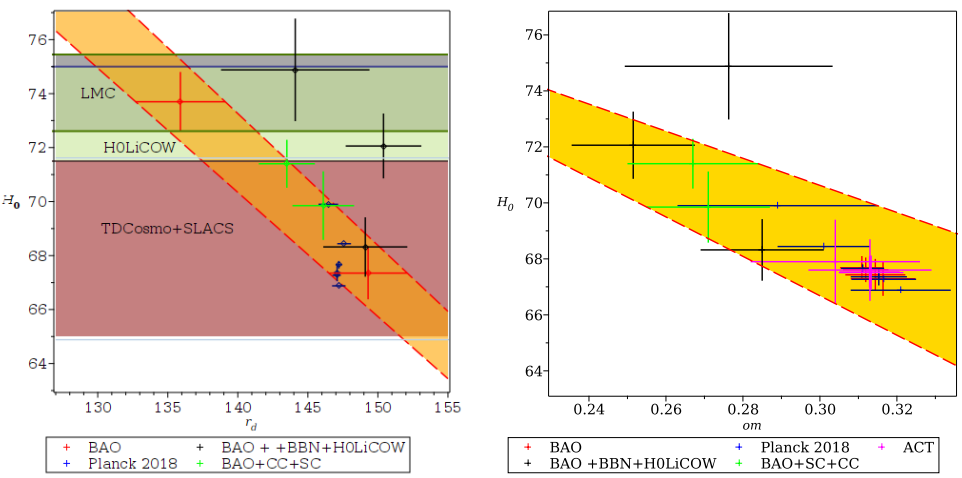
We use a nested sampler as implemented within the open-source package *Polychord*[59] with the *GetDist* package[60] to present the results. The priors we use

to obtain the results and the averaged mean values across the 3 models (ΛCDM, wCDM, Ω_kCDM) can be found in Table A1.

5. Comparison with other results

The complete numerical results for the three models and the three datasets (BAO+R19, BAO+SC+CC, BAO+SC+CC+R19) can be found in Table 3 in.[1] In this article we will focus on comparing our results with other works, by using only the *full* datasets with and without the R19 prior, referred to as BAO+SC+CC+R19 and BAO+SC+CC.

Specifically, on Fig. 1, we use some known measurements in the $H_0 - r_d$ and $H_0 - \Omega_m$ plane. It has been discussed in a number of papers, more notably,[61] that the H_0-tension is actually extended to a tension with respect to the main parameters H_0, r_d and Ω_m, since increasing Ω_m to reduce r_d leads to the opposite to the desired effect on H_0. To demonstrate this, we have plotted the following points: TDCosmo IV,[62] H0LiCOW XIII,[63] LMC Cepheids,[2] Planck 2018,[3] eBOSS SDSS-IV,[64] BAO +BBN+H0LiCOW and BAO +BBN+CC,[65] all listed for convenience in Table A2. Note, some references do not measure r_d, others omit mentioning Ω_m.



(a) (b)

Fig. 1. (a) $H_0 - r_d$ plane comparison of different results. (b) $H_0 - \Omega_m$ plane comparision. Our points are with green, for legend see the text.

On Fig. 1(a) we consider only $H_0 - r_d$ and we see that our results (in green) fit nicely between the results of the pure BAO points by eBOSS (in red) and the Planck 2018 points (in blue).

On this plot, the points we obtain with the R19 prior (top green point) are very close to the local universe measurements (LMC), while the points we obtain with

a uniform prior (the lower green point) are close to the early universe (i.e. Planck 2018 with bue). The numbers we obtain are surprisingly close to a measurement of the Tip of the Red Giants Branch $H_0 = 69.8 \pm 1.9(km/s)/Mpc$[66] — an independent measurement based on the distances to nearby galaxies (in this case based on TRGB stars in the Large Magellanic Cloud, grounded on detached eclipsing binaries).

As for r_d, we see that our points without the R19 prior are again close to the Planck measurement (Planck 2018 $r_d = 147.09 \pm 0.26Mpc$, ours: $r_d = 146.1 \pm 2.2Mpc$). The final measurements from the completed SDSS lineage of experiments in large-scale structure provide $r_d = 149.3 \pm 2.8Mpc$.[67] Using BAO, SNea, the ages of early-type galaxies, and local determinations of the Hubble constant, Ref.[68] reports $r_d = 143.9 \pm 3.1$ Mpc. Thus, one can see clearly the tension between different results from the early and late universe confirming the "tensions in the $r_d - H_0$ plane."[61] The model with the R19 prior gives $r_d = 143.5 \pm 2.0Mpc$. Importantly, the choice of a prior for r_d has a critical effect on H_0 decreasing or increasing the inferred value to a large extend independently of the prior on H_0.

Another part of the $H_0 - r_d$ puzzle is the effect of the matter energy density Ω_m. A comparison of different results for Ω_m can be seen on Fig. 1(b), where we have plotted the $H_0 - \Omega_m$ plane. Note that the eBOSS points used here are different from the ones used in Table 2, as we use different set of published points (Table 4 in Ref.[64]). Also, we add the points by ACT which can be found in Table 4 in Ref.[69]. Our points are once again in green and as we can see they fit very close to Plancks's results in blue which come with very small error on H_0 but rather large on Ω_m ($\Omega_m^{Planck} = .289, 0 \pm 0.03$). In our case, the matter density is lower than the expected. One can also note that removing the top right point (belonging to BAO +BBN+H0LiCOW, see Table 2) will make the points along with the error bars to lie on approximately one plane, similar to the one in the $H_0 - r_d$ plane and thus hinting at possible degeneracy (in orange and yellow respectively). This has been commented already in[61] and is related to the fact we do not know how exactly the phase space of all parameters looks like. The tension for $H_0 - r_d - \Omega_m$ appears in different measurements (Planck, BAO, ACT etc), some from the early Universe, others from the late one and the independent local measurements. This once again poses the question whether we need to consider the full parameter space when discussing the tension.

Finally, we would like to discuss the results we obtained about the spacial curvature energy density. As already mentioned we get $\Omega_k = -0.076 \pm 0.012$ which excludes flat universe at 68% CL and points to a closed Universe ($k = 1$). Due to the rather small prior used to obtain this number, we now repeat the inference with a larger prior $\Omega_k \in [-0.3, 0.3]$. The results can be seen on Fig. 2. Once again, when calculating for the full dataset with or without the R19 prior, we obtain values excluding flat universe. This has been reported already, for example by the Planck 2018 collaboration[3] for CMB alone which found a preference for a closed universe at 3.4σ. Also,[70] using the CC, Pantheon, and BAO measurements concluded that negative Ω_k also relieves the H_0 tension.

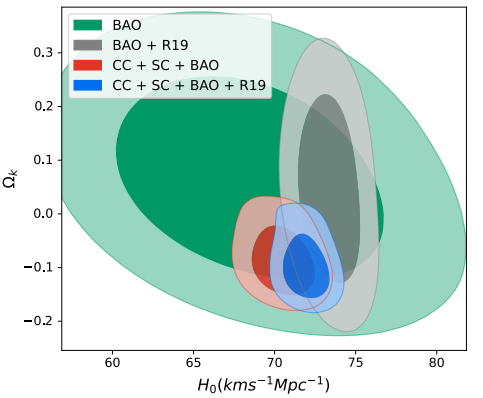


Fig. 2. 2d contour plot of Ω_k vs H_0 for the datasets BAO, BAO + R19, CC+SC+BAO and CC+SC+BAO+R19.

The issue of a possibility for a deviation from a flat Universe is extremely important and has been discussed in a number of works. On Fig. 3, we plot some of the published in the literature results with respect to Ω_k. The reference for the results are accordingly ($N = 1..12$) data from: Planck18Plk, Planck18CamSpec, ACT+WMAP, ACT+Planck, CC+Quasars,CC+SN, BAO+BBN+H0LiCOW, BAO+BBN+CC, taken from[71] to which we add the values we measured with the following dataset: BAO+R19, BAO+CC+SC (same as BAO+CC+SC+R19) and the extended prior points: BAO+CC+SCl, BAO+CC+SC+R19l. One can see that our results seem to add to a mounting evidence that maybe we observe an effect related to a non-flat universe.

The results for the full dataset for the extended prior can be seen in Table A3. We see now that the reported earlier in Ref.[1] lower matter energy density is no longer an issue as we get $\Omega_m \sim 0.326$, also we see that now H_0 is a bit larger, thus pointing to further alleviation of the H_0-tension due to a non-zero spatial curvature. Critically, we see that again $\Omega_k = 0$ is excluded from the 68% CL for both models. Thus we can claim this effect persists with the increase of the prior and it is a feature of the dataset.

On a side note, we mention the result we obtained in Ref.[1] with respect to the wCDM model. For BAO + R19 we get $w < -1$ for ($w = -1.067 \pm 0.065$), while the full datasets seem to tend to $w \geq -1$ ($w = -0.989 \pm 0.049$). Since $w = -1$ is included in the error, the results are essentially consistent with a cosmological constant.

To compare the extended models to ΛCDM we used well known statistical measures, i.e. the Akaike information criteria (AIC)[72–74,a]. We find that the ΛCDM

[a]The definition of AIC we use is $AIC = \chi^2_{min} + 2p$, where p is the number of parameters of the model.

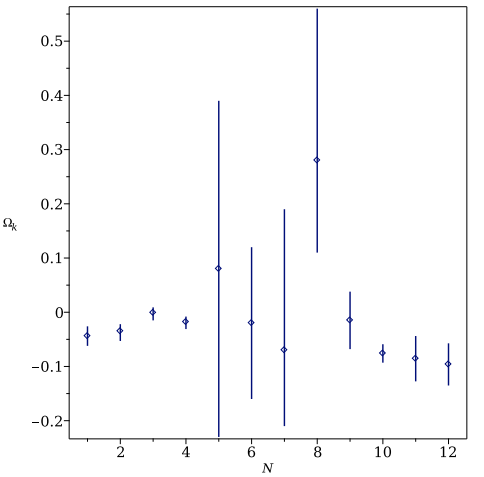

Fig. 3. Comparison of different measurements of Ω_k, see legend in text. Our points are $N = 9-12$, where points with $N = 11, 12$ are with larger prior for Ω_k.

model remains the best fit to the data with difference of 2.3 and 7.6 AIC units for the wCDM and the Ω_kCDM respectively. One can see that wCDM has a little bit more support than Ω_kCDM but also as we mentioned, $w = -1$ enters into the the 68% CL of w for the full dataset which may explain its closeness to ΛCDM in terms of AIC. Our results are consistent with the eBoss collaboration official results.[67] Interestingly, we see that in our case $w \geq -1$ for the full dataset, which differs from the estimations in some of the different cases considered in.[67] Our dataset differs from theirs by the inclusion of the quasars and the GRB data and the exclusion of Planck points, so this may point to a local universe effect.

6. Conclusion

We use a set of 17 uncorrelated BAO points to infer the cosmological parameters for 3 different models: ΛCDM, Ω_kCDM and wCDM. We find that by choosing the sound horizon at drag epoch as an independent parameter and adding additional datasets such as SNe, GRB and quasars, we are able to break the degeneracy between H_0 and r_d and to constrain the cosmological parameters for the different models. The Hubble parameter obtained from the full dataset is very close to the TGRB measurement, while the one with a R19 prior is close to the local universe measurement. We show that we are able to alleviate the H_0-tension to certain degree but not entirely. Another interesting result is the prediction of a non-flat but closed Universe at 68 % CL, which has been confirmed with an increased prior and seems to add to the mounting evidences there may be a deviation from flatness.

We present a phenomenological analysis of current observational constraints on classes of FLRW cosmological models in which the matter side of Einstein's equations includes, in addition to the canonical term, a term proportional to some function of the energy-momentum tensor ($T^2 = T_{\alpha\beta}T^{\alpha\beta} = \rho^2 + 3p^2$), or of its trace ($T = \rho - 3p$). Qualitatively, one may think of these models as extensions of general relativity with a nonlinear matter Lagrangian. As such they are somewhat different from the usual dynamical dark energy or modified gravity models: in the former class of models one adds further dynamical degrees of freedom to the Lagrangian (often in the form of scalar fields), while in the latter the gravitational part of the Lagrangian is changed. We study both of these models under two different scenarios: (1) as phenomenological two-parameter or three-parameter extensions of the standard ΛCDM, in which case the model still has a cosmological constant but the nonlinear matter Lagrangian leads to additional terms in Einstein's equations, which cosmological observations tightly constrain, and (2) as alternatives to ΛCDM, where there is no cosmological constant, and the nonlinear matter term would have to provide the acceleration (which would be somewhat closer in spirit to the usual modified gravity models). A comparative analysis of the observational constraints obtained in the various cases provides some insight on the level of robustness of the Λ model and on the parameter space still available for phenomenological alternatives.

Keywords: Cosmology; Dark energy; Modified gravity; Observational constraints.

1. Introduction

The observational evidence for the acceleration of the universe shows that our canonical theories of cosmology and particle physics are at least incomplete, and possibly incorrect. Mapping the dark side of the universe, in order to ascertain the physical mechanism behind this acceleration, in a compelling observational task for current and future facilities. The CosmoESPRESSO team uses the universe as a laboratory to address, with precision spectroscopy and other observational, computational and theoretical tools, this and other grand-challenge questions. In what follows we highlight recent contributions of the CosmoESPRESSO team to this fundamental quest, pertaining to dark energy phenomenology.

There has been some recent interest in the so-called energy-momentum-squared gravity models,[1] where the matter part of Einstein's equations is modified by the addition of a term proportional to $T^2 \equiv T_{\mu\nu}T^{\mu\nu}$, where $T_{\mu\nu}$ is the energy-momentum tensor. This we later extended[2,3] to the more generic form $(T^2)^n$, dubbed energy-momentum-powered gravity. Reference 4 provided low redshift constraints on these models, using in particular the Pantheon Type Ia supernova compilation[5] and a compilation of 38 Hubble parameter measurements.[6]

In practical terms, we may think of these models as extensions to the canonical ΛCDM, in which case the model still has a cosmological constant but the nonlinear matter Lagrangian leads to additional terms in Einstein's equations, and cosmological observations can constrain these additional model parameters. Typically there are two such additional parameters: the power n of the nonlinear part of the Lagrangian and a further parameter (to be defined below) quantifying the contribution of this term to the energy budget of the universe.

Alternatively, we may ask whether a suitably chosen nonlinear Lagrangian can reproduce the low redshift acceleration of the universe in a model which at low redshift only contains matter (plus a subdominant amount of radiation) but no true cosmological constant. In principle such a scenario is conceivable.[1] It is also somewhat closer in spirit to the usual modified gravity models—with the caveat that, as previously mentioned, in the latter models the modification occurs in the gravitational part of the Lagrangian and not in the matter part.

The analysis of Ref. 4 found that these models do not solve the cosmological constant problem *per se*, but they can phenomenologically lead to a recent accelerating universe without a cosmological constant at the cost of having preferred values of the cosmological parameters that are somewhat different from the standard ΛCDM ones. Here we revisit and update these constraints, and also provide new constraints on models where the new terms depend on the trace of the energy-momentum tensor, $T = \rho - 3p$. As before, we can consider both the scenario with a cosmological constant (in which case the model is an extension of ΛCDM) and the scenario without a cosmological constant (in which case we can check whether such models can accelerate at all). These have been qualitatively studied in the literature,[7,8] and in what follows we provided quantitative constraints on them. We note that in all the analysis that follows the Hubble constant is analytically marginalized as discussed in Ref. 9.

2. Energy-momentum-powered models

The general action for these models is[2]

$$S = \frac{1}{2\kappa}\int \left[R + \eta(T^2)^n - 2\Lambda\right] d^4x + S_{matter}\,, \tag{1}$$

where $\kappa = 8\pi G$, and η is a constant quantifying the contribution of the T^2-dependent term. In a flat Friedmann-Lemaitre-Robertson-Walker universe and assuming a perfect fluid we have $T^2 = \rho^2 + 3p^2$ and the generalized Friedmann and

Raychaudhuri equations and the corresponding continuity equation can be written

$$3\left(\frac{\dot{a}}{a}\right)^2 = \Lambda + \kappa\rho + \eta(\rho^2+3p^2)^{n-1}\left[\left(n-\frac{1}{2}\right)(\rho^2+3p^2)+4np\rho\right] \tag{2}$$

$$6\frac{\ddot{a}}{a} = 2\Lambda - \kappa(\rho+3p) - \eta(\rho^2+3p^2)^{n-1}\left[(n+1)(\rho^2+3p^2)+4np\rho\right] \tag{3}$$

$$\dot{\rho} = -3\frac{\dot{a}}{a}(\rho+p)\frac{\kappa\rho + n\eta\rho(\rho+3p)(\rho^2+3p^2)^{n-1}}{\kappa\rho + 2n\eta(\rho^2+3p^2)^{n-1}\left[\left(n-\frac{1}{2}\right)(\rho^2+3p^2)+4np\rho\right]}. \tag{4}$$

As usual, the Bianchi identity implies that only two of these equations are independent.

If we consider the low redshift limit of these models, further assuming that the universe is composed of matter and possibly also a cosmological constant, we can simplify the Einstein equations to

$$3\left(\frac{\dot{a}}{a}\right)^2 = \Lambda + \kappa\rho + \left(n-\frac{1}{2}\right)\eta\rho^{2n} \tag{5}$$

$$6\frac{\ddot{a}}{a} = 2\Lambda - \kappa\rho - (n+1)\eta\rho^{2n} \tag{6}$$

$$\dot{\rho} = -3\frac{\dot{a}}{a}\rho\frac{\kappa + n\eta\rho^{2n-1}}{\kappa + (2n-1)n\eta\rho^{2n-1}}\,. \tag{7}$$

Broadly speaking, we inspection of the equations leads to the expectation that $n < 1/2$ may be interesting at late times. In general these equations need to be solved numerically. However, there are three particular cases for which analytic solutions can be found (at least approximate, low redshift solutions), corresponding to the values $n = 1$, $n = 1/2$ and $n = 0$ (the latter actually corresponds to the ΛCDM case). These have been studied in the literature, in a general mathematical context,[1,2,10] and also observationally constrained in Ref. 4.

Generically we can treat n as a further model parameter, to be constrained by observations. In order to do this we define a dimensionless cosmological density r, via $\rho = r\rho_0$, where ρ_0 is the present day density, as well as a generic parameter

$$Q = \frac{\eta}{\kappa}\rho_0^{2n-1}\,. \tag{8}$$

With these assumptions, and keeping for the time being the matter assumption, the continuity equation expressed in terms of redshift has the form

$$\frac{dr}{dz} = \frac{3r}{1+z}\times\frac{1+nQr^{2n-1}}{1+(2n-1)nQr^{2n-1}}\,; \tag{9}$$

$$E^2(z) = \frac{H^2(z)}{H_0^2} = \Omega_\Lambda + \Omega_M r + \left(n-\frac{1}{2}\right)Q\Omega_M r^{2n}\,, \tag{10}$$

where, since we must have $E(0) = 1$, the model parameters are related by the requirement that $\Omega_\Lambda = 1-\Omega_M[1+(n-1/2)Q]$, and therefore the Friedmann can be

recast in the two alternative forms

$$E^2(z) = \Omega_\Lambda + \Omega_M r + (1 - \Omega_M - \Omega_\Lambda) r^{2n} \tag{11}$$

$$E^2(z) = 1 + \Omega_M (r - 1) + \left(n - \frac{1}{2}\right) Q \Omega_M (r^{2n} - 1)\,, \tag{12}$$

the first one is generic, while the second applies only if $\Omega_\Lambda \neq 0$. On the other hand, if $\Omega_\Lambda = 0$ we can also use the flatness assumption to eliminate Q in the continuity equation, writing it as

$$\frac{dr}{dz} = \frac{3r}{1+z} \times \frac{(2n-1)\Omega_M + 2n(1-\Omega_M) r^{2n-1}}{(2n-1)[\Omega_M + 2n(1-\Omega_M) r^{2n-1}]}\,. \tag{13}$$

This shows that in a phenomenological sense these models could explain the recent acceleration of the universe without invoking a cosmological constant but relying instead on the nonlinearities of the matter Lagrangian in a matter-only universe with $n = 0$. However, we note that even if these models can lead to accelerating universes without a cosmological constant, this is not per se sufficient to solve the 'old' cosmological constant problem of why it should be zero. For n close to but not equal two zero, two things happen: the (formerly) constant term in the Friedmann equation becomes slowly varying, and the continuity equation implies that the matter density does not behave exactly as $r \propto (1+z)^3$. In what follows we discuss the extent to which deviations from the $n = 0$ case are observationally allowed, and also the most general parameter space where a standard cosmological constant is also allowed.

We can also consider a generalization: instead of considering a universe with a matter fluid, we can assume that this fluid has a constant equation of state $w = p/\rho = const.$ (with the matter case corresponding to $w = 0$). In this case the continuity equation becomes

$$\frac{dr}{dz} = \frac{3r}{1+z}(1+w) \times \frac{1 + nQ f_1(n,w) r^{2n-1}}{1 + 2nQ f_2(n,w) r^{2n-1}}\,, \tag{14}$$

where for convenience we defined

$$f_1(n,w) = (1+3w)(1+3w^2)^{n-1} \tag{15}$$

$$f_2(n,w) = (1+3w^2)^{n-1} \left[\left(n - \frac{1}{2}\right)(1+3w^2) + 4nw\right]\,. \tag{16}$$

In this case the Friedmann equation can be written

$$E^2(z) = \Omega_\Lambda + \Omega_M r + f_2(n,w) Q \Omega_M r^{2n}\,, \tag{17}$$

together with the consistency relation $\Omega_\Lambda = 1 - \Omega_M[1 + f_2 Q]$. It follows that we can also re-write it as

$$E^2(z) = \Omega_\Lambda + \Omega_M r + (1 - \Omega_M - \Omega_\Lambda) r^{2n} \tag{18}$$

$$E^2(z) = 1 + \Omega_M (r - 1) + f_2(n,w) Q \Omega_M (r^{2n} - 1)\,, \tag{19}$$

where again the first is generic—and indeed identical to Eq. (11), although the redshift dependence of r will now be different—while the second holds for $\Omega_\Lambda \neq 0$. Here, if $\Omega_\Lambda = 0$ the continuity equation can also be written in a way that eliminates the parameter Q,

$$\frac{dr}{dz} = \frac{3r}{1+z}(1+w) \times \frac{\Omega_M f_2 + n(1-\Omega_M) f_1 r^{2n-1}}{f_2[\Omega_M + 2n(1-\Omega_M) r^{2n-1}]} \,. \tag{20}$$

Table 1. One sigma posterior likelihoods on the power n, the matter density Ω_M and the constant equation of state w (when applicable) for various flat energy-momentum-powered models containing matter, with or without a cosmological constant. The last column lists the reduced chi-square for each best-fit model.

Model assumptions	Ω_M	n	w	χ^2_ν
$\Omega_\Lambda = 0$, $w = 0$	0.39 ± 0.08	0.04 ± 0.04	N/A	0.64
$\Omega_\Lambda \neq 0$, $w = 0$	$0.29^{+0.05}_{-0.03}$	Unconstrained	N/A	0.64
$\Omega_\Lambda = 0$, $w = const.$	$0.28^{+0.12}_{-0.10}$	$-0.08^{+0.06}_{-0.02}$	$-0.11^{+0.07}_{-0.04}$	0.62

Note: The specific assumptions for each case are described in the main text. The constraints come from the combination of the Pantheon supernova data and Hubble parameter measurements.

3. Constraints on energy-momentum-powered models

In what follows we briefly summarize constraints on the generic energy-momentum-powered models, revising and updating the analysis in Ref. 4. We carry out a standard likelihood analysis, using the datasets already mentioned in the introduction, and separately considering three different theoretical scenarios within this class of models. An overview of the results can be found in Table 1.

The constraints for the $\Omega_\Lambda = 0$ matter case are summarized in the top panel pf Fig. 1 and also in the first row of Table 1. As expected given the form of the Friedmann and continuity equations, there is a clear degeneracy between the two parameters. The best-fit values are about one standard deviation away from the canonical values $n = 0$ and $\Omega_M \sim 0.3$, and a non-zero $n \sim 0.04$ and a slightly higher matter density are preferred. However, at the two sigma level the results are consistent with ΛCDM; one should also bear in mind that the $n = 0$ does correspond to the ΛCDM case.

Constraints on the $\Omega_\Lambda \neq 0$ matter case are shown in the bottom panel of Fig. 1 and also in the second row of Table 1. Here there is a strong degeneracy between Q and n, both of which are unconstrained. On the other hand, the matter density is still well constrained (indeed, the constraint is tighter than in the case without a cosmological constant) and fully consistent with the canonical ΛCDM value.

Finally, constraints on the $\Omega_\Lambda = 0$ case while allowing for a constant equation of state, $w = const$ are in Fig. 2 and also in the final row of Table 1. In this case

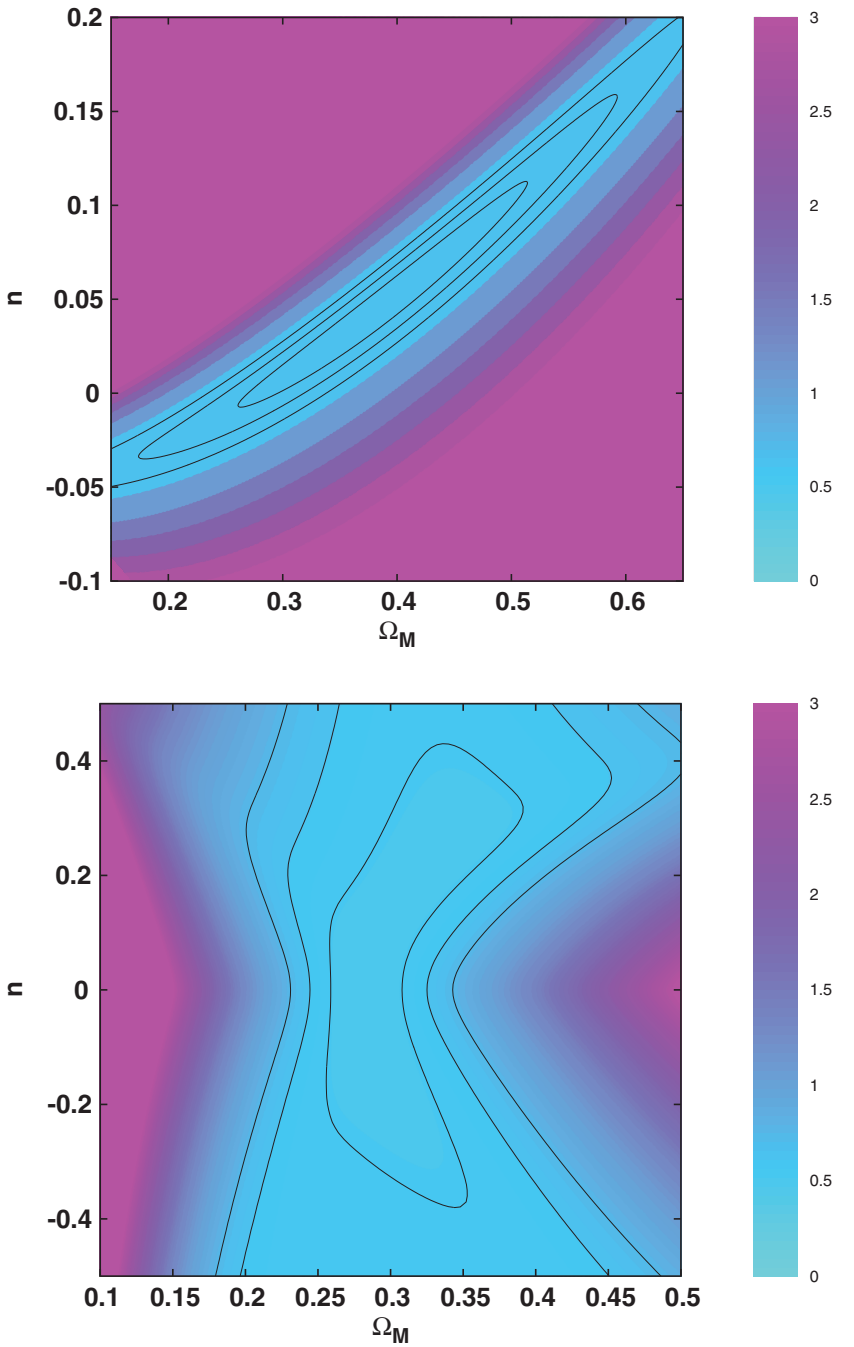

Fig. 1. Constraints on the n–Ω_M parameter space for flat universes with $w = 0$. Top and bottom panels correspond to the $\Omega_\Lambda = 0$ and $\Omega_\Lambda \neq 0$ cases, respectively. The black solid curves show the one, two, and three sigma confidence levels, while the color map depicts the reduced chi-square.

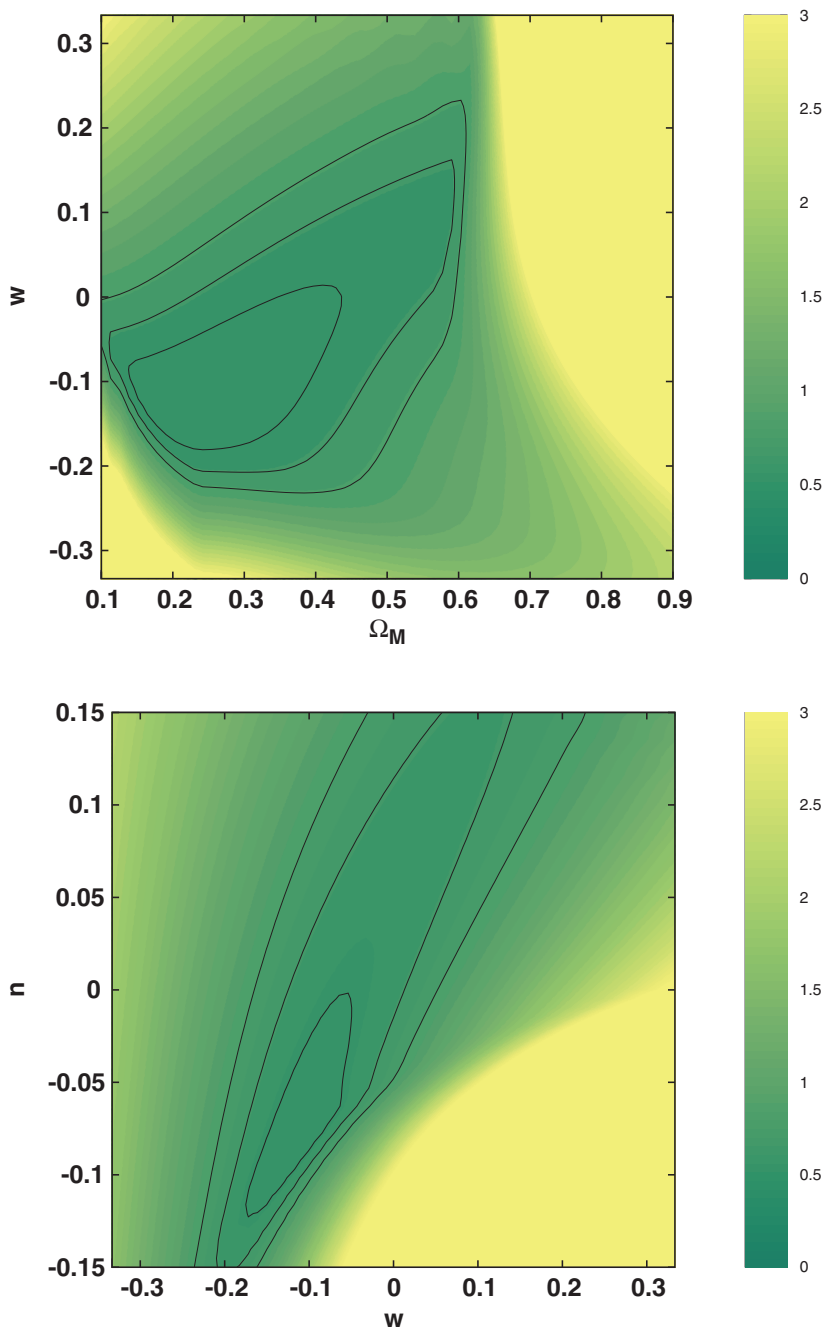

Fig. 2. Constraints on the n–Ω_M–w parameter space for flat universes with $\Omega_\Lambda = 0$. The black solid curves show the one, two, and three sigma confidence levels, while the color maps depict the reduced chi-square.

one can constrain the three model parameters. The preferred value of the matter density is again consistent with the canonical ΛCDM value, while there is a mild preference (less than two standard deviations) for negative values on the exponent n and the equation of state parameter w.

Overall, we note that the best-fit value for the matter density is compatible, within the uncertainties, with the standard one, and there is no significant evidence for deviations from ΛCDM. On the other hand, it is worthy of note that the values of the reduced chi-square for all the best-fit models is significantly below unity, so the models clearly overfit the low redshift data that we are considering.

4. A simple $f(R,T)$ model

We will now explore the modified gravity model recently discussed in Ref. 7. This is actually one case of a larger set of $f(R,T)$ models, to be discussed elsewhere. A class of modified gravity models now dubbed $f(R)$ gravity, R being the scalar curvature, was first considered in Ref. 11, but these models are subject to tight cosmological constraints.[12] A phenomenologically broader (if physically less well motivated) class is that of the so-called $f(R,T)$ models, where T is the trace of the stress energy tensor. A particular subclass of these models has separable function, $f(R,T) = R + f_2(T)$,. These models have been the subject of several mathematical studies but so far they have not been put through a detailed comparison with cosmological observations, with the exception of the recent qualitative analysis of Ref. 8.

Qualitatively, the main difference is that here the new terms depend on the trace of the energy-momentum tensor $T = \rho - 3p$, while in the model considered in the previous sections they depended on $T^2 \equiv T_{\mu\nu}T^{\mu\nu} = \rho^2 + 3p^2$. The procedure for studying the two models should otherwise be similar.

This model,[7] also previously considered in Ref. 8, has the action

$$S = \frac{1}{2\kappa}\int \left[R + \xi\sqrt{T} - 2\Lambda\right] d^4x + S_{matter}\,. \tag{21}$$

In a flat FLRW universe the Friedmann and Raychaudhuri equations now have the following form[a]

$$3\left(\frac{\dot{a}}{a}\right)^2 = \Lambda + \kappa\rho + \xi\frac{(\rho - p)}{\sqrt{\rho - 3p}} \tag{22}$$

$$6\frac{\ddot{a}}{a} = 2\Lambda - \kappa(\rho + 3p) + \frac{\xi}{2}\frac{(\rho - 7p)}{\sqrt{\rho - 3p}}\,. \tag{23}$$

As a simple comparison, in the $p = 0$ case this model leads to a Friedmann equation of the form

$$3H^2 = \Lambda + \kappa\rho + \xi\sqrt{\rho}\,, \tag{24}$$

[a]We note that there is a minus sign typo in the last term of Eq. (10) in Ref. 7.

while in the energy-momentum-powered model, choosing $n = 1/4$, one has

$$3H^2 = \Lambda + \kappa\rho - \frac{\eta}{4}\sqrt{\rho}\,. \tag{25}$$

We note that the two Friedmann equations coincide (if one identifies $\xi = -\eta/4$), but the corresponding continuity equations differ in the two cases.

We will again assume constant equations of state ($p = w\rho$), use the standard definitions of Ω_M and Ω_Λ together with $\rho = r\rho_0$ and additionally define

$$\zeta = \frac{\xi}{2\kappa\sqrt{\rho_0}}\,. \tag{26}$$

We can then rewrite the Friedmann equation as follows

$$E^2(z) = \Omega_\Lambda + \Omega_M r + 2\zeta\frac{(1-w)}{\sqrt{1-3w}}\Omega_M\sqrt{r}\,. \tag{27}$$

In principle there are therefore 3 free parameters, since the $E(0) = 1$ condition requires that the model parameters are related by $\Omega_\Lambda = 1 - \Omega_M[1 + 2\zeta(1 - w)/\sqrt{1-3w}]$. We can also rewrite it as

$$E^2(z) = \Omega_\Lambda + \Omega_M r + (1 - \Omega_M - \Omega_\Lambda)\sqrt{r} \tag{28}$$

$$E^2(z) = 1 + \Omega_M(r-1) + 2\zeta\frac{(1-w)}{\sqrt{1-3w}}\Omega_M(\sqrt{r}-1)\,; \tag{29}$$

the first of these is generic, while the second is only valid if $\Omega_\Lambda \neq 0$. However, note that in general the parameters (ζ, w) still affect the continuity equation, which can be written as

$$\frac{dr}{dz} = \frac{3r}{1+z}(1+w) \times \frac{\sqrt{1-3w} + \zeta/\sqrt{r}}{\sqrt{1-3w} + (1-w)\zeta/\sqrt{r}}\,. \tag{30}$$

We note that the usual behaviour, $r \propto (1+z)^3$, is recovered for $\zeta = 0$ and that (less trivially) this also occurs for the matter case ($w = 0$) for any value of the parameter ζ. As an illustration of the role of this parameter we can solve the continuity in the $\zeta \to 0$ limit. One finds

$$r(z) = \left[\left(1 + \frac{w\zeta}{\sqrt{1-3w}}\right)(1+z)^{3(1+w)/2} - \frac{w\zeta}{\sqrt{1-3w}}\right]^2\,, \tag{31}$$

which again has the appropriate limits.

5. Observational constraints on the $\sqrt{T}$ model

The model can now be constrained, and in particular we can again consider both the scenario with a cosmological constant (in which case the model is an extension of ΛCDM) and the scenario without a cosmological constant (in which case we can check whether such models can account for the recent acceleration of the universe at all). An overview of the results can be found in Table 2.

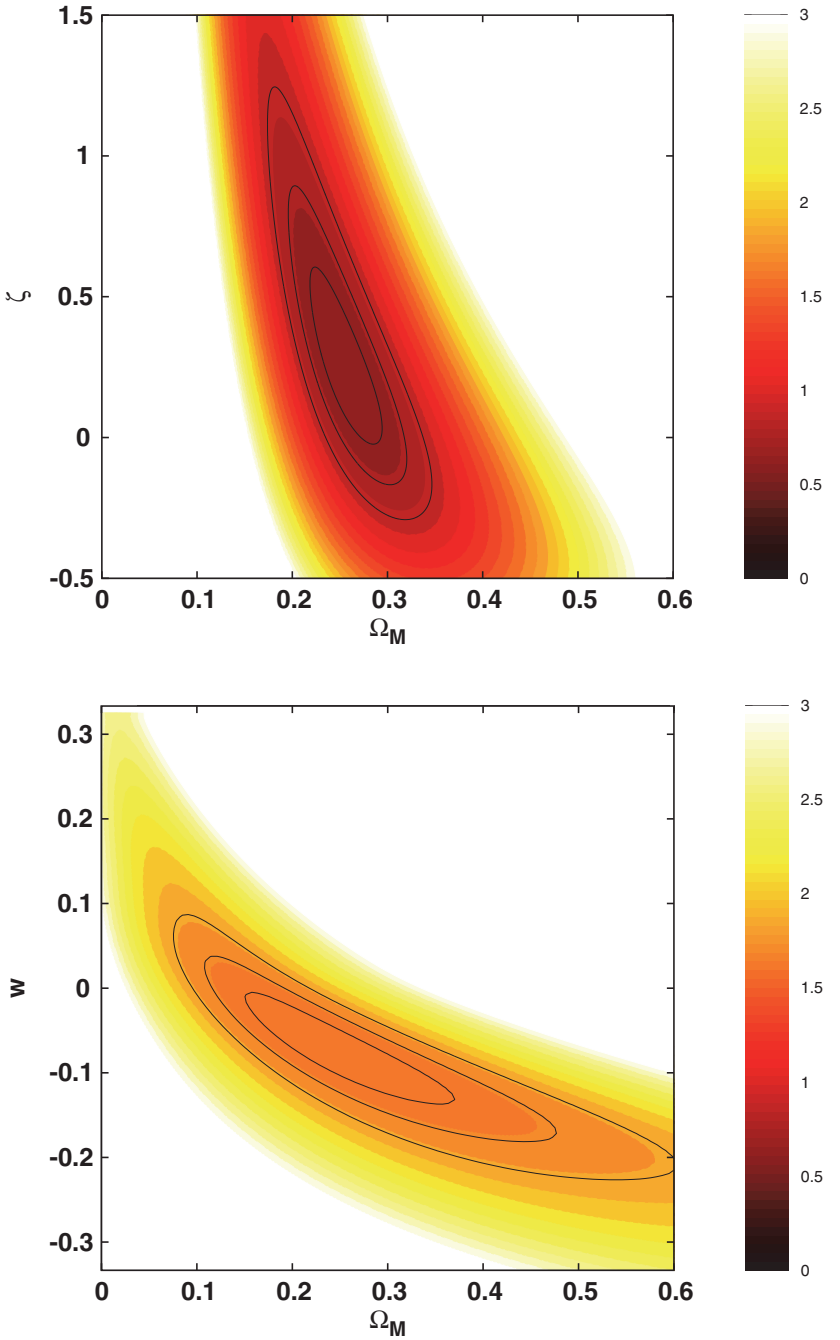

Fig. 3. Constraints on flat $\sqrt{T}$ models. The top panel shows constraints for $\Omega_\Lambda \neq 0$ and $w = 0$, and the bottom panel shows constraints for $\Omega_\Lambda = 0$ and $w = const.$ The black solid curves show the one, two, and three sigma confidence levels, and the color maps depict the reduced chi-square.

Table 2. One sigma posterior likelihoods on the matter density Ω_M, the coupling ζ and the constant equation of state w (when applicable) for various flat energy-momentum-powered models containing matter, with or without a cosmological constant. The last column lists the reduced chi-square for each best-fit model.

Model assumptions	Ω_M	ζ	w	χ^2_ν
$\Omega_\Lambda = 0$, $w = 0$	0.15 ± 0.02	2.78 ± 1.72	N/A	1.80
$\Omega_\Lambda \neq 0$, $w = 0$	$0.25^{+0.03}_{-0.02}$	$0.23^{+0.22}_{-0.18}$	N/A	0.63
$\Omega_\Lambda = 0$, $w = const.$	$0.24^{+0.08}_{-0.07}$	Unconstrained	$-0.08^{+0.04}_{-0.05}$	1.80

Note: The specific assumptions for each case are described in the main text. The constraints come from the combination of the Pantheon supernova data and Hubble parameter measurements.

Starting with the case of $\Omega_\Lambda = 0$ and $w = 0$, we effectively have only one independent parameter, since the matter density and coupling parameter are related through $(1 + 2\zeta)\Omega_M = 1$. The obtained constraints are listed in the first row of Table 2. It is clear from the very large value of the reduced chi-square that this model, containing only matter but no cosmological constant, does not fit the data. In other words, this model can not be a true alternative to ΛCDM.

The top panel of Fig. 3 and the second row of Table 2 summarize the constraints for the case of $\Omega_\Lambda \neq 0$ and $w = 0$. In this case we have two independent parameters, and the model is effectively a one parameter extension of ΛCDM. Here, as in the previously discussed case of energy-momentum-powered models, the model slightly overfits the data, and there is no statistically significant preference for a non-zero coupling parameter ζ, The best fit value of the matter density is not significantly changed with respect to its value, for the same datasets, in the ΛCDM model.[13]

Finally, the bottom panel of Fig. 3 and the third row of Table 2 show the constraints for $\Omega_\Lambda = 0$ and $w \neq 0$, where we have three independent parameters. There are now additional degeneracies between the parameters, but the main conclusion remains the same as for the $w = 0$ case: without a cosmological constant this model severely underfits the data, and therefore it is not viable as an alternative to ΛCDM.

6. Outlook

We have discussed observational current low redshift background constraints on classes of FLRW cosmological models in which the matter side of Einstein's equations includes, in addition to the canonical term, either a term proportional to a function of the energy-momentum tensor ($T^2 = \rho^2 + 3p^2$), or of its trace ($T = \rho - 3p$). Both of these can be phenomenologically thought of as extensions of general relativity with a nonlinear matter Lagrangian.

We considered both models under two different scenarios: (1) as phenomenological two-parameter or three-parameter extensions of the standard ΛCDM, in which case the model still has a cosmological constant but the nonlinear matter Lagrangian

leads to additional terms in Einstein's equations, which cosmological observations tightly constrain, and (2) as alternatives to ΛCDM, where there is no cosmological constant, and the nonlinear matter term would have to provide the acceleration (which would be somewhat closer in spirit to the usual modified gravity models).

Overall, our analysis suggests that the ΛCDM paradigm is fairly robust or, pragmatically, it is a good phenomenological approximation to a still unknown more fundamental model. In other words, if there is no true cosmological constant, the alternative mechanism must effectively be like one, at least at low redshifts. On the other hand, for parametric extensions of ΛCDM, subdominant (ca. 10% level) contributions are allowed by the low redshift background cosmology data that we have considered. These constraints can of course be tightened by including additional datasets, such as that from cosmic microwave background observations. Our work can be extended to broader classes of $f(R,T)$ models, a discussion of which is left for a subsequent publication.

Various observations have shown that dark energy accounts for nearly two-thirds of the energy density of the Universe. The simplest model to explain the nature of dark energy is the cosmological constant (ΛCDM) model. Although Planck observations supports using ΛCDM model as the base cosmological model, there exist some inconsistencies in parameter estimates when compared with independent observations. The most important is the inconsistency in the H_0 estimates from the Planck collaboration which reports $H_0 = 67.5^{+0.5}_{-0.5}\ km\ s^{-1}\ Mpc^{-1}$, a considerably lower value when compared with the direct local distance ladder measurements. This value shows a discrepancy at the level greater than 4σ with the constraints reported by SH0ES collaboration in 2019, $H_0 = 74.3^{+1.42}_{-1.42}$ $km\ s^{-1}\ Mpc^{-1}$. These disagreements, called the Hubble tension, point towards a new physics that deviates from the standard ΛCDM model and to resolve this various methods have been proposed. In this work, a quintessence scalar field with an inverse power potential ($V(\phi) \sim \phi^{-n}$) is assumed as a description of dark energy and we focus on an interacting dark energy dark matter model where the interacting term is taken to be linear in the field (Φ). We study in detail the evolution of the model and provide constraints on the model parameters using low redshift cosmological observations of Type Ia Supernovae (SN), baryon acoustic oscillations (BAO), direct measurements of Hubble parameter (Hz) and high redshift HII galaxy measurements (HIIG). We find that the model agrees with the existing values of the nonrelativistic matter density parameter, Ω_m and dark energy equation of state parameter, w_0. The analysis shows that the observations prefer a negative value of coupling constant and gives the best fit value of $H_0 = 69.9^{+0.46}_{-1.02}\ km\ s^{-1}\ Mpc^{-1}$ and thereby can be used to alleviates the H_0 tension between Planck measurements and the observations considered.

Keywords: Cosmological parameter, observations, dark energy - dark matter interaction, based on the work [arXiv:2102.12367].[1]

1. Introduction

Many cosmological observations suggest that, at the present epoch, the energy content of the universe is dominated by dark energy, and to explain the observed accelerated expansion of the universe, this dark energy component must have a negative pressure.[2–5] However, the nature of dark energy is still a mystery, and many models are proposed in the literature to explain what dark energy might be. The simplest model is the ΛCDM model, which is also the most consistent model for cosmological observations. The latest results from the Planck mission provide good support to the ΛCDM model as the base cosmological model and also improve upon the uncertainties in parameter estimation.[6,7] With more accurate and precise measurements, the

uncertainties from various experiments have been studied and are in disagreement with each other. The most glaring tension is found in the estimation of the Hubble parameter reported by the Planck collaboration and the low redshift cosmological probes.[8–10] In some cases, the tension stands at level greater than 4σ, e.g., Planck 2018 results, which assume standard ΛCDM model as the base cosmological model, report Hubble parameter to be $H_0 = 67.4 \pm 0.5\ km\ s^{-1}\ Mpc^{-1}$,[7] whereas SH0ES collaboration estimates $H_0 = 73.5 \pm 1.4\ km\ s^{-1}\ Mpc^{-1}$.[11] Another discrepancy, although not as severe, is found in the estimation of σ_8 reported by Planck 2018 and low redshift observation with stands at a level of 2σ-3σ level.[12–17] The high precision of the data from Planck collaboration and low redshift probes insinuate that the H_0 tension between these experiments cannot result from the systematics and hence, points towards a new physics that deviates from the standard ΛCDM model.

Many models have been proposed and studied to resolve these disagreements in literature. One such proposal is to consider a non-zero interaction between dark energy and dark matter which could alleviate these disagreements.[18–21] In this work, we focus on an interacting dark sector model, which is introduced in.[22] In most cases, this interaction term is introduced in fluid equations by hand, which might not be consistent with the classical field theory action. In the Ref.,[22] instead of putting it by hand, the authors derive the interaction term, which is consistent with both fluid descriptions and classical field theory description. We use this interaction term in our work and study whether the interaction model is consistent with low redshift observations such as direct measurement of Hubble parameter (Hz),[23–28] measurements of HII galaxy (HIIG),[29,30] baryon acoustic oscillations (BAO),[31–36] and type Ia supernovae (SN).[37] We constrain the model parameters, and after analyzing, find that using only the background observations, we cannot distinguish between interacting and noninteracting scenarios. Two see a clear distinction between the two cases; we have to study the evolution of perturbed quantities.

2. Dark Energy Dark Matter Interaction Model

The interacting model is described by the action

$$S = \int d^4x\sqrt{-g}\left(\frac{1}{2\kappa^2}R - \frac{1}{2}g^{\mu\nu}\nabla_\mu\phi\nabla_\nu\phi - U(\phi) - \frac{1}{2}e^{2\alpha(\phi)}g^{\mu\nu}\nabla_\mu\chi\nabla_\nu\chi - e^{4\alpha(\phi)}V(\chi)\right). \tag{1}$$

where dark energy is denoted by the scalar field ϕ, $U(\phi)$ is the scalar field potential, dark matter is represented by the scalar fieldχ, and $\alpha(\phi)$ denotes the dark energy dark matter interaction (For more details, see[22]).

The Einstein equation in terms of the scalar field (ϕ) and dark matter fluid, specified by four-velocity energy density and pressure, is given by[22]

$$G_{\mu\nu} = 16\pi G\left[\nabla_\mu\phi\nabla_\nu\phi - \frac{1}{2}g_{\mu\nu}\nabla^\sigma\phi\nabla_\sigma\phi - g_{\mu\nu}V(\phi) + p_m g_{\mu\nu} + (\rho_m + p_m)u_\mu u_\nu\right], \tag{2}$$

and the energy-momentum tensor for the dark matter fluid is given by

$$T_{\nu}^{(m)\mu} = p_m g_{\mu\nu} + (\rho_m + p_m) u_\mu u_\nu \,. \tag{3}$$

The interaction term is described by $\nabla_\mu T_{\nu}^{(m)\mu} = Q_\nu^{(\mathrm{F})}$, and by demanding that the interaction term Q_ν must have a field theory description, they obtained a unique form of interaction term, given by[22]

$$Q_\nu^{(\mathrm{F})} = T^{(m)} \nabla_\nu \alpha(\phi) \,. \tag{4}$$

We study the evolution of cosmological equations in the presence of the interaction and obtain constraints on the model parameters by assuming a specific form of scalar field potential and the interaction term. In this work, we assume a quintessence scalar field described by the inverse power law potential and an interaction term that is linear in the field (ϕ),

$$U(\phi) \sim \frac{1}{\phi^n}, \qquad n \;=\; 1, 2, \tag{5}$$

$$\alpha(\phi) \sim \phi, \qquad \alpha(\phi) = C\phi \tag{6}$$

where C is the interaction strength. The evolution of the scalar field is described by the Klein-Gordon equation given by

$$(\ddot{\phi} + 3H\dot{\phi} + U_{,\phi})\dot{\phi} = Q \,,$$

where $Q = Q_0^{(\mathrm{F})}$. The scalar field potential in terms of dimensionless parameter $\tilde{\phi}$ is

$$U(\tilde{\phi}) = \frac{\kappa}{2} m_{\mathrm{Pl}}^2 \tilde{\phi}^{-n} \tag{7}$$

where κ is a constant and m_{Pl}, is the Planck mass. The evolution of non-relativistic matter density in the presence of interaction is given by

$$\dot{\rho}_m + 3H\rho_m = -Q \,.$$

For interaction term, $Q = -\alpha_{,\phi}\dot{\phi}\rho_m$, on solving the above equation we get, $\rho_m = \rho_{m_0} e^{\alpha(\phi)-\alpha(\phi_0)} a^{-3}$.

We use these equations to study the universe's evolution in the presence of nonzero interaction and establish the consistency of the model with the latest low redshift observations. The observations used in the analysis are: a) the direct measurements of Hubble parameter (Hz) with observations in the redshift range of $0.070 \leq z \leq 1.965$, b) the baryon acoustic oscillations (BAO) data ($0.106 \leq z \leq 2.36$), c) High-redshift HII Galaxy measurements (HIIG) which spans in a range $0.0088 \leq z \leq 2.42935$, and d) type Ia Supernovae (SN) observations with data points between range $0.05 \leq z \leq 1.4$. To obtain the constraints on model parameters, we use the chi-squared minimization technique, which tells about the goodness of the fit by comparing the observed values of an observable with the theoretically expected values for a specific model (dark energy dark matter interaction model in our case).

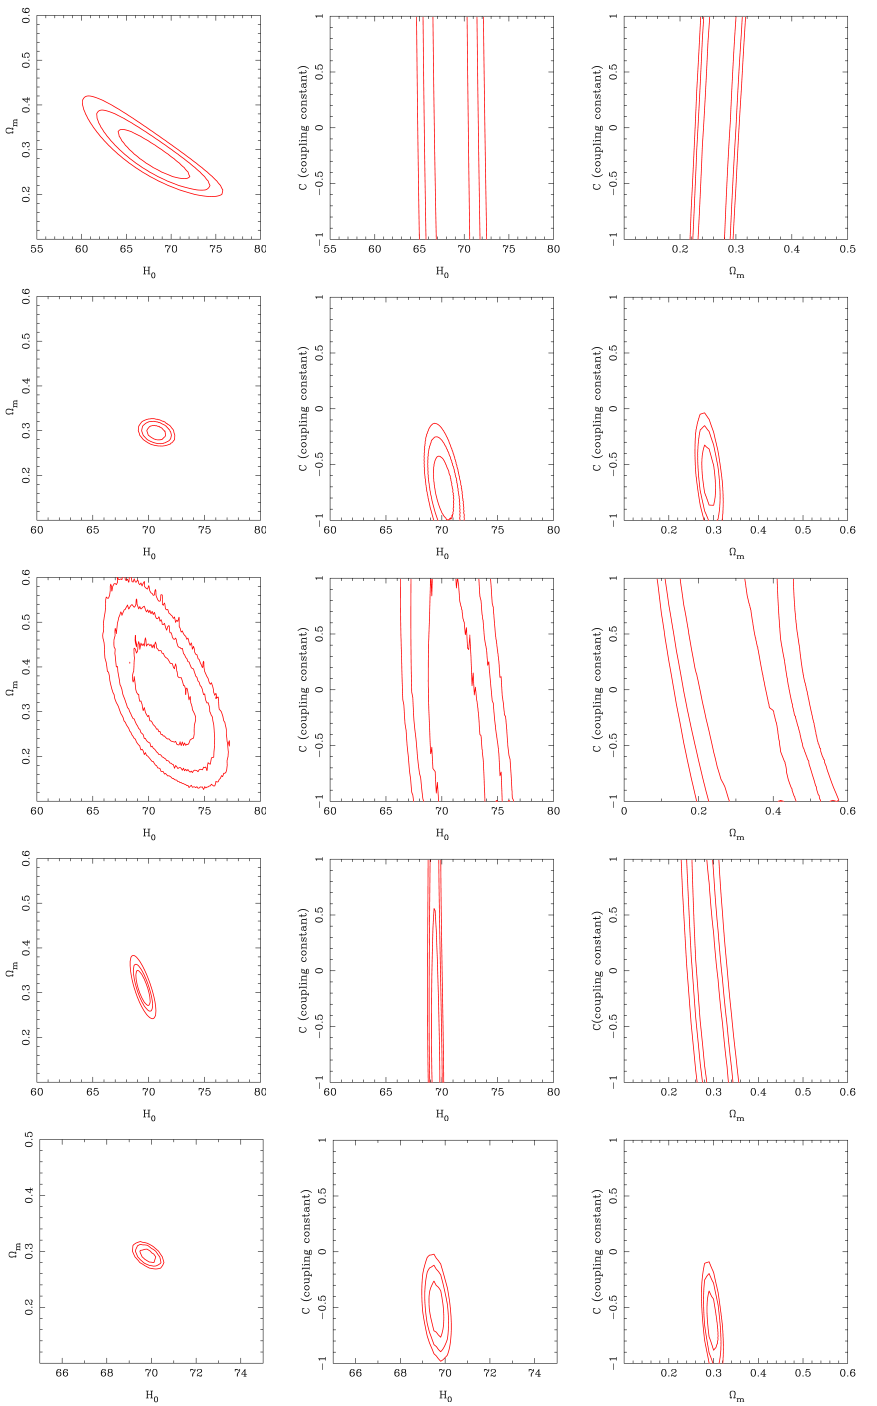

Fig. 1. 1,2,3-σ confidence regions for Hz data (I row), BAO+Hz data (II row), HIIG data (III row), SN+Hz data (IV row) and all four data sets (V row).

3. Observational Constraints

In the analysis, the parameter describing the model are: the Hubble parameter at present (H_0), nonrelativistic matter density parameter (Ω_m), dark energy equation of state parameter at present (w_0), and the interaction strength (C). The priors used in the analysis are given in table below.

Parameter	Lower Limit	Upper Limit
H_0	60.0	80.0
Ω_m	0.1	0.6
w_0	-1.0	1.0
C	-1.0	1.0

We perform the chi-squared minimization technique to obtain the $1, 2, 3 - \sigma$ confidence regions for the four observations we considered in the analysis and provide the results in two-dimensional planes in Fig. 1. We assume $n = 1$ in the analysis and have marginalized over the other parameters to obtain the results in the two-dimensional plane. The results from Hz observation are shown in the first row. The allowed range from Hz data for Ω_m and H_0 parameters are fairly large as compared to the allowed uncertainties obtained from BAO measurements (second row) and SN data (fourth row). On the other hand, the interaction strength parameter C is not constrained by Hz observations, and the entire range is allowed by the observations. BAO+Hz data (second row) provides the tightest constraints on the cosmological parameters, and these observations also obtain the upper limit on interaction strength.

Constraints from HIIG data are presented in the third row (where we have not included the systematic error in the analysis for HIIG data); the HIIG data is unable to constrain the H_0 parameter and provides the largest allowed range for Ω_m among the data sets considered in the analysis. In the fourth row, results from SN+Hz are presented. SN+Hz data also provides narrow constraints on H_0 and Ω_m parameters and gives an upper limit on the interaction strength. Finally, the results from combining the data sets (Hz+BAO+HIIG+SN) are given in row fifth. We find that by performing combined analysis, we get a very narrow range of uncertainties in parameter estimation, and the best fit values of parameters are given by $H_0 = 69.9\ km\ s^{-1}\ Mpc^{-1}$, $\Omega_m = 0.29$, and $C = -0.47$. From the analysis, we find that all the observations are consistent with negative values of C, and the upper on C is given by SN+Hz and BAO+Hz observations which drive the combined results.

We show the results in $\Omega_m - w_0$ plane obtained from Hz (first row, left), BAO+Hz (first row, right), HIIG (the second row, left), and SN+Hz (second row right) observations in Fig. 2. For all the observations, we find that the model is consistent with the cosmological constant model, and BAO+Hz data provides the narrowest

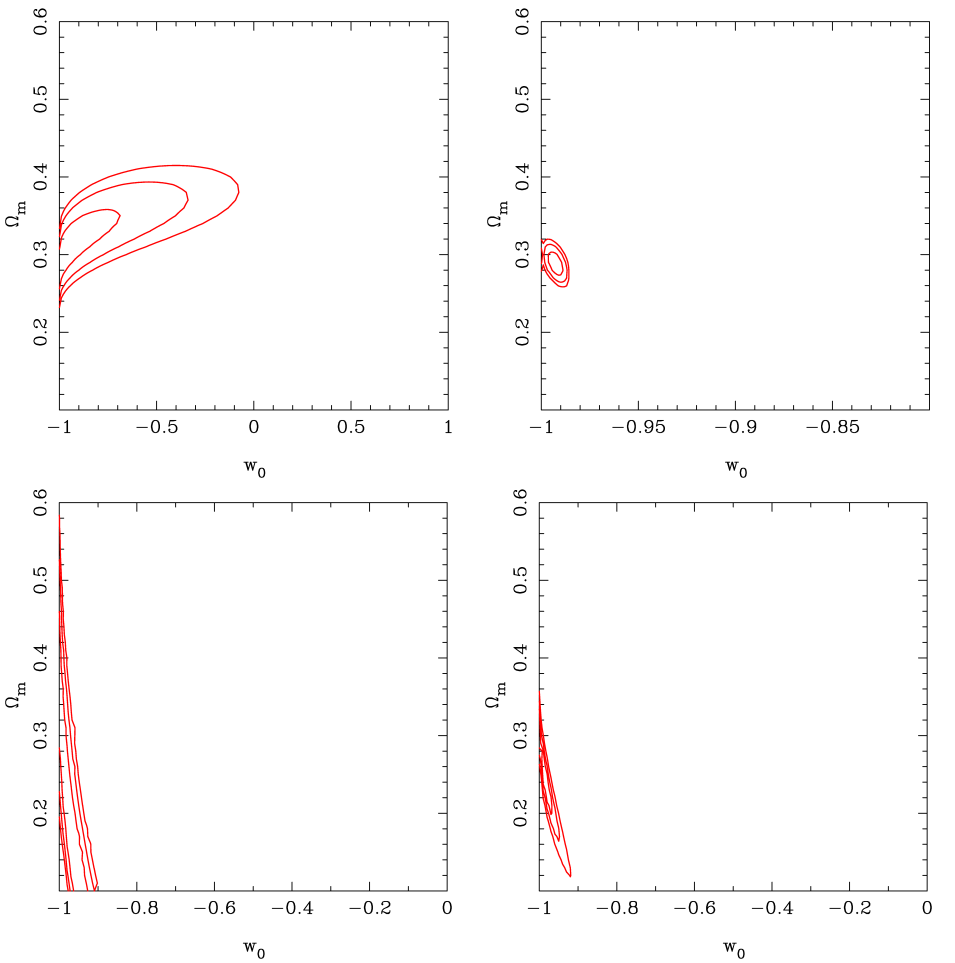

Fig. 2. 1,2,3-σ confidence regions in 'w_0-Ω_m' plane. The first row shows constraints from Hz data (left) and BAO+Hz observations (right). The second row shows constraints from HIIG measurements (left) and SN+Hz observations (right).

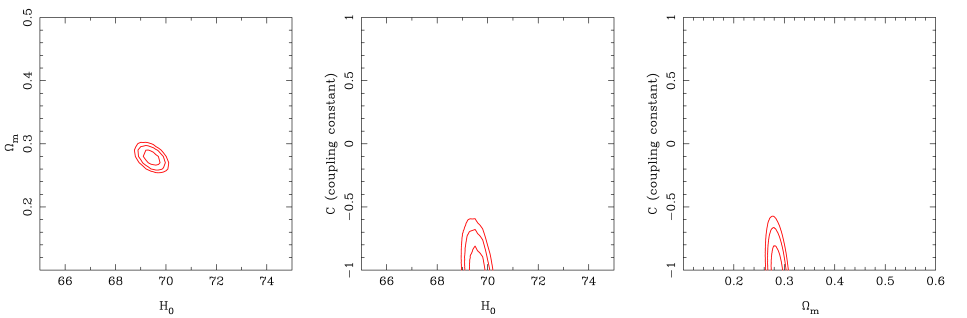

Fig. 3. 1,2,3-σ confidence regions for combined analysis of all four data sets.

constraints on Ω_m and w_0 parameters followed by Sn+Hz measurements. However, Hz data also allows for non-accelerating universe scenarios.

We have also performed the chi-squared analysis for the $n = 2$ case. And we find that the key conclusions from $n = 1$ remain the same that all the observations constrain H_0 to be close to 70 $km\ s^{-1}\ Mpc^{-1}$ and the narrowest constraints are obtained from BAO+Hz and SN+Hz, followed by Hz and HIIG observation. The change in results from individual observations is not significant as we move from $n = 1$ to $n = 2$ case. The only difference worth mentioning is that as n changes from 1 to 2, the contours show a slight shift value of C towards -1, and the model seems to prefer negative values of interaction strength. This preference is more notable in the results from the combined analysis of all the previously mentioned observations. In Fig. 3, we show the 1,2,3-σ confidence regions for combined analysis from all the four data sets considered in the analysis. The effect on Ω_m and H_0 constraints is not significant as we go from $n = 1$ to $n = 2$ case, and the constraints obtained from each dataset are consistent with each other.

Examining the constraints obtained through the evolution of background cosmological equations and using low redshift observations, it is evident that we cannot distinguish between interacting and noninteracting scenarios. Therefore, in the next section, we study the evolution of first-order perturbations in the presence of a nonzero interacting term.

4. Evolution of Perturbations

In this section, we study the evolution of quantities that depends upon the evolution of first-order cosmological perturbations and are related to the observations in current cosmological experiments. The cosmological quantities we discuss are related to structure formation, gravitational lensing and integrated Sachs-Wolfe effect, denoted by δ_m, $\Phi + \Psi$, and $\Phi' + \Psi'$ respectively.

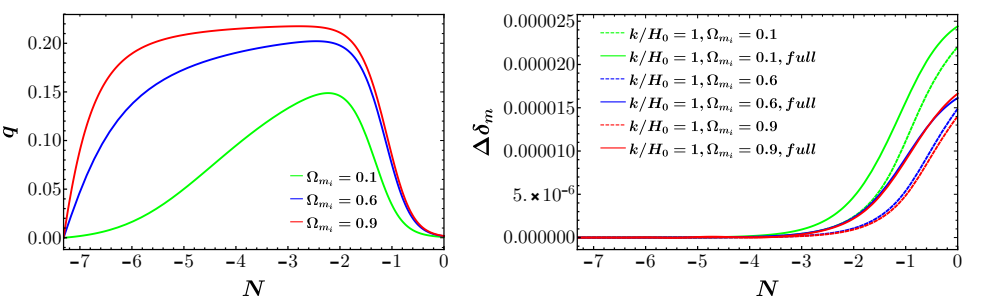

Fig. 4. Evolution of q (left panel) and $\Delta\delta_m$ (right panel) as a function of N with $C = -0.6$.

Structure formation: To study the effect of interaction between dark energy and dark matter on structure formation, we study the evolution of matter density per-

turbation denoted by δ_m, for various length scales. The parameter δ_m is defined as $\delta_m(t,x,y,z) \equiv \frac{\delta\rho_m(t,x,y,z)}{\overline{\rho_m}(t)}$, where $\overline{\rho_m}(t)$ is the mean matter density at time t.

In Fig. 4, the left plot shows the evolution of the scaled interaction term given by $q = \frac{Q}{H^3 M_{Pl}^2}$ as a function of N for different initial values of matter density parameter Ω_m, where $N = ln(a)$ is the number of e-foldings. We see that for a larger value of initial matter density, the contribution of the interaction term is greater and becomes significant at an earlier time than for smaller initial matter density values. The right plot shows the evolution of $\Delta\delta_m = \delta_{m_i} - \delta_{m_{ni}}$ as a function of N. The plot shows the difference in the evolution of matter density perturbations in the interacting and noninteracting models denoted by parameters δ_{m_i} and $\delta_{m_{ni}}$ respectively. The dotted lines are for the case when the perturbed interaction term is neglected, and the solid line is when we consider the perturbed interaction term. The different colors correspond to the different initial values of the matter density parameter. We see that at around $N \sim 2$, the curves deviate from one another, showing that considering the interaction term changes the evolution of matter perturbations, and the maximum change is observed in smaller Ω_{m_i} case. This demonstrates that its possible to detect the signature of dark energy and dark matter interactions in future large scale structure observations.[38–40]

Weak gravitational lensing: The quantity $\Phi + \Phi$ contributes to the weak gravitational lensing effect that is the result of deviation in photon trajectory because of the mass distribution in space. This section discusses the evolution of Φ as in standard cosmology, $\Phi = \Psi$. The evolution of Φ as a function of N is shown in Fig. 5. The plot on the left is for dark energy dark matter interaction scenario with interaction strength $C = -0.6$, and the right plot is for noninteracting scenarios. The different curves correspond to different length scales represented by different values of k. The curves are obtained by evolving the system of equations with the same initial conditions starting at a redshift of $z_i = 1500$. We find that the effect of interaction is clear on the smallest scale considered in the analysis, i.e., at $k/H_0 = 1$. Therefore, we can use the evolution of scalar perturbations to distinguish between the interacting and noninteracting dark energy dark matter scenarios by the future observations of weak gravitational lensing.[41]

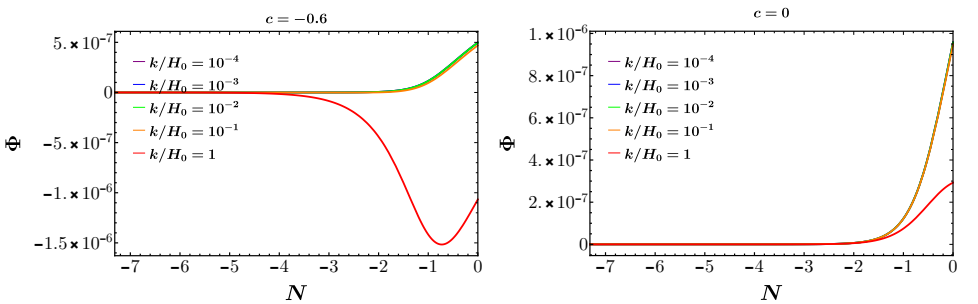

Fig. 5. Evolution of Φ as a function of N. Left: $C = -0.6$, Right: $C = 0$.

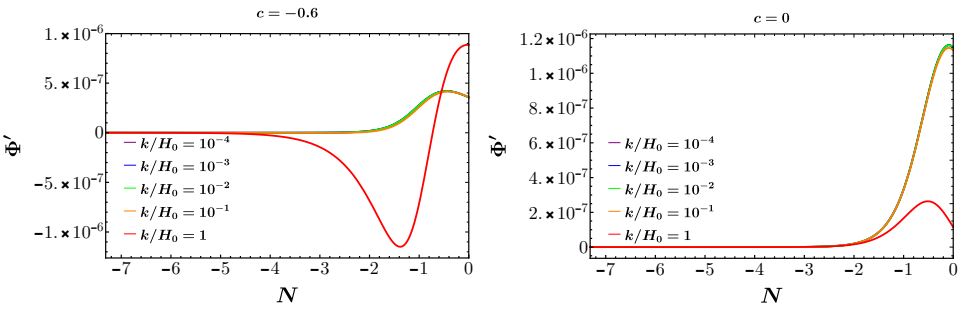

Fig. 6. Evolution of Φ' as a function of N. Left: $C = -0.6$, Right: $C = 0$.

Integrated Sachs-Wolfe effect: This effect manifests in cosmic microwave background radiation anisotropies because of the change in gravitational potential in the path of photons as the photons travel after decoupling from the last scattering surface towards the observer. This effect is given by $\Phi' + \Psi'$, where $'$ denotes the rate of change with respect to conformal time. The change in the evolution of Φ' as a function of N for interacting case with interaction strength $C = -0.6$ (left plot) and noninteracting (right plot) scenarios is given Fig. 6. The different curves correspond to different length scales. The change in the evolution of Φ' because of interaction is observed at $N \sim 3$ where the Φ' is suppressed as compared to the noninteracting scenario. And the maximum change is observed on the smaller scales, and hence, this effect could be observed in the CMB anisotropies. Therefore, using the ISW observations, we can distinguish between interacting and noninteracting scenarios.

5. Conclusion

In this work, we consider a dark energy dark matter interaction model and check the consistency of the model with low redshift observations. In this model, the interaction term is obtained by assuming a one-to-one mapping between the classical field description and the fluid description of the interacting model. We perform the chi-squared minimization technique and obtain the constraints on model parameters. The observations we use in the analysis are direct measurements of Hubble parameter (Hz), baryon acoustic oscillation (BAO) data, measurements of HII galaxies (HIIG), and type Ia supernovae data (SN). We obtain narrow constraints on Hubble parameter H_0, non-relativistic matter density parameter Ω_m, and dark energy equation of state parameter at present w_0. The BAO+Hz and SN+Hz observations provide an upper limit on interaction parameter C. The constraints from these observations are consistent with one another, and the best fit value from all the observations are close to $H_0 \sim 70\ km\ s^{-1}\ Mpc^{-1}$. So there is no tension in the estimated value of H_0 from these observations for the interaction model considered.

The Interaction model is consistent with the abovementioned low redshift observations used in the analysis.

From background analysis, we also observed that it is difficult to distinguish between the interacting and noninteracting models, and therefore we must look at the evolution of perturbations. Therefore, we studied the evolution of first order perturbation quantities such as δ_m, Φ, and Φ' in the interacting and noninteracting case. We find that the evolution of these quantities is modified in the presence of dark energy dark matter interaction terms. Therefore, using the observations of structure formation, weak gravitational lensing, and integrated Sach-Wolfe effect, which depends upon the evolution perturbed quantities mentioned above and carries the signature of the interaction, we can distinguish between the interacting and noninteracting scenarios.

We focus on weak inhomogeneous models of the Universe at low redshifts, described by the Lemaître-Tolman-Bondi (LTB) metric. The principal aim of this work is to compare the evolution of inhomogeneous perturbations in the ΛCDM cosmological model and $f(R)$ modified gravity theories, considering a flat Friedmann-Lemaître-Robertson-Walker (FLRW) metric for the background. More specifically, we adopt the equivalent scalar-tensor formalism in the Jordan frame, in which the extra degree of freedom of the $f(R)$ function is converted into a non-minimally coupled scalar field. We investigate the evolution of local inhomogeneities in time and space separately, following a linear perturbation approach. Then, we obtain spherically symmetric solutions in both cosmological models. Our results allow us to distinguish between the presence of a cosmological constant and modified gravity scenarios, since a peculiar Yukawa-like solution for radial perturbations occurs in the Jordan frame. Furthermore, the radial profile of perturbations does not depend on a particular choice of the $f(R)$ function, hence our results are valid for any $f(R)$ model.

Keywords: Cosmology, Modified gravity, Inhomogeneous Universe, Late Universe, Large Scale Structure

Introduction

The well-known ΛCDM model,[1,2] which includes a cosmological constant Λ and a cold dark matter (CDM) component, is based on General Relativity (GR), and it provides a robust and accurate description of our Universe, supported by cosmological data. Moreover, the Universe appears homogeneous and isotropic at very large scales[3] (cosmological principle), and this kind of geometry is described by the FLRW line element. In this work, based on a paper in preparation,[4] we investigate possible deviations from two pillars of the standard ΛCDM model, focusing on a local inhomogeneous description of the Universe and modified gravity models.

Here, we adopt the LTB metric,[2] a spherically symmetric solution of the Einstein field equations, to account for local deviations of the Universe from the homogeneity. Hence, we regard the weakly inhomogeneous LTB solution as the standard FLRW geometry plus small spherically symmetric perturbations.

Furthermore, in recent years increasing interest raised to provide features able to distinguish between GR and modified gravity approaches. Some open problems in cosmology, such as the Hubble constant tension,[5] may require new physics.[6] The aim of the present work is to compare the evolution of linear inhomogeneous perturbations in the ΛCDM and $f(R)$ modified gravity models.[7,8] More in detail, we used the equivalent formalism in the Jordan frame,[7–9] and we adopt the $f(R)$ Hu-Sawicki model,[10] which is a promising theoretical framework to reproduce the cosmic acceleration in the late Universe via the dynamics of a non-minimally coupled scalar field without a cosmological constant.

Then, we investigate the dynamics of inhomogeneous perturbations in the two cosmological models abovementioned. Moreover, the separable variables method is implemented in the analysis at the first-order of perturbation, and our approach is the same used in Ref. 11. We obtain an analytic expression only for the radial dependence of the linear perturbations, while their time evolution must be numerically evaluated. The most relevant issue, emerging from our analysis, is the different morphology of the radial dependence of the LTB solution in the ΛCDM formulation and Hu-Sawicki dynamics. Indeed, a distinctive Yukawa-like behavior occurs in the Jordan frame gravity regardless of the choice of a specific $f(R)$ model. Hence, we have found a peculiar feature to distinguish a modified gravity model from a cosmological constant scenario.

This work is organized as follows: in Sec. 1 we introduce the framework of the $f(R)$ extended gravity models; in Sec. 2 we adopt the LTB metric; then, in Sec. 3 we implement a perturbation approach to deal with local inhomogeneities. Finally, we summarize our work in Sec. 4. We adopt the metric signature $(-,+,+,+)$, and we set $c = 1$.

1. $f(R)$ models in the Jordan frame

A generalization of the Einstein-Hilbert theory is provided by the so-called $f(R)$ modified gravity models.[7,8] In this context, the gravitational Lagrangian density is expressed as a free function f of the Ricci scalar R, namely an extra degree of freedom compared to GR. The extended field equations in $f(R)$ gravity are fourth-order partial differential equations in the metric tensor components. In particular, if $f(R) = R$, the gravitational field equations end up in the Einstein equations in GR, trivially.

It is often convenient to reformulate $f(R)$ gravity in the scalar-tensor representation in the Jordan frame.[7–9] In doing so, the extra degree of freedom of the $f(R)$ function is converted into a non-minimally coupled scalar field. It can be checked

that the following action

$$S_J = \frac{1}{2\,\chi}\int_\Omega d^4x\,\sqrt{-g}\,\left[\phi\,R - V\,(\phi)\right] + S_M\,(g_{\mu\nu},\psi) \tag{1}$$

is dynamically equivalent to the action in the $f\,(R)$ metric formalism, if $f''\,(R) \neq 0$, where we have defined a scalar field $\phi = f'\,(R) = df/dR$, and a scalar field potential $V\,(\phi) = \phi\,R\,(\phi) - f\,(R\,(\phi))$. In Eq. (1), $\chi \equiv 8\,\pi\,G$ is the Einstein constant, G is the Newton constant, g is the determinant of the metric tensor $g_{\mu\nu}$, while S_M is the matter action, and ψ denotes matter fields. The advantage of the Jordan frame is that the corresponding field equations[8] are now second-order differential equations, but one has to deal with the non-minimally coupling.

The increasing attention to these extended gravity models is motivated by the consideration that the actual cosmic acceleration of the Universe might be obtained by geometry rather than a cosmological constant. A geometrical modification, indeed, could be regarded as an effective matter source.

Among several suggested $f\,(R)$ models,[7,8,12,13] we focus on the Hu-Sawicki proposal,[10] which is largely studied in the late Universe. The deviation $F\,(R) \equiv f\,(R) - R$ with respect to the GR scenario for the Hu-Sawicki (HS) model with $n = 1$ assumes the following form

$$F\,(R) = -m^2\frac{c_1\,R/m^2}{c_2\,R/m^2 + 1}\,, \tag{2}$$

where $m^2 \equiv \frac{\chi\,\rho_{m0}}{3}$ is related to the present matter density ρ_{m0}, while c_1 and c_2 are dimensionless parameters. It can be checked[10] that an effective cosmological constant is obtained for $R \gg m^2$. Furthermore, c_1 and c_2 can be constrained[10] specifying $F_{R0} \equiv dF\,/\,dR\;(z = 0)$ at the present cosmic time (redshift $z = 0$).

Finally, we write the scalar field potential $V\,(\phi)$ in the Jordan frame for the HS model with $n = 1$:

$$V\,(\phi) = \frac{m^2}{c_2}\,\left[c_1 + 1 - \phi - 2\sqrt{c_1\,(1-\phi)}\right]\,. \tag{3}$$

It can be shown[14] that the potential (3) ends in an asymptotically stable de Sitter Universe.

2. Inhomogeneous solutions in GR and in the Jordan frame

An inhomogeneous Universe can be described by using the LTB line element,[2] which is a spherically symmetric solution of the Einstein equations. The Universe in the LTB geometry appears inhomogeneous, but isotropic, from a single preferred point located at the center of the spherical symmetry. For instance, a cosmological dust or a spherical overdensity mass are well described by such a metric.

In the synchronous gauge, the LTB line element may be regarded as a generalization of the FLRW one, and it is given by

$$ds^2 = -dt^2 + e^{2\alpha}dr^2 + e^{2\beta}\,\left(d\theta^2 + sin^2\theta\,d\phi^2\right)\,, \tag{4}$$

where r is the radial distance from the preferred point, while $\alpha = \alpha(t, r)$ and $\beta = \beta(t, r)$ are two metric functions.

Considering a pressure-less dust ($p = 0$) and a cosmological constant Λ in GR, we can write the Einstein equations in the LTB metric. For instance, the 01 component of field equations is written as

$$\frac{\dot{\beta}'}{\beta'} - \dot{\alpha} + \dot{\beta} = 0 \tag{5}$$

where $\dot{()}$ and $()'$ denote derivatives with respect to time t and radial coordinate r, respectively. The other non-zero equations are the 00 and 11 components,[4] while different components vanish due to spherical symmetry.

It is possible to simplify the LTB metric within the framework of GR, using Eq. (5), which allows us to find a relation between the metric functions α and β. Following the approach in Ref. 2, the LTB line element (4) becomes

$$ds^2 = -dt^2 + \frac{[(a\,r)']^2}{1 - r^2\,K^2} dr^2 + (a\,r)^2 \left(d\theta^2 + sin^2\theta\, d\phi^2\right) , \tag{6}$$

where $a = a(t, r) = e^{\beta}/r$ is a generalized scale factor in a inhomogeneous geometry, and $K = K(r)$. Note that if $a(t, r)$ and $K(r)$ are independent of r, the metric (6) coincides with the FLRW line element, describing an isotropic and homogeneous geometry. Moreover, the 00 and 11 components of the Einstein equations in the LTB metric provides a generalization of the Friedmann equations in the ΛCDM model.

Concerning the $f(R)$ modified gravity scenario in the equivalent Jordan frame, the 01 component of the gravitational field equations in the LTB metric is written as

$$\frac{\dot{\beta}'}{\beta'} - \dot{\alpha} + \dot{\beta} = -\frac{1}{2\,\phi\,\beta'} \left(\dot{\phi}' - \dot{\alpha}\,\phi'\right) . \tag{7}$$

Furthermore, we can compute[4] also the 00 and 11 of field equations, as well as the scalar field equation in the Jordan frame. Observe that ϕ, ρ, α, and β are all functions of t and r in a inhomogeneous scenario.

Comparing Eq. (7) with the respective equation (5) obtained in GR, an extra term occurs in the Jordan frame due to non-minimal coupling between ϕ and the metric functions α, β. As a consequence, we can not relate α and β to rewrite the LTB metric as in the GR scenario. Moreover, the scalar field potential $V(\phi)$ does not affect Eq. (7), but it is included in the remaining field equations. $V(\phi)$ represents an extra degree of freedom with respect to GR, and the dynamics in the Jordan frame deviates from that of the Einstein theory.

3. Perturbation approach in GR and in the Jordan frame

In this Section, we investigate the different evolution of local inhomogeneities within the framework of GR and modified gravity.[4] Here, we stress one important

difference: we can not adopt the LTB metric in the form (6) in the Jordan frame, but we have to refer to the line element in Eq. (4), as motivated in Sec. 2.

Then, we consider the LTB metric to describe local inhomogeneities as small linear perturbations with respect to a flat FLRW metric as background. Hence, we can write all the physical quantities as a background term, denoted with (), plus a linear perturbation, which depends on t and r, and it is denoted with δ. For instance, the energy density is written as $\rho(t,r) = \bar{\rho}(t) + \delta\rho(t,r)$. Similarly, we rewrite the scale factor $a(t,r)$ in GR, the scalar field $\phi(t,r)$, the metric functions $\alpha(t,r)$, and $\beta(t,r)$ in the Jordan frame. We also assume that perturbation terms are small corrections if compared with respective background quantities, i.e. $\delta\rho \ll \bar{\rho}$. Furthermore, we consider $K^2(r)$ in the LTB metric (6) as a linear term, since it is related to inhomogeneities. It should be noted that, comparing the LTB line element (4) and a flat FLRW metric, we have to require two constraints: $\bar{\alpha}(t) = \ln(\bar{a}(t))$ and $\bar{\beta}(t,r) = \ln(\bar{a}(t)\, r)$.

Concerning the scalar-tensor formalism in the Jordan frame, we expand the scalar field potential $V(\phi)$ to the first order in $\delta\phi$. It can be easily checked that the zeroth order term $V\left(\bar{\phi}(t)\right)$ depends only on the background scalar field.[4]

Once we have split background and linear contributions, we focus on the dynamics in the ΛCDM cosmological model and in the Jordan frame gravity. Hence, we rewrite the field equations in GR and in the Jordan frame, separating background and perturbation terms.

3.1. *Comparing background solutions*

To study the time evolution, we define a dimensionless variable $\tau = t/t_0$, where t_0 is the actual time in the synchronous gauge. Note that t_0 is approximately $t_0 \approx 1/H_0$ in terms of the Hubble constant.

In GR, the 00 component of the Einstein equation in the LTB geometry becomes the Friedmann equation in the FLRW metric at background level. We set $\bar{a}_0 = \bar{a}(\tau = 1)$ today, and we neglect relativistic componenents in the late Universe. Hence, we obtain an analytical solution:[4] the evolution of the background scale factor in terms τ is written as

$$\bar{a}(\tau) = \left(\frac{\Omega_{m0}}{\Omega_{\Lambda 0}}\right)^{1/3} \left\{\sinh\left[\frac{3}{2}\sqrt{\Omega_{\Lambda 0}}\,(\tau - 1) + \operatorname{arcsinh}\left(\sqrt{\frac{\Omega_{\Lambda 0}}{\Omega_{m0}}}\right)\right]\right\}^{2/3} . \qquad (8)$$

We used the cosmological density parameters $\Omega_{m0} = \rho_{m0}/\rho_{c0}$, and $\Omega_{\Lambda 0} = \Lambda/\left(\chi\,\rho_{c0}\right)$ for matter and cosmological constant components, respectively, where $\rho_{c0} = 3H_0^2/\chi$ is the actual critical energy density of the Universe. We recall also that $\bar{\rho}(\tau) \propto \bar{a}(\tau)^{-3}$ for a matter component.

In Fig. 1 we plot the deceleration parameter $\bar{q}(\tau) \equiv -\ddot{\bar{a}}/\left(\bar{a}\,\bar{H}^2\right)$, fixing $\Omega_{m0} = 0.3111$ and $\Omega_{\Lambda 0} = 1 - \Omega_{m0}$ from Ref. 3. Here, the dot denotes the derivative with respect to τ. The scale factor $\bar{a}(\tau)$ increases for growing values of τ, and note that $\bar{q} \to -1$ in the future.

We point out that the solution (8) in the ΛCDM cosmological model is viable only at late times ($\tau \gg 10^{-6}$) in the Universe, otherwise we have to include relativistic components, and solve numerically the Friedmann equation.

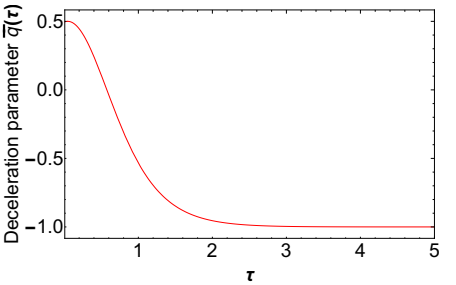

Fig. 1. Background deceleration parameter $\bar{q}(\tau)$ in the FLRW geometry in terms of a dimensionless variable τ. The background scenario in the ΛCDM model are graphically the same comparing it with the one in the $f(R)$ Hu-Sawicki model in the Jordan frame.

Now, we focus on the background field equations in the Jordan frame gravity. Starting from the 01, 00, 11 components of the gravitational field equations in the LTB metric and the scalar field equation, if we do not include local inhomogeneities, we get the respective equation system in the Jordan frame for the background FLRW metric (see the field equations in Ref. 8). We use the Hu-Sawicki model in the Jordan frame, which is characterized by the scalar field potential in Eq. (3).

To solve numerically the equation system, we fix Ω_{m0} at the same value used in the previous study for the ΛCDM model, and we choose[10] $|F_{R0}| = 10^{-7}$ to obtain $c_1 = 2.0 \cdot 10^6$ and $c_2 = 1.5 \cdot 10^5$. We set the free parameters in a way that the Hu-Sawicki model in the Jordan frame is very close to the ΛCDM scenario for the background level. In Fig. 2 note that the scalar field potential (3) exhibits a slow-roll mimicking a cosmological constant.

Finally, we solve numerically the equation system in the Jordan frame,[4] imposing the conditions at $\tau = 1 : \bar{\phi}(1) = 1 - |F_{R0}|$ and $d\bar{\phi}/d\tau\,(1) = 0$. The resulting plot of the deceleration parameter $\bar{q}(\tau)$ are graphically undistinguishable from the respective ones in the ΛCDM model (see Fig. 1). Concerning the evolution of the scalar field, we plot in Fig. 2 the deviation $\left|1 - \bar{\phi}(\tau)\right|$ from the GR limit ($\bar{\phi} = 1$) with a scale 10^{-7}. Note that the dynamics of the Jordan frame is very close to the one in ΛCDM model at the background order for any τ. Now, we can move on to the linearized solutions to highlight the differences between the two cosmological models.

3.2. *Comparing linear solutions*

To examine separately the time and radial evolution of local inhomogeneities, we use the separable variables method at the first-order perturbation theory. So, we

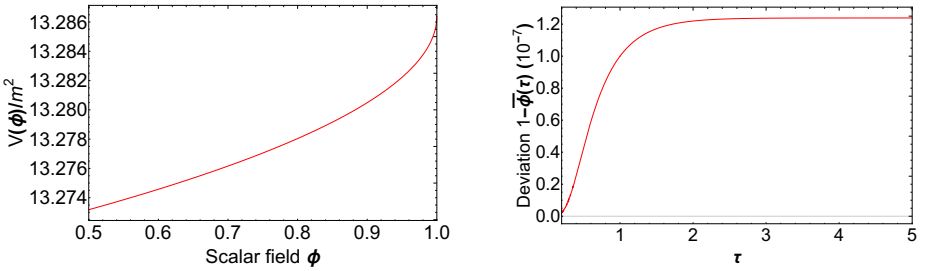

Fig. 2. Plots referred to the Hu-Sawicki model in the Jordan frame, adopting the FLRW metric (background solution). Left panel: scalar field potential of the Hu-Sawicki model in the Jordan frame. Right panel: deviation $|1-\bar{\phi}(\tau)|$ from the GR scenario.

factorize all the linear perturbations into time and radial functions. More specifically, we rewrite the perturbations of the scale factor $\delta a(\tau,r) \equiv \delta \mathfrak{a}(\tau)\, \delta \mathfrak{a}(r)$, the metric functions $\delta\alpha(\tau,r) \equiv \delta A(\tau)\, \delta\mathcal{A}(r)$ and $\delta\beta(\tau,r) \equiv \delta B(\tau)\, \delta\mathcal{B}(r)$, the energy density $\delta\rho(\tau,r) \equiv \delta P(\tau)\, \delta\varrho(r)$, and the scalar field $\delta\phi(\tau,r) \equiv \delta\Phi(\tau)\, \delta\varphi(r)$. The factorization is assumed at the linear level to find analytical solutions, but the separation of variables is not a general method, if we also include non-linear terms.

Then, we investigate the effect of inhomogeneities in the dynamics, according to the cosmological model considered. We focus on the linearized equations in the LTB metric within the framework of the ΛCDM cosmological model.

Using the factorization abovementioned, it is easy to show that the 11 component of the linearized Einstein equations in the LTB metric can be separated in two parts.[4] The radial behavior is $\delta\mathfrak{a}(r) = K^2(r)$,while we have an ordinary differential equation in terms of τ for the time evolution:

$$\delta\ddot{\mathfrak{a}}(\tau) + \frac{\dot{\bar{a}}(\tau)}{\bar{a}(\tau)}\,\delta\dot{\mathfrak{a}}(\tau) - \delta\mathfrak{a}(\tau)\left[\frac{\ddot{\bar{a}}(\tau)}{\bar{a}(\tau)} + \left(\frac{\dot{\bar{a}}(\tau)}{\bar{a}(\tau)}\right)^2\right] = 0\,. \tag{9}$$

This equation is solved numerically, once you specify the background solution (8). We impose the following conditions at $\tau = 1$ today: $\delta\mathfrak{a}(1) = 10^{-5}$ and $\delta\dot{\mathfrak{a}}(1) = 0$. In Fig. 3 we plot the numerical solution, after we have defined the ratio $\eta(\tau)$ between the perturbed scale factor and the background respective quantity, namely $\eta(\tau) \equiv |\delta\mathfrak{a}(\tau)\,/\,\bar{a}(\tau)|$. Note that the perturbations of the scale factor remain stable, since the background scale factor $\bar{a}(\tau)$ dominates for any τ in the late Universe, i.e. $\eta \ll 1$.

After that, we consider the 00 component of the linearized Einstein equations in the LTB metric, and we combine it with the continuity equation. After long but straightforward calculations,[4] we obtain $\delta\mathfrak{a} \propto 1/r^3$ in GR. According to the cosmological principle, inhomogeneities decay for increasing values of r. Furthermore, we also obtain that the perturbation of the energy density for a matter component follows the same dependence of the respective background quantity in the FLRW metric, namely $\delta P(\tau) \propto 1/\bar{a}^3(\tau)$. However, we can provide $\delta P(\tau) \ll \bar{\rho}(\tau)$ at any times, setting the constant of integration.

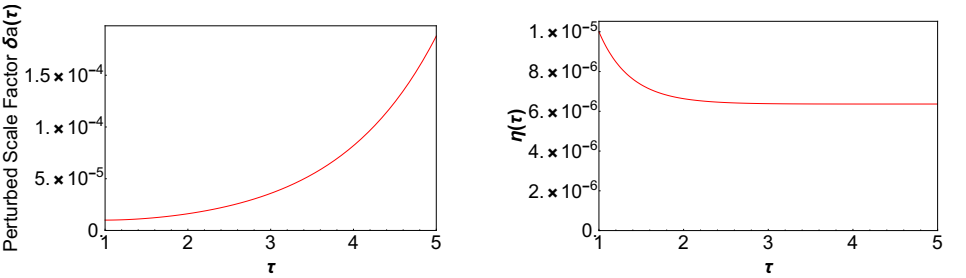

Fig. 3. Left panel: time evolution of the linear perturbation of the scale factor $\delta \mathrm{a}(\tau)$. Right panel: the ratio between the linear deviation and background scale factor.

Now, we repeat the same approach in the modified gravity dynamics in the Jordan frame, considering the corresponding linearized field equations in the LTB metric. Expanding the scalar field potential and its derivative around the background scalar field, as mentioned at the beginning of Sec. 3, it can be proved that the potential $V(\phi)$ is involved only in the time evolution of the linearized field equations.[4] As a result, we expect that the radial evolution of local inhomogeneities is completely independent of the choice of a particular $f(R)$ model, since $V(\phi)$ is directly related to $f(R)$.

In what follows, we do not focus on the time evolution of perturbations, but we just mention that we find a numerical solution using again the Hu-Sawicki model (Sec. 1), and we have checked that inhomogeneous perturbations remain smaller than respective background contribution for any time τ.

To obtain an analytical solution for the radial part with the separable variables method, we assume two simplifying conditions: $\delta \dot{A}(\tau) = \delta \dot{B}(\tau)$ and $\delta \varrho(r) \propto \delta \varphi(r)$. After long but straightforward calculations,[4] combining the linearized field equations, we obtain a Yukawa-like solution for the radial part of the linear perturbation of the scalar field

$$\delta \varphi(r) = \frac{C}{r} \exp\left(-\frac{r}{r_c}\right), \tag{10}$$

where C and r_c are constants. We also have a similar behavior for $\delta \mathcal{A}(r)$ and $\delta \mathcal{B}(r)$. It should be emphasized that modified gravity introduces a typical spatial scale, r_c, such that for $r \gg r_c$ the inhomogeneities decay faster than ones in GR. We stress again that this kind of solutions applies to any $f(R)$ model, and the radial evolution is different from the one in GR.

4. Summary and conclusions

We have investigated local inhomogeneities in the LTB metric regarded as small deviations from a flat FLRW background metric. To date, there are no modified gravity models that predict significant deviations from GR, reconciling all possible cosmological data. Hence, to try to discriminate between several cosmological

models, it is crucial to test gravity in different regimes or by using other techniques. Here, we have suggested one possible method, studying the different dynamics of inhomogeneous perturbations. Our results have pointed out a distinctive element in the evolution of local inhomogeneities of the Universe from a theoretical point of view, allowing to distinguish between the ΛCDM cosmological model and $f(R)$ modified gravity theories. We have shown that the radial evolution of inhomogeneous perturbations within the framework of the Jordan frame gravity is independent of the scalar field potential $V(\phi)$: the distinctive radial solution is a feature of any $f(R)$ model, and the radial behavior is completely different from the one in GR. This work may be an interesting arena to account for the effects of local inhomogeneities in cosmological observables,[15] when forthcoming missions such as Euclid Deep Survey,[16] will be able to test the large-scale properties of the Universe.

Soft dark energy and soft dark matter

Emmanuel N. Saridakis
National Observatory of Athens, Lofos Nymfon, 11852 Athens, Greece
E-mail: msaridak@noa.gr

We present "soft cosmology", namely we investigate small deviations from the usual framework due to the effective appearance of soft-matter properties in the Universe sectors. One effect of such a case would be the dark energy to exhibit a different equation-of-state parameter at large scales (which determine the universe expansion) and at intermediate scales (which determine the sub-horizon clustering and the large scale structure formation). Concerning soft dark matter, we show that it can effectively arise due to the dark-energy clustering, even if dark energy is not soft. We propose a novel parametrization introducing the "softness parameters" of the dark sectors. As we see, although the background evolution remains unaffected, due to the extreme sensitivity and significant effects on the global properties even a slightly non-trivial softness parameter can improve the clustering behavior and alleviate e.g. the $f\sigma_8$ tension.

Keywords: Dark energy; Dark matter; Cosmological perturbations; Growth rate; σ_8 tension; MG16 Proceedings.

1. Introduction

Standard cosmology has been proven very efficient, qualitatively and quantitatively, in describing the Universe evolution and properties at early and late times, as well as at large and small scales. Nevertheless, since cosmology has now become an accurate science, with the appearance of a huge amount of data of progressively increasing precision, slight disagreements, deviations and tensions between theory and observations lead to a large variety of extensions and modifications of the concordance paradigm (a procedure that might be assisted by purely theoretical investigation).

Although in the usual ways of extensions one may add various novel fields, fluids, sectors and their mutual interactions,[1,2] or alter the underlying gravitational theory,[3–5] there is a rather strong assumption that is maintained in all of them, namely that the sectors that constitute the Universe are simple, or equivalently that one can apply the physics, the hydrodynamics and thermodynamics of usual, "hard" matter. Nevertheless, in condensed matter physics it is well known that there is a large variety of "soft" matter forms, which are characterized by complexity, simultaneous co-existence of phases, entropy dominance, extreme sensitivity, viscoelasticity, etc, properties that arise effectively at intermediate scales due to scale-dependent effective interactions that are not present at the fundamental scales.[6,7]

In this work, based on,[8] we examine the possibility of "soft cosmology", namely small deviations from the usual framework due to the effective appearance of

soft-matter properties in the Universe sectors. We mention that due to the extreme sensitivity and significant effects of softness on the global properties, one does not need to consider a large deviation from standard considerations, since even a very slight departure would be adequate to improve the observed cosmological behavior at the required level. Finally, we stress that new fundamental physics is not directly needed, since the dark energy dynamical evolution and clustering, which is a widely accepted possibility in many scenarios beyond ΛCDM paradigm, is adequate to effectively induce the soft behavior.

2. Standard Cosmology

Let us briefly present the basics of cosmology.[9] The cosmological principle (the universe is homogeneous and isotropic at large scales) allows to consider the Friedmann-Robertson-Walker (FRW) metric $ds^2 = dt^2 - a^2(t)\,\delta_{ij}dx^i dx^j$. Concerning the universe content, one considers the usual baryonic matter and radiation (i.e. all Standard Model particles), the dark matter sector, as well as the dark energy sector. The microphysics of dark matter is unknown, and its source may be most probably some particle(s), however it may arise from black holes, from modified gravity, or even from a combination of the above, i.e. a multi-component dark matter.[10] The microphysics of dark energy is unknown too, and it may arise from new fields or matter forms in the framework of general relativity, or it may have an effective nature of gravitational origin due to modifications of gravity.

The next step is to consider that (at least after a particular stage of the universe evolution) cosmological scales are suitably large in order to allow one to neglect the microphysics of the universe ingredients and describe them effectively through fluid dynamics and continuum flow (at earlier stages one should use the Boltzmann equation). Hence, one can ignore the microscopic Lagrangian of the various sectors, and write their energy momentum tensors as $T^{(i)}_{\mu\nu} = (\rho_i + p_i)u_\mu u_\nu + p_i g_{\mu\nu}$, with ρ_i and p_i the energy density and pressure of the fluid corresponding to the i-th sector, u_μ the 4-velocity vector field and $g_{\mu\nu}$ the metric. Note that one can extend the above expression by including viscosity or/and heat flux.

Under the above considerations, any cosmological scenario will be determined by the two Friedmann equations

$$H^2 = \frac{\kappa^2}{3}(\rho_b + \rho_r + \rho_{dm} + \rho_{de}), \tag{1}$$

$$2\dot{H} + 3H^2 = -\kappa^2(p_b + p_r + p_{dm} + p_{de}), \tag{2}$$

with $\kappa^2 = 8\pi G$, and where $H \equiv \dot{a}/a$ is the Hubble parameter. We mention that the above equations are of general validity, holding for every model of dark matter and dark energy. Additionally, the conservation equation $\nabla^\mu T^{(tot)}_{\mu\nu} = \nabla^\mu \left[\sum_i T^{(i)}_{\mu\nu}\right] = 0$ in the case of FRW geometry and for non-interacting fluids gives rise to the separate conservation equations $\dot{\rho}_i + 3H(\rho_i + p_i) = 0$, while the extension to interacting

cosmology can be realized through phenomenological descriptors Q_i of the interaction with $\sum_i Q_i = 0$ and with $\dot{\rho}_i + 3H(\rho_i + p_i) = Q_i$.

In order for the equations to close we need to impose the equation of state for each sector. The usual consideration is to assume barotropic fluids, in which the pressure is a function of the energy density only, with the simplest case being $p_i = w_i \rho_i$ with w_i the equation-of-state parameter. Lastly, note that the above framework provides ΛCDM cosmology for $\rho_{de} = -p_{de} = \Lambda/\kappa^2$, with Λ the cosmological constant.

The above formulation of cosmological evolution allows one to proceed to a more subtle investigation, and study small perturbations around the FRW background. Focusing without loss of generality to the linear theory of scalar isentropic perturbations in the Newtonian gauge, imposing $ds^2 = -(1+2\Psi)dt^2 + a^2(t)(1-2\Phi)\gamma_{ij}dx^i dx^j$, then in a general non-interacting scenario which includes the aforementioned sectors the scalar perturbations are determined by the equations[11,12]

$$\dot{\delta}_i + (1+w_i)\left(\frac{\theta_i}{a} - 3\dot{\Psi}\right) + 3H[c_{\rm eff}^{(i)2} - w_i]\delta_i = 0, \tag{3}$$

$$\dot{\theta}_i + H\left[1 - 3w_i + \frac{\dot{w}_i}{H(1+w_i)}\right]\theta_i - \frac{k^2 c_{\rm eff}^{(i)2}\delta_i}{(1+w_i)a} - \frac{k^2\Psi}{a} = 0, \tag{4}$$

assuming zero anisotropic stress and with k the wavenumber of Fourier modes (in the case of ΛCDM paradigm the corresponding dark-energy perturbation equations are not considered). In the above equations $\delta_i \equiv \delta\rho_i/\rho_i$ are the density perturbations and θ_i is the divergence of the fluid velocity. Furthermore, $c_{\rm eff}^{(i)2} \equiv \delta p_i/\delta\rho_i$ is the effective sound speed square of the i-th sector (it determines the amount of clustering). Note that the above equations can be simplified through the consideration of the Poisson equation, which at sub-horizon scales can be written as:[11,12]

$$-\frac{k^2}{a^2}\Psi = \frac{3}{2}H^2 \sum_i \left[\left(1 + 3c_{\rm eff}^{(i)2}\right)\Omega_i\delta_i\right]. \tag{5}$$

Finally, we note here that in general the above formulation can be applied also in the cases where the dark energy sector is an effective one arising from gravitational modifications.

We close this section by mentioning that one can find a big variety and many versions of the above formalism. However, there is a rather strong assumption that is maintained in all of them, namely that the sectors that constitute the Universe are simple, or equivalently that one can apply the physics of usual matter. In particular, the underlying assumption is that the laws that determine the Universe behavior at large scales can be induced by the laws that determine the interactions between its individual constituents. Focusing on the hydrodynamic description, the use of fluid energy densities and pressures arises from the assumption that we can define fundamental "particles" of the corresponding sector, the collective flow of which gives rise to ρ_i and p_i, while all physics below the particle scale has been integrated out.

3. Soft Cosmology

The above formulation of standard cosmology is definitely correct and can provide a quite successful quantitative description of the Universe evolution. However, the question is: could it miss something on the details?

One source of possible information loss is the assumption that the Universe sectors and interactions are simple and more or less scale-independent. For instance, two regions of the dark-matter fluid will mutual interact in the same way in the intermediate- and late-time universe, or the interaction of two big clusters of dark matter can arise by the superposition of all individual interactions of their sub-clusters, etc. In other words, in the concordance cosmological formulation one assumes that the sectors that constitute the Universe behave as usual, "hard" matter.

"Soft" matter is a research field that has attracted a large amount of interest of the condensed matter community,[6,7] since it has very interesting and peculiar properties far different than those of hard matter. The problem is that there is not a definition of what is soft matter. In particular, the best definition we have is that soft matter is the one that has the properties of soft materials. Examples of soft materials are the polymers (plastic, rubber, polystyrene, lubricants etc), the colloids (paints, milk, ice-cream etc), the surfactants, granular materials, liquid crystals, gels, biological matter (proteins, RNA, DNA, viruses, etc), etc. Although these examples of soft matter are very different from each other, they have some common properties and features that distinguish them from usual, hard, matter. Amongst others these include complexity (new qualitative properties arise at intermediate scales due to interactions that are not present at the fundamental scales), co-existence of phases (they have different phase properties depending on the scale at one examines them, e.g at the same time they can be fluid at small scales and solid at large scales), entropy dominance instead of energy dominance, flexibility, extreme sensitivity to reactions, viscoelasticity (they exhibit viscous and elastic properties simultaneously) etc.

In the following we examine the possibility that the dark sectors of the universe may exhibit (intrinsically or effectively) slight soft properties, which could then lead to small corrections to the corcodance model. We mention here that the discussion below holds independently of the underlying gravitational theory, i.e it is valid both in the framework of general relativity as well as in modified gravity, nevertheless in the latter case we have richer possibilities to obtain scale-dependent interactions.

3.1. *A. Soft Dark Energy*

The nature and underlying physics of dark energy is unknown. The basic framework that has been studied in extensive detail is that the dark energy fluid has the same fluid properties at all scales at a given moment/redshift. However, as we saw, in soft matter the complexity that arises at intermediate scales may lead the material to have a different equation of state (EoS) at different scales simultaneously.

As a simple phenomenological model of soft dark energy we may consider the case where dark energy has the usual EoS at large scales, namely at scales entering the Friedmann equations, but having a different value at intermediate scales, namely at scales entering the perturbation equations. In this case the Universe's expansion history will remain identical to standard cosmology, nevertheless the large-scale structure evolution can deviate from the standard one and can be brought closer to observations. In summary one can obtain richer behavior. We mention that in the following we focus on sub-horizon scales $k \gg aH$ and thus to perturbation modes affected only by the intermediate-scale dark-energy EoS. The full analysis, in which different perturbation modes are affected by different EoS according to their scale, will be presented elsewhere.

A first approach on the subject would be to introduce the effective "softness parameter" s_{de} of the dark energy sector. This implies that while at cosmological, large scales (ls) dark energy has the usual EoS, namely w_{de-ls}, at intermediate scales (is) we have[8]

$$w_{de-is} = s_{de} \cdot w_{de-ls}, \tag{6}$$

and standard cosmology is recovered for $s_{de} = 1$.

For instance let us assume that the large-scale dark energy EoS w_{de-ls} is a constant one $w_{de-ls} = w_0$ or e.g. the CPL one $w_{de-ls} = w_0 + w_a(1-a)$. According to (6) at intermediate scales the dark energy EoS w_{de-is} is different, either constant $w_{de-is} = w_2$ or time-varying. Hence, the background Universe evolution will remain the same, however since $c_{\rm eff}^{(de)}$ will change, through the Poisson equation and (3),(4) we will acquire a different evolution for the matter overdensity δ_m. Hence, the resulting $f\sigma_8 \equiv f(a)\sigma(a)$ value, with $f(a) = d\ln\delta_m(a)/d\ln a$ and $\sigma(a) = \sigma_8\delta_m(a)/\delta_m(1)$, will be different than the corresponding one of standard cosmology with the above dark energy EoS (note that since the background behavior remains unaffected we do not need to worry about incorporating fiducial cosmology.[13] As we observe, we have a straightforward way to alleviate the σ_8 tension since we can suitably adjust w_{de-is} in order to obtain slightly lower $f\sigma_8$. As a specific example in Fig. 1 we depict the $f\sigma_8$ as a function of z. The dashed curve is for ΛCDM. The solid curve is for soft dark energy with $s_{dm} = 1.1$, i.e. with $w_{de-is} = -1.1$, and $c_{\rm eff}^{(de)} = 0.1$, while dark matter is the standard one (i.e. not soft) with $w_{dm} = 0$. Note that in principle s_{de} can be varying too and one could introduce its parametrization, or one could additionally have more complicated situations in which w_{de-is} and w_{de-ls} have different parametrizations. In this first approach on soft dark energy we consider the simplest case of (6).

Finally, note that soft materials may exhibit different EoS properties not only at different scales, but at different directions too. In this case, one may think of a dark energy sector that has a different EoS at different directions, namely an anisotropic dark energy. However, such an analysis would require to deviate from FRW and consider explicitly anisotropic geometries such as the Bianchi ones. We will study this possibility in a separate work.

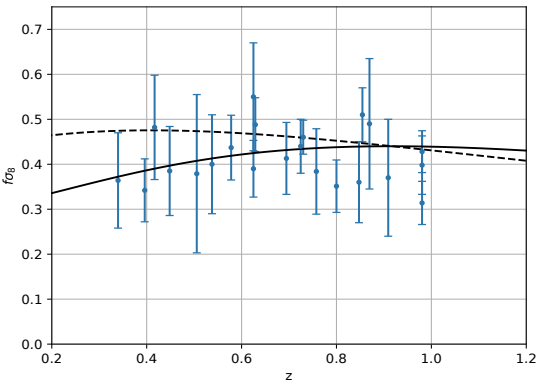

Fig. 1. The $f\sigma_8$ as a function of z. The dashed curve is for ΛCDM. The solid curve is for soft dark energy with $s_{de} = 1.1$, i.e. with $w_{de-ls} = -1$ and $w_{de-is} = -1.1$, and $c_{\rm eff}^{(de)} = 0.1$, while dark matter is standard (i.e. not soft) with $w_{dm} = 0$.

3.2. *B. Soft Dark Matter*

In this subsection we examine the possibility that the dark matter sector exhibits soft properties. In the framework of general relativity the gravitational interaction of dark matter with itself or with baryonic matter cannot produce internal complexity (unless the unknown microphysics of dark matter does impose an intrinsic soft structure). However, even if it is not intrinsic, soft behavior in the dark matter sector can still arise in an effective way due to the presence of non-trivial dark energy. Specifically, if the dark energy is clustering then, even if dark energy is not intrinsically soft, it will induce scale-dependent, qualitatively different intermediate structures in the dark matter clustering, at scales similar to the dark energy clusters. In particular, the interaction between two dark-matter clusters below the dark-energy clustering scale (i.e. two dark-matter clusters with sparse dark energy between them) will be different from the interaction between two dark-matter clusters with a dark-energy cluster between them. Hence, one will have the effective appearance of screening effects at intermediate scales, and thus of complexity (this is the standard way that complexity appears in the colloids, namely due to the non-trivial, scale-dependent structure of the bulk between them). In summary, one could have a dark matter sector which at large scales, namely at scales entering the Friedmann equations, behaves in the usual dust way, but which at intermediate scales, namely at scales entering the (sub-horizon) perturbation equations, it could slightly deviate from that.

We can introduce the dark matter softness parameter s_{dm} (standard cosmology is recovered for $s_{dm} = 1$) as:

$$w_{dm-is} + 1 = s_{dm} \cdot (w_{dm-ls} + 1), \tag{7}$$

(mind the difference in the parametrization comparing to soft dark energy, in order to handle the fact that the dark matter EoS at large scales w_{dm-ls} is 0). Similarly to the example of the previous subsection, the background evolution will remain identical with that of standard cosmology, but the perturbation behavior (at sub-horizon scales) and the large-scale structure can be improved. In order to provide a specific example, in Fig. 2 we depict the $f\sigma_8$ as a function of z, in the case of soft dark matter with $w_{dm-is} = 0.05$, i.e for dark matter with softness parameter $s_{dm} = 1.05$.

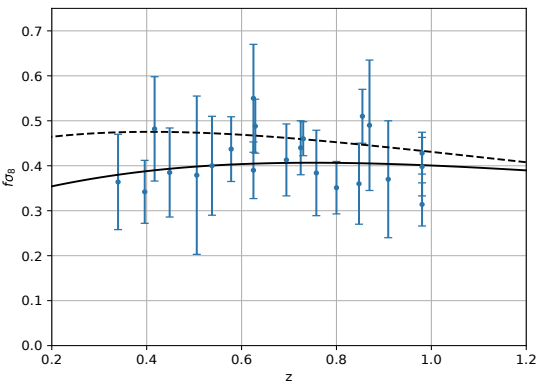

Fig. 2. The $f\sigma_8$ as a function of z. The dashed curve is for ΛCDM. The solid curve is for soft dark matter with softness parameter $s_{dm} = 1.05$, i.e. for dark matter with $w_{dm-ls} = 0$ and $w_{dm-is} = 0.05$ (note that dark energy is not soft).

In the above analysis we did not consider the dark energy sector to be soft. Definitely, proceeding to such a possibility would make the induced soft bahavior for dark matter easier. Moreover, this would be the case if one considers a mutual interaction between dark matter and dark energy too, since a different than usual dark-energy clustering behavior would be transferred to a different than usual dark-matter clustering behavior, due to the interaction. Finally, deviating from general relativity would provide additional possibilities to induce effective soft properties to the dark matter sector, since dark matter will implicitly interact in a scale-dependent way (one would have the additional screening behavior due to the extra (scalar) graviton degrees of freedom that dress the dark matter in a scale-dependent way, altering its self-interaction[16]).

Let us make a comment here on the clustering features. The clustering behavior of soft matter has been extensively studied, and indeed it has been shown that the resulting spectrum, factorial moments, fractal dimension, etc, depend on the specific intermediate-scale features. For instance the fractal dimension has been experimentally found to cover all the range from 1 to 3 according to different materials (e.g. colloids of gold nanoparticle in aqueous media give $d_f = 1.75 \pm 0.05$ for

diffusion-limited kinetics and $d_f = 2.01 \pm 0.10$ for reaction-limited kinetics)[17,18]). On the other hand, the large scale structure and the galaxy distribution in the Universe has a fractal dimension $d_f = 1.63 \pm 0.20$.[19,20] The fact that soft matter clustering exhibits naturally non-trivial dynamics due to its intermediate-scale complexity, could be useful in describing the details of the observed large-scale structure. We mention here that the non-trivial clustering of soft matter changes at scales below the intermediate ones, and hence soft dark matter could alleviate the cuspy halo problem,[21] the dwarf galaxy problem,[22] and other clustering-related problems that seem to puzzle the standard collisionless dark matter.

4. Conclusions

We examined the possibility of "soft cosmology", namely small deviations from the usual framework due to the effective appearance of soft properties in the Universe sectors. We started by considering the possibility of soft dark energy due to intermediate-scale features that could arise from its unknown microphysics. One effect of such a case would be the dark energy to exhibit a different EoS at large and intermediate scales. As we saw, although the background evolution remains unaffected, even a slight softness at intermediate scales can improve the clustering behavior and alleviate e.g. the $f\sigma_8$ tension.

We proceeded to the examination of soft dark matter, which can effectively arise just due to the dark-energy clustering even if dark energy is not soft. By considering a slightly different equation of state at large and intermediate scales we were able to improve the clustering behavior. Furthermore, in the additional incorporation of soft dark energy, and/or modified gravity, the effective soft properties of dark matter could be richer, due to the extra screening mechanisms.

We mention that in this work we incorporated softness by phenomenologically introducing a slightly different EoS at different scales. Clearly, in order to incorporate complexity and estimate the scale-dependent behavior of the equation of states from first principles one should revise and extend the cosmological perturbation theory and perform a detailed mesoscopic statistical mechanical analysis. Such a full investigation is necessary and would provide a robust argumentation in favour of soft cosmology.

We proposes a phenomenological generalisation of the standard model with only one extra degree of freedom that parametrises the evolution of a scalar field responsible for the cosmic acceleration. The model also foresees an additional parameter in the form of a coupling between dark energy and dark matter. This model captures a large diversity of dark energy evolutions at low redshift and could usefully complement common CPL parametrisations widely used. In this context, we have been constraining the parametrisation with data from Planck and KiDS, bringing different results between the early and late universe observations.

Keywords: Quintessence, dark matter, observational cosmology.

1. Introduction

The discovery in 1998 that the Universe is accelerating[1,2] was really stunning at the time. While the source of the cosmic acceleration is yet to be unveiled, the existence of a dark energy component has been postulated to explain it.[3,4] In the standard model, dark energy takes the form of a cosmological constant Λ which by definition possesses a constant energy density and negative pressure that fights the attractive pull of matter.[5] That model is, at the moment, compatible with all observations and it is the simplest one,[6] at least from a parametrisation point of view. One of the outstanding issue in the concordance model is the so-called coincidence problem.[7] Given how the energy densities dilute with the expansion, the fact that the cosmological constant is catching up with matter at the present time necessitates initial conditions at the origin that are dramatically precise. This issue has been paving the way to study varying dark energy[8] in order to reproduce more dynamically the current abundances.

The simplest and model independent approach is phenomenological. It consists in parametrising the dark energy equation of state, being the pressure over the energy density that equals -1 for a cosmological constant. The detection of a time dependence would exclude a cosmological constant. Introducing the fewest

possible parameters is ideal to limit degeneracies between them. A simple and popular parametrisation[9] is a Taylor expansion at first order which has a very limited domain of validity. Various improvements have been introduced, like the Chevallier-Polarski-Linder (CPL) parametrisation.[10,11] Also, to account for the possibility of early dark energy, a parametrisation stepwise in redshift[12] has been proposed with a larger number of additional parameters.

Here, we explore an alternative way to parametrise dark energy by proposing to parametrise a scalar field ϕ called quintessence that would be responsible for dark energy both in the early and late Universe.[13] Instead of setting an equation of state parameter evolution, or a scalar potential, this method parametrises the dark energy scalar field itself. We argue that with a single parameter we recover the generic behaviour of the previous parametrisations. We test this approach with data from Planck and KiDS to constrain its specific parameters, identifying contrasting results between the early and late universe observations. This is a comprehensive work going from the analytical solutions to parameter constraints.

2. Scalar field parametrisation

We consider that the cosmological fluid is composed of matter (m), i.e. baryons (b) and cold dark matter (c), as well as the scalar field itself in a flat Friedmann-Lemaitre-Robertson-Walker background. The scalar field is supposed to be canonical and homogeneous at large scale,[14,15] approximated by a perfect fluid. We choose to work with the number of e-folds, $N \equiv \ln a$, as the time variable. In the following, the prime stands for the derivative with respect to the number of e-foldings, and the dot the derivative with respect to cosmic time.

By combining the Friedmann equation,

$$H^2 = \frac{\kappa^2}{3}\left(\rho_b + \rho_c + \rho_\phi\right), \tag{1}$$

with the continuity equation of the scalar field,

$$\rho'_\phi + 3H^2\phi'^2 = 0, \tag{2}$$

and the continuity equation of matter,

$$\rho'_c + 3\rho_c = 0, \tag{3}$$

one obtains[16] a differential equation for the dark energy density (where we conventionnally set $\kappa = 1$),

$$\frac{\rho'_\phi}{\rho_{m_0}} = -\phi'^2\left(a^{-3} + \frac{\rho_\phi}{\rho_{m_0}}\right), \tag{4}$$

whose general solution is our starting point,

$$\frac{\rho_\phi}{\rho_{m_0}} = e^{-\int_0^N dN\phi'^2} \times \left[\frac{\Omega_{\phi_0}}{\Omega_{m_0}} - \int_0^N dN\phi'^2 e^{-3N+\int_0^N dN\phi'^2}\right]. \tag{5}$$

Among possible parametrisations enabling us to solve the former equation analytically,

$$\phi' = \epsilon\phi, \tag{6}$$

$$\phi' = \sigma\phi^{-1}, \tag{7}$$

$$\phi' = \lambda, \tag{8}$$

where ϵ, σ and λ are given constants, we explore the simplest one in Eq. (8).[16]

The advantage of this parametrisation is three folds. Firstly, it is very simple, as we only add one single parameter to extend the standard model. It allows to reconstruct analytically the form of the potential,[16]

$$V(\phi) = A\, e^{-\frac{3}{\lambda}\phi} + B\, e^{-\lambda\phi}, \tag{9}$$

with the following mass scales,

$$A = \frac{3}{2}\frac{\lambda^2}{3-\lambda^2} H_0^2\, \Omega_{m_0}\, e^{\frac{3}{\lambda}\phi_0}, \tag{10}$$

$$B = \frac{3}{2}\frac{\lambda^2-6}{3-\lambda^2} H_0^2 \left(\frac{\lambda^2}{3} - \Omega_{\phi_0}\right) e^{\lambda\phi_0}, \tag{11}$$

where H_0 is today's Hubble expansion rate and $\Omega_{i_0} = \rho_{i_0}/3H_0^2$ today's abundance parameter of species i. Having a simple form of the potential allows a straightforward implementation of the model within the existing Boltzmann code CLASS[17,18] that can be validated by comparing the numerical results with the expected asymptotic behaviour of the analytic expressions. Given the small number of parameters involved and thanks to its simplicity, our analysis permits to effectively constrain the model parameters with current data as in the next section.

Secondly, this scalar potential, being the sum of two exponential terms, does alleviate the severe fine-tuning of the initial conditions as illustrated in Fig. 1. For small values of the parameter λ, when the first exponential term in the potential is steep enough, the scalar field energy density is attracted and temporarily scales with the background as the universe expands, be it dominated by radiation and then matter. Later, thanks to the second shallow exponential, whose slope is the inverse of the first one, the scalar field energy density eventually freezes, mimicking a cosmological constant. By freezing, dark energy overcomes matter at late time, enabling the acceleration of the universe that we are currently experiencing. This well-known attractor mechanism[19] ensures that one can start from a large domain of initial conditions for the scalar field, to reach unavoidably the tracking solution and end up with the correct order of magnitude both during matter and dark energy domination.

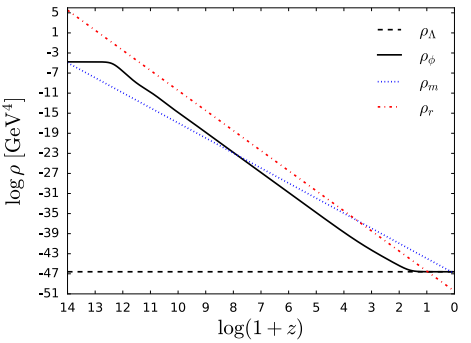

Fig. 1. Energy density dilution of a cosmological constant, as well as quintessence, matter and radiation for the scalar field parametrisation ($\lambda = 0.01$).

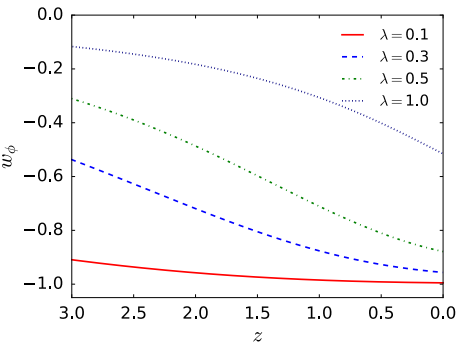

Fig. 2. Dynamics of the dark energy equation of state for given values of the parameter λ.

Last but not least, despite just one extra parameter, the model covers a wide range of possible dark energy evolution at low redshift as displayed in Fig 2. The parametrisation is thus able to capture a large variety of possible dynamics for dark energy. The observational data might even become precise enough in the future for discriminating between these different evolutions.

As a step further, we decide to complement our parametrisation by assuming a non-minimally coupling between dark energy and cold dark matter.[20] Again for the sake of simplicity, we consider a conformal and constant coupling β that parametrises the interaction between dark matter and the scalar field. The stress-energy tensor is jointly conserved within the dark sector in order to ensure the covariance of the theory,

$$\nabla_\mu \left(T^{(\phi)}{}^{\mu}_{\nu} + T^{(c)}{}^{\mu}_{\nu} \right) = 0, \tag{12}$$

$$\nabla_\mu T^{(\phi)}{}^{\mu}_{\nu} = +\beta \rho_c \nabla_\mu \phi, \tag{13}$$

$$\nabla_\mu T^{(c)}{}^{\mu}_{\nu} = -\beta \rho_c \nabla_\mu \phi. \tag{14}$$

Assuming that dark energy does not interact with baryons, the latter are separately conserved contrary to dark matter and quintessence,

$$\rho_b = \rho_{b_0}\, e^{-3N}, \tag{15}$$

$$\rho_c = \rho_{c_0}\, e^{-3N+\beta(\phi-\phi_0)}, \tag{16}$$

$$\rho'_\phi + 3H^2\phi'^2 = -\beta\phi'\rho_c. \tag{17}$$

The sign of the product $\beta\phi'$, i.e. $\beta\lambda$ in our parametrisation, determines whether energy is being pumped from the scalar field or from dark matter. Similarly to Ref. 16, we use the Friedmann equation (1) with the solution we find for the scalar field energy density,

$$\begin{aligned}\rho_\phi = &\left(\rho_{\phi_0} + \frac{\lambda^2+\beta\lambda}{\lambda^2+\beta\lambda-3}\,\rho_{c_0} + \frac{\lambda^2}{\lambda^2-3}\,\rho_{b_0}\right) e^{-\lambda^2 N} \\ &- \frac{\lambda^2+\beta\lambda}{\lambda^2+\beta\lambda-3}\,\rho_{c_0}\, e^{(\beta\lambda-3)N} - \frac{\lambda^2}{\lambda^2-3}\,\rho_{b_0}\, e^{-3N},\end{aligned} \tag{18}$$

to reconstruct, for the first time, the corresponding potential with similar properties of the dynamical system as in the minimally coupled case,

$$V(\phi) = A\, e^{\left(-\frac{3}{\lambda}+\beta\right)\phi} + B\, e^{-\lambda\phi} + C\, e^{-\frac{3}{\lambda}\phi}, \tag{19}$$

where the mass scales are now the following,

$$A = \frac{3}{2}\,\frac{\lambda^2+2\beta\lambda}{3-\lambda^2-\beta\lambda}\; H_0^2\,\Omega_{c_0}\, e^{\left(\frac{3}{\lambda}-\beta\right)\phi_0}, \tag{20}$$

$$B = \frac{6-\lambda^2}{2}\, H_0^2 \left(1 + \frac{3}{\lambda^2-3+\beta\lambda}\Omega_{c_0} + \frac{3}{\lambda^2-3}\Omega_{b_0}\right) e^{\lambda\phi_0}, \tag{21}$$

$$C = \frac{3}{2}\,\frac{\lambda^2}{3-\lambda^2}\; H_0^2\,\Omega_{b_0}\, e^{\frac{3}{\lambda}\phi_0}. \tag{22}$$

We modify the CLASS code to accommodate that potential as well as the coupled equations (16) and (17) to simulate the model with the two additional parameters λ and β. The numerical results plotted in Fig. 3 are in line with the asymptotic solution for the dark energy equation of state during matter domination when baryonic matter is neglected,

$$w_\phi \approx -\frac{\beta}{\lambda+\beta}. \tag{23}$$

One can note that today's equation of state, w_0, does not depend on the coupling, and drops close to -1 during the scalar field dominated epoch for small values of λ,

$$w_{_0} = -1 + \frac{\lambda^2}{3\Omega_{\phi_0}}. \tag{24}$$

Furthermore, in order to numerically predict observables that we use to constrain the parameters with observational datasets at the perturbative level, we again modify CLASS to implement the coupled evolution of the scalar fluctuations at linear

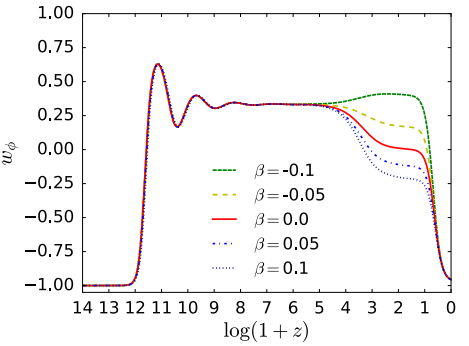

Fig. 3. Dark energy evolution in the coupled parametrisation. Beta negative corresponds to the transfer of energy from the dark matter component to the scalar field.

level in the synchronous gauge adopting usual conventions.[21] We modify the existing perturbed Klein-Gordon equation, as well as the equation of motion for the dark matter density contrast δ_c and velocity perturbations θ_c to account for the coupling, by adding the relevant sources term in the right-hand side,

$$\ddot{\varphi} + 2\mathcal{H}\dot{\varphi} + \left(k^2 + a^2 V_{,\phi\phi}\right)\varphi + \frac{\dot{h}\dot{\phi}}{2} = -\beta a^2 \bar{\rho}_c \delta_c, \tag{25}$$

$$\dot{\delta}_c + \theta_c + \frac{\dot{h}}{2} = \beta\dot{\varphi}, \tag{26}$$

$$\dot{\theta}_c + \mathcal{H}\theta_c = \beta\left(k^2\varphi - \dot{\phi}\theta_c\right), \tag{27}$$

where the overbar denotes the background quantities. Additionally, we adapt the transformation from the synchronous gauge into the comoving gauge to maintain the matter density source function δ_m gauge-invariant,

$$\delta_m^C = \frac{\delta\rho_m}{\bar{\rho}_m} + \left(3 - \frac{\beta\phi'\bar{\rho}_c}{\bar{\rho}_c + \bar{\rho}_b}\right)\frac{\mathcal{H}}{k^2}\theta_m. \tag{28}$$

In parallel, to provide for the code validation, we derive the analytic equation of motion of the dark matter fluctuations in the Newtonian limit during the domination of matter, precisely when the coupling makes a difference,

$$\delta_c'' + \frac{1}{2}\left(1 + 3\lambda\beta\right)\delta_c' - \frac{3}{2}\left(1 - \frac{\lambda^2}{3} - \frac{\lambda\beta}{3}\right)\left(1 + 2\beta^2\right)\delta_c = 0. \tag{29}$$

In the left panel of Fig 4, we note that the scalar field slows the growth of perturbations against the standard model, by decreasing the dynamical term in the equation of motion. On the other hand, the existence of the coupling brings competitive effects that further slow the fluctuation or, on the contrary, accelerate them, depending on whether energy is being transferred from the scalar field or into it. We are also able to get an analytic expression of the growth rate $m+$ under the

Newtonian approximation,

$$m_+ = \frac{1}{4}\left[-1 - 3\lambda\beta + \sqrt{24\left(1 - \frac{\lambda^2}{3} - \frac{\lambda\beta}{3}\right)(1 + 2\beta^2) + (1 + 3\lambda\beta)^2}\right]. \qquad (30)$$

One can see in the right panel of Fig. 4 that the numerical results in the matter era on a small scale are very much in line with it. The standard growth, which equals 1, is obviously recovered for vanishing values of the parameters λ and β.

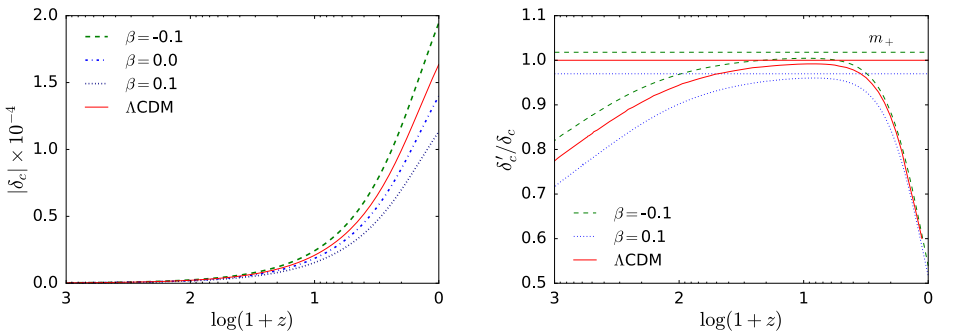

Fig. 4. $\lambda = 0.3$ on scale $k = 0.1\ h/\mathrm{Mpc}$. (a) Dark matter fluctuations. (b) Growth rate function.

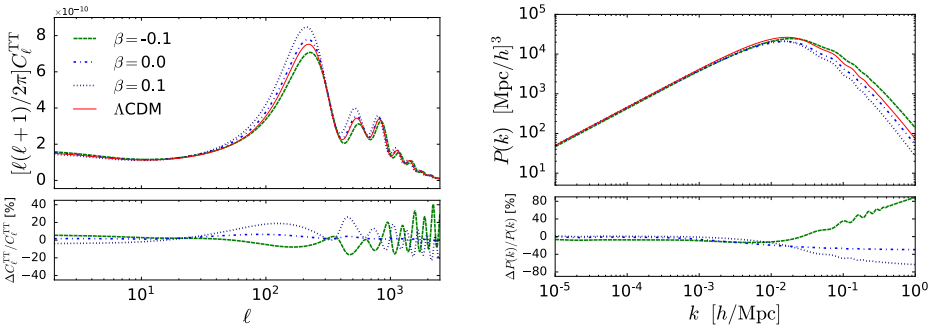
3. Observational constraints

We turn now our attention to the observations in order to constrain the value of the posteriors λ and β through Bayesian inference with MontePython[22–27] and GetDist.[28] Given that it affects the growth of dark matter perturbations, our parametrisation leaves observational signatures, both on the CMB anisotropies and matter power spectrum that we can numerically predict with our adapted version of CLASS and compare with observations.

As for the CMB anisotropies, early dark energy as well as the coupling affect the amplitude and position of the acoustic peaks as illustrated on the left panel of Fig. 5. We use the data from the Planck 2018 likelihood[29] on the temperature and polarisation of the CMB in the MCMC analysis. As regards today's linear matter power spectrum, the delay or the acceleration in the growth of dark matter perturbations has consequences too (right panel of Fig. 5). We use the gravitational weak lensing measurements, cosmic shear, from the KiDS-450 survey[30] in the Bayesian fitting.

The probability contours and posterior distribution we obtain in the parameter space are displayed on Fig. 6 for the two specific degrees of freedom of the model. On the one hand, the parameter estimation done with Planck provides an upper bound for the posterior λ which is compatible with a cosmological constant, that



(a) (b)

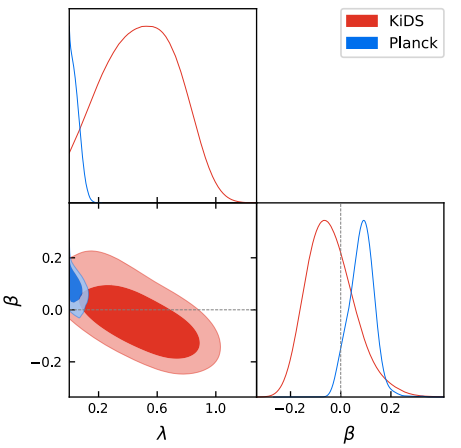

Fig. 6. Constraints on the (λ,β) posterior plane. Contours with 68% and 95% probability.

cannot be discarded. The coupling posterior corresponds to the energy injection from dark energy to dark matter. However, on the other hand, weak lensing data brings a different constraint on the posterior λ, not favouring a vanishing value. It also slightly detects energy transfer from dark matter to dark energy.

We also undertake the same likelihood analysis with the standard model as a benchmark to compare the goodness-of-fit of the parametrisation (Table 1). In light of the reduced chi-square, the two models look more or less equivalent. Nonetheless, according to the Akaike Information Criterion (AIC),[31] since it further penalises model complexity, the favourite cosmology for both probes is ΛCDM, this is particularly true for KiDS.

Table 1. Standard ΛCDM model vs scalar field parametrisation

	Planck		KiDS	
	ΛCDM	ϕ param.	ΛCDM	ϕ param.
χ^2	602.6	599.7	321.5	321.7
$\chi^2_{\rm red}$	1.0	1.0	2.6	2.7
AIC	616.6	617.7	335.5	339.7
ΔAIC	0	1.1	0	4.2

4. Concluding remarks

Despite its simplicity, the parametrisation we propose is able to cover a large span of dark energy evolution with a limited number of parameters. Constraints on more complex parametrisations are usually limited by the degeneracies between the various degrees of freedom. The model preserves the fact that dark matter and dark energy are in comparable ratios today, while relaxing the initial conditions thanks to the existence of tracking solutions. It is thus capable of reproducing the evolution of the background, as well as the CMB anisotropies and the formation of Large Scale Structures. Since the parametrisation has a ΛCDM limit for small λ and vanishing coupling β, it allows a direct test of departures from the standard model. We therefore argue that the parametrisation does help constrain the evolution of the equation of state and the departure from ΛCDM, even though the approach is purely phenomenological. Finally, the MCMC analysis carried out at perturbation level identifies tensions on the posteriors between early and late time probes. Background data is not expected to provide stronger constraints but the upcoming Euclid data will certainly improve the situation.

For a flat ΛCDM (standard) cosmology, a small sample of gravitationally lensed quasars with measured time delays has recently provided a value of the Hubble constant H_0 in tension with the *Planck* flat ΛCDM result. Trying to check if this tension is real or not, we used basic observational constraints for two double quasars of the GLENDAMA sample (SBS 0909+532 and SDSS J1339+1310) to discuss the underlying value of H_0 in a standard cosmology. For SBS 0909+532, we were not able to obtain a reliable measurement of H_0. However, the current data of SDSS J1339+1310 are consistent with H_0 around 67.8 km s^{-1} Mpc^{-1} and $\sigma(H_0)/H_0 \sim 10\%$. Although the formal uncertainty is still large and mainly due to the lack of details on the mass density profile of the main lens galaxy, the central value of H_0 coincides with that of the TDCOSMO+SLACS collaboration (using gravitational lens systems) and is within the 1σ interval from *Planck* cosmic microwave background data. After getting these preliminary encouraging results through only one double quasar, we are currently planning to use several GLENDAMA systems to accurately measure the Hubble constant and put constraints on other cosmological parameters.

Keywords: Gravitational lensing: strong; quasars: individual (SBS 0909+532, SDSS J1339+1310); cosmological parameters.

1. Introduction

Optical photometric monitoring of gravitationally lensed quasars (GLQs) brings plenty of astrophysical information.[1] For example, time delays between correlated brightness variations of their multiple images are used to estimate the current expansion rate of the Universe (the so-called Hubble constant H_0), provided lensing mass distributions can be constrained by observational data.[2,3] Throughout this paper, H_0 is expressed in standard units of km s^{-1} Mpc^{-1}, so units only are explicitly given in tables and figures.

Very recently, the H0LiCOW collaboration performed a joint analysis of six GLQs with measured time delays.[4] For a flat ΛCDM standard cosmology, they obtained $H_0 = 73.3^{+1.7}_{-1.8}$, in good agreement with $H_0 = 74.03 \pm 1.42$ from SNe data by

the SH0ES collaboration,[5] but in apparent tension with Cosmic Microwave Background (CMB) data.[6] *Planck* observations of the CMB suggested a narrow 1σ interval ranging from 66.9 to 67.9, which is clearly inconsistent with H0LiCOW/SH0ES results. It is also worth noting that Freedman *et al.*[7] obtained an intermediate value of $H_0 = 69.8 \pm 1.9$.

The big question is whether the tension between early and late-Universe probes is due to systematic errors or has a physical origin. Possible systematic errors in some methods may fix this issue, avoiding hasty rejection of the standard cosmological model. Thus, we use two doubly imaged quasars of the Gravitational LENses and DArk MAtter (GLENDAMA) sample[8] to discuss the influence of observational constraints, and hypotheses and priors on the mass model in the estimation of the Hubble constant in a standard cosmology. Section 2 briefly presents the GLENDAMA project and the framework of time-delay cosmography through double quasars, while Sec. 3 and Sec. 4 include preliminary results for the GLQs SBS 0909+532 and SDSS J1339+1310, respectively. A discussion of results and future prospects appear in Sec. 5.

2. GLENDAMA project and H_0 from doubles

The GLENDAMA project[a] is aimed to accurately study a sample of ten GLQs in the Northern Hemisphere over a period of about 25 years, basically covering the first quarter of this century.[8] The sample includes seven double quasars with two images (A and B) each, and three quads having four images (A, B, C and D) each. Figure 1 shows the distribution on the sky of the selected, optically bright GLQs. The Gran Telescopio CANARIAS (GTC) is being used to obtain deep spectroscopy of the lens systems, while the optical variability of quasar images is traced from light curves mainly based on observations with the Liverpool Telescope (LT). These optical light curves are allowing us to measure the time delay $\Delta t_{\rm AB}$ in doubles, and three independent delays $\Delta t_{\rm AB}$, $\Delta t_{\rm AC}$ and $\Delta t_{\rm AD}$ in quads (see results in Table 1). Current GLENDAMA delays have been estimated to a typical accuracy of about 5%, with only two exceptions: the relative error in the delay of QSO 0957+561 is well below 5%, and the three delays of the quad HE 1413+117 have larger relative uncertainties.

The time delay between the two images of a double quasar can be expressed in terms of the so-called time-delay distance $D_{\Delta t}$, the speed of light c and a dimensionless factor $\Delta\Phi_{\rm AB}$, so that[3] $\Delta t_{\rm AB} = (D_{\Delta t}/c)\Delta\Phi_{\rm AB}$. Here, $D_{\Delta t}$ depends on the source (quasar) and deflector (main lens galaxy) redshifts, as well as cosmological parameters. Measuring the redshifts, and assuming a flat ΛCDM cosmological model with $\Omega_{\rm M} = 0.3$ (matter density) and $\Omega_\Lambda = 0.7$ (dark energy density), $D_{\Delta t}/c$ is given as a known constant divided by H_0[b]. Additionally, $\Delta\Phi_{\rm AB}$ depends on the position

[a] `https://gravlens.unican.es/`.

[b] The time-delay distance does not appreciably change when matter and dark energy densities are slightly different to 0.3 and 0.7, respectively.

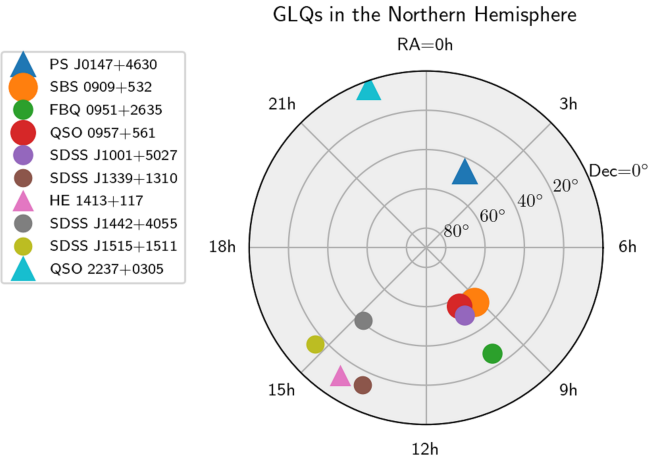

Fig. 1. GLENDAMA GLQs in the Northern Hemisphere. Triangles and circles represent quadruply and doubly imaged quasars, respectively. Larger symbols mean brighter quasars.

Table 1. GLENDAMA time delays from light curves in the SDSS r band.

Note: pm = preliminary measure.

of both images and the source, and the lens potential at the image positions.[2,3] Hence, the lensing mass distribution determines the value of the multiplicative factor $\Delta\Phi_{AB}$.

We used a lens model to describe the primary lensing mass in SBS 0909+532 and SDSS J1339+1310. For each of these two double quasars, our lens model consisted of an elliptical surface mass density to account for the main lens galaxy G and an external shear γ due to the gravitational action of other galaxies around the lens system. The surface mass density of G was modeled as a singular power-law distribution since a composite model (treating baryons and dark matter individually) leads to similar results.[15,16] In this preliminar study, instead of using high-resolution imaging to put constraints on the power-law index of G, we focused on an isothermal distribution, i.e., a singular isothermal ellipsoid (SIE). Such distribution

is consistent with stellar and gas motions in the Milky Way, as well as observations of many spiral and elliptical galaxies. We also did not use the stellar kinematics of G.[17]

We considered constraints on the time delay, the relative astrometry and the flux ratio between images, along with some observationally-motivated priors on SIE+γ lens model parameters. These constraints/priors and the LENSMODEL software[18] allowed us to simultaneously fit lens model parameters, position and flux of the source quasar, and $H_0^{\rm model}$ with dof = 0, where "dof" means degrees of freedom. In addition to the mass that is explicitly included in the lens model (main deflector plus external shear), we must take the mass along the line of sight to G into account. This additional effect can be approximated as an external convergence in the lens plane $\kappa_{\rm ext}$, which may be positive or negative depending on the mass distribution along the sightline. The true time-delay distance $D_{\Delta t}^{\rm true}$ relates to that derived from the lens model and measured delay $D_{\Delta t}^{\rm model}$ by $D_{\Delta t}^{\rm true} = D_{\Delta t}^{\rm model}/(1-\kappa_{\rm ext})$ (e.g., see Eq. (4) of Ref. 4), which leads to $H_0^{\rm true} = H_0^{\rm model}(1-\kappa_{\rm ext})$. Therefore, when accounting for an external convergence, the Hubble constant decreases/increases in a factor $1-\kappa_{\rm ext}$. The two next sections deal with estimates of $H_0^{\rm model}$ from observations of SBS 0909+532 and SDSS J1339+1310.

3. SBS 0909+532

SBS 0909+532 is a doubly imaged quasar in which the background source (quasar) and the foreground early-type lens galaxy (main deflector) have redshifts $z_{\rm s} = 1.377$ and $z_{\rm d} = 0.830$, respectively.[19–21] Our first set of observational constraints consisted of the SBS 0909+532 time delay in Table 1 taking a symmetric uncertainty (50 ± 3 days)[c], the relative astrometry of B and G (their positions with respect to A at the origin of coordinates) and the flux of B in units such that the flux of A is equal to one. These last astro-photometric constraints were taken from the *HST* near-IR data in Table 3 of Ref. 22. We also considered priors on the ellipticity e and external shear of the SIE+γ lens model described in Sec. 2: $e \leq 0.5$ (see Table 3 of Ref. 23) and $\gamma \leq 0.1$ (see Table 4 of Ref. 22).

Although the data fit yielded a best solution for $H_0^{\rm model}$ of 68.4 (see Table 2), unfortunately, the *HST* relative astrometry of Lehár *et al.*[22] is not so good as would be desirable. For instance, the relative position of the faint lens galaxy G was determined with a large uncertainty of about 100 mas (1 mas = 0.″001). The insufficiently accurate astrometric measures were responsible for a broad valley in the χ^2 curve (see the black solid line in Fig. 2), so the 1σ confidence interval for $H_0^{\rm model}$ included values below 55 and above 80. If we were able to improve the Lehár *et al.*'s astrometry, e.g., reducing errors in relative positions of B and G in factors 3 and 10, respectively, the best solution of $H_0^{\rm model}$ would be practically the same, but

[c]Despite 49 ± 3 days is fully consistent with the measurement in Table 1, initially we have preferred to keep its central value and divide the error bar into two identical halves.

Table 2. Results for $H_0^{\rm model}$ using a SIE+γ lens model (see main text).

	48 ± 2									67.6	67.8 ± 4.4

Note:
[a] Time delay between both images in days. Some errors have been made symmetric.
[b] Relative positions of B and G with respect to A at the origin of coordinates. Here, Δx and Δy are given in arc seconds, and their positive directions are defined by west and north, respectively. For SBS 0909+532, some errors have been conveniently approximated.
[c] Flux ratio. For SBS 0909+532, errors are enlarged to 10% to account for moderate microlensing effects.
[d] Ellipticity and position angle of the SIE. The position angle (θ_e) is measured east of north.
[e] External shear strength.
[f] Best solution and 1σ confidence interval for $H_0^{\rm model}$. We use standard units of km s^{-1} Mpc^{-1}.
[g] Plausible but not real measurement. Astrometric errors have been reduced to "achievable" values (see next row).
[h] Real measurement, but based on a biased astrometry or an inappropriate (strongly affected by microlensing) flux ratio.
[i] Measurement relying on an old, innacurate time delay.

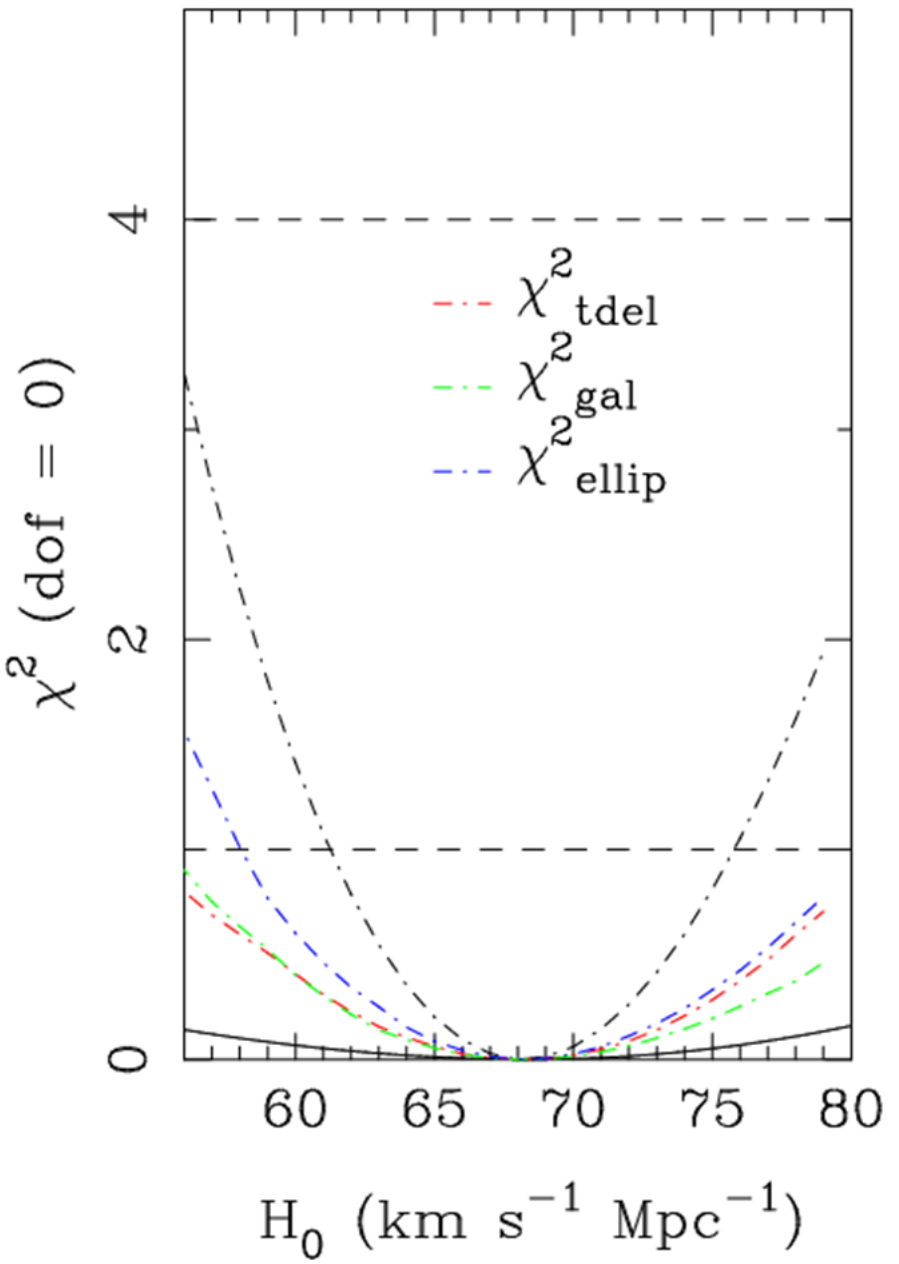

Fig. 2. Estimation of $H_0^{\rm model}$ from the SBS 0909+532 time delay and the astro-photometric constraints of Lehár *et al.*[22] We also used observationally-motivated priors on the ellipticity of the lens galaxy and the external shear. We show the χ^2 curve (black solid line) along with its 1σ and 2σ maximum thresholds (horizontal dashed lines). The black dashed-dotted line corresponds to an "improved" astrometry (see main text), with blue, green and red dashed-dotted lines describing some contributions to the total χ^2.

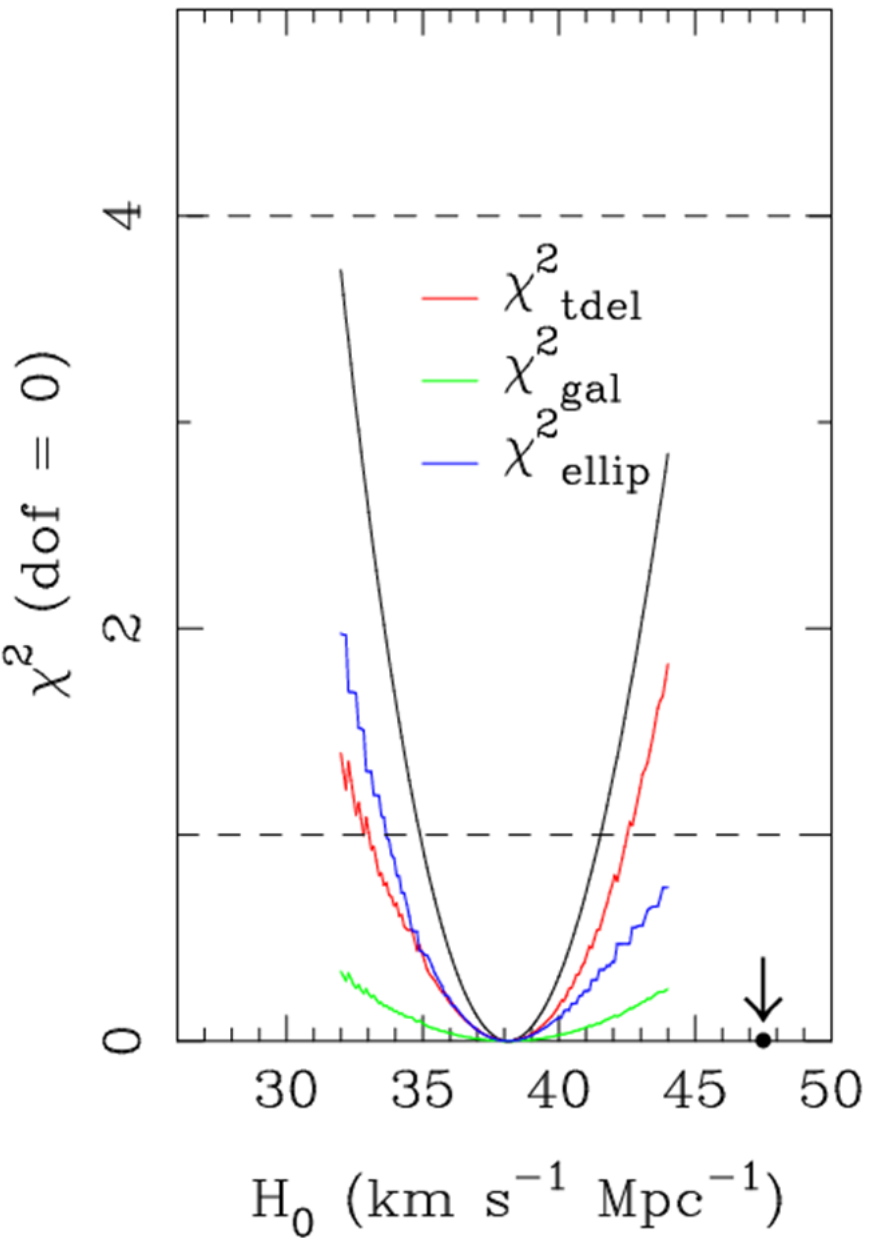

Fig. 3. Estimation of $H_0^{\rm model}$ from the SBS 0909+532 time delay and the astro-photometric constraints of Sluse *et al.*[23] The solid lines are related to priors on the shape of the lens galaxy (ellipticity and position angle; the black solid line represents the total χ^2), while the black dot and vertical arrow indicate the best solution when using priors on the ellipticity and the external shear.

its uncertainty would be dramatically decreased to about 10%. Using "achievable" uncertainties of 1 mas in B and 10 mas in G, we obtained the black dashed-dotted line in Fig. 2 and $H_0^{\rm model} = 68.5 \pm 7.5$.

In addition to new observations of the lens system, a reanalysis of the available *HST* frames of SBS 0909+532 might produce a better astrometry for the system, and thus provide an accurate measure of the Hubble constant. This is a promising task that we and other astronomers are exploring. Sluse *et al.*[23] have reanalysed the available *HST* near-IR frames, obtaining a formally improved astrometry and even details on the structure of G. The error in the relative position of G was only 3 mas; about 30−40 times smaller than the uncertainty derived by Lehár *et al.* We also considered these new constraints to measure $H_0^{\rm model}$. Using the SBS 0909+532 time delay with symmetric error (see above) and the astro-photometric solutions in Table 4 of Sluse *et al.*, along with the ellipticity and position angle of G in Table 3 of Sluse *et al.* (priors on the SIE+γ lens model), we found $H_0^{\rm model} = 38.2 \pm 3.3$ (see Table 2 and the black solid line in Fig. 3). Even the 2σ confidence interval only includes values below 45. Although a moderate increase in the best solution of $H_0^{\rm model}$ is found when taking the previous priors $e \leq 0.5$ and $\gamma \leq 0.1$ (see the black dot and vertical arrow in Fig. 3), the Sluse *et al.*'s relative astrometry leads to best solutions below 50. Hence, either such astrometry is biased or the near-IR fluxes of the quasar images (optical emission) are strongly affected by microlensing in the lens galaxy.[24]

4. SDSS J1339+1310

The gravitational lens system SDSS J1339+1310 was discovered by Inada *et al.*[25] It consists of two quasar images (A and B) at $z_{\rm s} = 2.231$ and an early-type galaxy G at $z_{\rm d} = 0.607$ acting as main deflector.[26] The first set of observational constraints included the relative astrometry of B and G in the last column of Table 1 of Ref. 27, the macrolens magnification ratio from narrow-line/line-core flux ratios and a standard extinction law (based on emission lines in GTC spectra),[26] and an old time delay from LT light curves.[26] We note that the first time delay we used (47.0 ± 5.5 days) is more inaccurate than the updated delay in Table 1. Additionally, we have taken the ellipticity and position angle of G in the last column of Table 1 of Shalyapin et al.[27] as priors on the SIE+γ lens model. The data fit led to an 1σ confidence interval $H_0^{\rm model} = 69^{+10}_{-8}$ (accuracy of $\sim$13%; see Table 2 and the black line in Fig. 4). The observational constraint on the time delay is the primary contribution to the χ^2 curve (see the red line in Fig. 4), while other constraints/priors (e.g., the position of G; see the green line in Fig. 4) play a secondary role.

Results in Fig. 4 suggest that a tighter constraint on the time delay would produce a more accurate determination of the Hubble constant. Therefore, in a second approach, we used the updated time delay with a 4% error that appears in Table 1 to more accurate estimate $H_0^{\rm model}$. The new χ^2 curve in Fig. 5(a) indicates that $H_0^{\rm model} = 67.8 \pm 4.4$ (see also Table 2). This is a quite robust measurement of

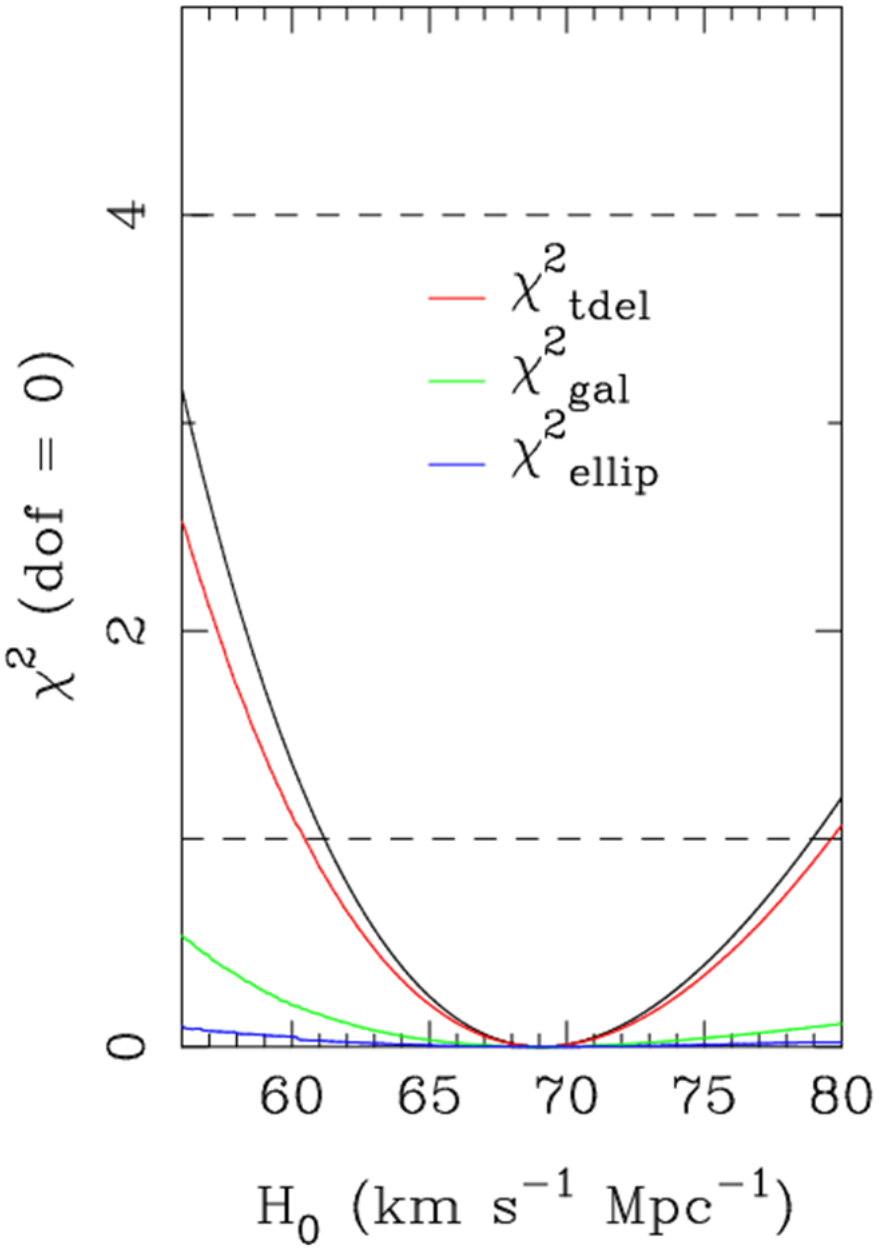

Fig. 4. Estimation of $H_0^{\rm model}$ from an old time delay of SDSS J1339+1310 with an accuracy of $\sim$12% and constraints/priors from results in Refs. 26 and 27. The black line represents the total χ^2, while the blue, green and red lines describe three different contributions to the total curve. The 1σ and 2σ maximum thresholds are also depicted (horizontal dashed lines).

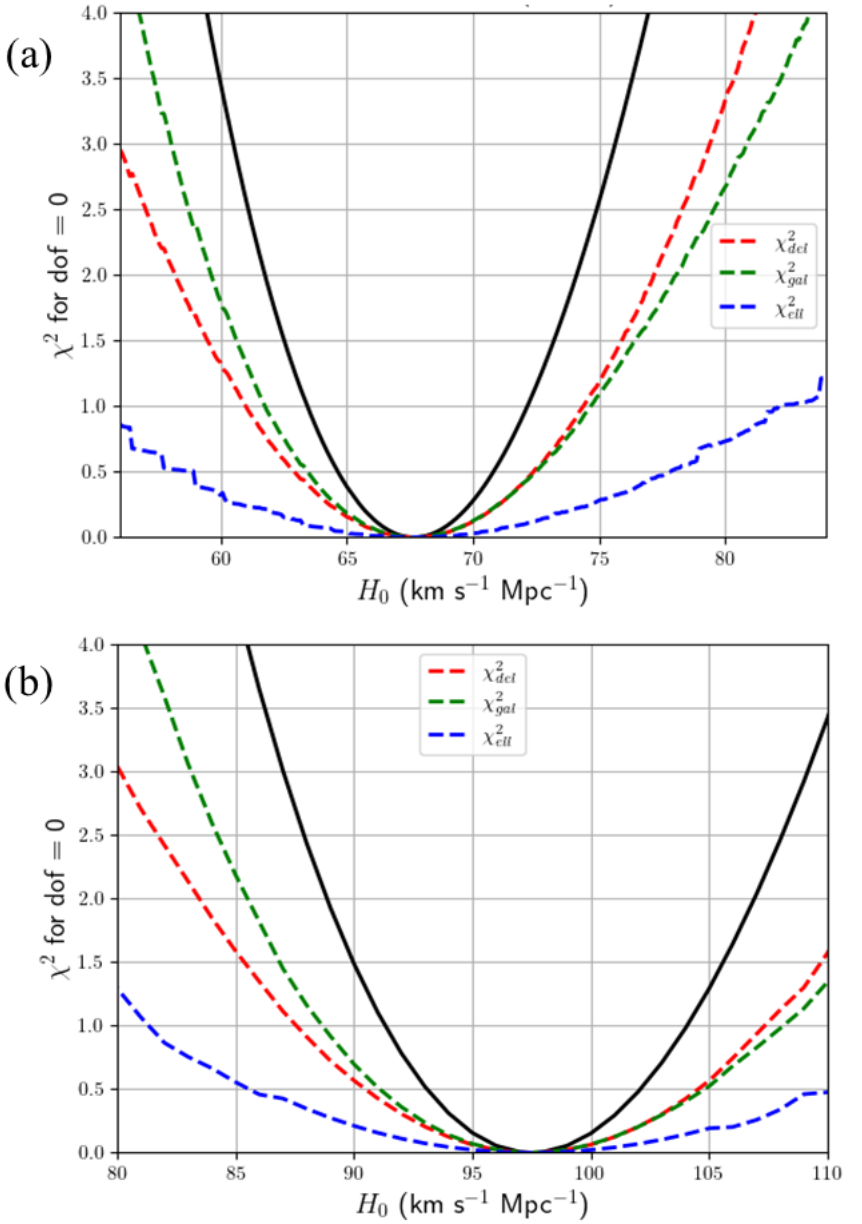

Fig. 5. Estimation of $H_0^{\rm model}$ from the updated time delay of SDSS J1339+1310 with an accuracy of ∼4% and constraints/priors from results in Refs. 26 and 27. (a) SIE+γ lens model. (b) DV+γ lens model. To obtain the χ^2 curve in this bottom panel, we have assumed that light traces mass of the main lens galaxy (see main text).

$H_0^{\rm model}$ because its relative error is small (only 6.5%), and the priors on e and θ_e do not play a relevant role (see the blue dashed line in Fig. 5(a)). In addition, the macrolens magnification ratio is not affected by microlensing/extinction effects, and only one major issue must be addressed: the hypothesis about an isothermal mass distribution for G. Using 58 gravitational lens systems from the SLACS Survey, Koopmans *et al.*[28] concluded that massive early-type galaxies have close to isothermal total density profiles, with a scatter between their logarithmic density slopes below 10%. For a particular lens galaxy, a small deviation from the isothermal power-law index is plausible, and this potential deviation can be taken into account by increasing the error in $H_0^{\rm model}$ (see a more complete discussion in Sec. 5).

It is easy to demonstrate the need for dark matter (e.g., a power-law mass distribution) and the fact that a model in which light traces mass produces biased results. To this end, we again considered the updated time delay in Table 1 and added a new prior, i.e., we worked with three priors instead two. Assuming that light traces mass of G, i.e., a de Vaucouleurs (DV) mass distribution instead a singular isothermal one, in a self-consistent way, the optical structure of G in the last column of Table 1 of Ref. 27 (effective radius, ellipticity and position angle) was used to describe the structure of its mass. This scheme led to a biased $H_0^{\rm model}$ value of about 100 (97.7 ± 6.4; see Fig. 5(b)). Even the 2σ lower limit is above 85.

5. Discussion and future prospects

Using two double quasars of the GLENDAMA sample (see Fig. 1), we focused on the role that some observational constraints and hypotheses/priors on the mass model play in estimating $H_0^{\rm model}$ in a standard cosmology. The main lens galaxies in SBS 0909+532 and SDSS J1339+1310 were modelled with a singular isothermal ellipsoid, in agreement with observations in the Milky Way and SLACS Survey results for massive early-type galaxies acting as gravitational lenses.[28] Adding the external shear γ that is caused by galaxies around a lens system, we initially considered a SIE+γ lens (mass) model.

For SBS 0909+532, there are two different astrometric solutions based on the same *HST* near-IR data. While the Lehár *et al.*'s solution[22] led to a best value of $H_0^{\rm model}$ equal to 68.4 and a broad 1σ interval for this parameter, the Sluse *et al.*'s solution[23] provided an 8.6% measurement of $H_0^{\rm model}$ around a central value of 38.2 (we derived biased results making different choices of priors). Assuming that the time delay and flux ratio between quasar images that we used are right, the last astrometry would be biased. However, the observed near-IR fluxes correspond to optical emission from the quasar accretion disk, so they could be strongly affected by microlenses (stars) in the main lens galaxy.[24] Hence, an accurate and reliable astrometric solution along with a detailed analysis of the macrolens magnification ratio (flux ratio free from extinction and microlensing effects) is required before robustly measuring $H_0^{\rm model}$ for a SIE+γ scenario.

Results for SDSS J1339+1310 are really encouraging because its current astrometry, updated time delay and macrolens magnification ratio through GTC spectra allowed us to accurately measure $H_0^{\rm model}$ (67.8 ± 4.4), with priors on the ellipticity and position angle of the SIE not playing a relevant role. It is also noteworthy that our 1σ interval is not in tension with other recent estimates from GLQs[4] and the CMB[6] (see also Ref. 7), and the central value practically coincides with the upper limit of the *Planck* collaboration. Accounting for a potential microlensing effect on the time delay[29] ($\sim$1 day) would only modify $H_0^{\rm model}$ by $\sim$2%. Additionally, the use of a main galaxy mass model with an unrealistic density profile may have a significant impact on $H_0^{\rm model}$ and be responsible for an error of about 10%.[30–32] At present, we do not know details about the mass density profile of the main deflector in SDSS J1339+1310, and thus we should adopt an uncertainty in $H_0^{\rm model}$ greater than that obtained with a SIE. Very recently, assuming that the deflectors of the H0LiCOW GLQs and the SLACS lenses share the same mass density properties, Birrer *et al.*[33] have obtained $H_0 = 67.4^{+4.1}_{-3.2}$. This new GLQ-based result is in excellent agreement with ours and the CMB-based estimation of H_0, notably reduces tension between early and late-Universe probes, and illustrates the importance of assumptions on mass distributions.

Future time-domain observations of large collections of GLQs will lead to robust constraints on H_0, and the matter and dark energy components of the Universe.[3] The GLENDAMA project includes the first initiative to robotically monitor a small sample of 10 GLQs for about 20 years.[8] This project and the associated robotic monitoring with the LT will end in 2025, after providing accurate time delays for several GLQs and discussing their cosmological implications. In next few years, other ongoing monitoring projects will also measure accurate delays for small/medium samples of GLQs (see the paper by Geoff Chih-Fan Chen in these proceedings), which will contribute to a rich database of tens of measured delays. Despite this optimistic perspective about time-domain results, some issues must be fixed before sheding light on unbiased values of cosmological parameters from such delay database. Deep spectroscopy, high-resolution imaging and other complementary observations will be required. For example, unaccounted mass along GLQ sightlines may produce overestimated/underestimated values of H_0 (see the end of Sec. 2), so accurate H_0 estimates cannot ignore external convergences. Here, although we ignored the external convergence for SDSS J1339+1310, the unaccounted mass is expected to translate to a few percent relative uncertainty in H_0,[33,34] noticeably less than that related to the mass density profile of G (see above).

Acknowledgments

We thank the organizers of Sixteenth Marcel Grossmann Meeting for planning a very interesting event and allowing us to give a talk in the parallel session "Cosmography with Gravitational Lensing". We also thank the chairs of such parallel session for

creating a pleasant environment. We acknowledge Claudio Grillo, Mimoza Hafizi and Sherry Suyu for helpful comments that have significantly contributed to prepare the final text of this contribution. Among other things, the Gravitational LENses and DArk MAtter (GLENDAMA) project aims to construct accurate optical light curves of SBS 0909+532 and SDSS J1339+1310, and measure robust time delays for both systems. Although these optical variability studies mainly rely on observations with the Liverpool Telescope (LT), we are particularly grateful to our collaborators working in several institutions, who provide us with complementary data from the Maidanak Astronomical Observatory and the US Naval Observatory, and participate actively in the project development. The LT is operated on the island of La Palma by the Liverpool John Moores University (with financial support from the UK Science and Technology Facilities Council), in the Spanish Observatorio del Roque de los Muchachos of the Instituto de Astrofísica de Canarias. We thank the staff of the telescope for a kind interaction before, during and after the observations. This research has been supported by the grant AYA2017-89815-P funded by MCIN/AEI/10.13039/501100011033 and by "ERDF A way of making Europe", and the grant PID2020-118990GB-I00 funded by MCIN/AEI/10.13039/501100011033.

Dark energy and dark matter unification from dynamical space time: BBN constraints

D. Benisty

DAMTP, Centre for Mathematical Sciences, University of Cambridge, Wilberforce Road, Cambridge CB3 0WA, United Kingdom

Institute of Astronomy, University of Cambridge, Madingley Road, Cambridge, CB3 0HA, UK

E-mail: benidav@post.bgu.ac.il

A unification of dark matter and dark energy based on a dynamical space time theory is suggested. By introducing a dynamical space time vector field χ_μ as a Lagrange multiplier, a conservation of an energy momentum tensor $T^{\mu\nu}_{(\chi)}$ is implemented. This Lagrangian generalizes the Unified dark energy and dark matter from a scalar field different from quintessence which did not consider a Lagrangian formulation. This generalization allows the solutions which were found previously, but in addition to that also non singular bouncing solutions that rapidly approach to the ΛCDM model. The BBN constraint is also studied.

Keywords: Dark Matter; Dark Energy

1. Introduction

Dark energy and Dark matter constitute most of the observable Universe. Yet the true nature of these two phenomena is still a mystery. One fundamental question with respect to those phenomena is the coincidence problem which is trying to explain the relation between dark energy and dark matter densities. In order to solve this problem, one approach claims that the dark energy is a dynamical entity and hope to exploit solutions of scaling or tracking type to remove dependence on initial conditions. Others left this principle and tried to model the dark energy as a phenomenological fluid which exhibits a particular relation with the scale factor,[1] Hubble constant[2] or even even the cosmic time itself.[3]

Unifications between dark energy and dark matter from an action principle were obtained from K-essence type actions,[4] or by introducing a complex scalar field.[5] Beyond those approaches, a unified description of Dark Energy and Dark Matter using a new measure of integration has been formulated.[6,7] Also a diffusive interacting of dark energy and dark matter models was introduced in[8,9] and it has been found that diffusive interacting dark energy — dark matter models can be formulated in the context of an action principle based on a generalization of those Two Measures Theories in the context of quintessential scalar fields,[10,11] although these models are not equivalent to the previous diffusive interacting dark energy — dark matter models.[8,9]

A model for a unification of dark energy and dark matter from a single scalar field ϕ, was suggested by Gao, Kunz, Liddle and Parkinson.[12] Their model is close

to traditional quintessence, and gives dynamical dark energy and dark matter, but introduces a modification of the equations of motion of the scalar field that apparently are impossible to formulate in the framework of an action principle. The basic stress energy tensor which was considered in addition to Einstein equation was:

$$T^{\mu\nu} = -\frac{1}{2}\phi^{,\mu}\phi^{,\nu} + U(\phi)g^{\mu\nu} \tag{1}$$

where ϕ is a scalar field and $U(\phi)$ is the potential for that scalar. Assuming homogeneous and isotropic behavior the scalar field should be only time dependent $\phi = \phi(t)$. Then the kinetic term $-\frac{1}{2}\phi^{,\mu}\phi^{,\nu}$ is parameterzing the dark matter because it contains only energy density with no pressure and $U(\phi)g^{\mu\nu}$ is parameterzing the dark energy. The basic requirement for this stress energy tensor is it's conservation law $\nabla_\mu T^{\mu\nu} = 0$. By assuming a constant potential $U(\phi) = \mathbf{Const}$ the model provides from the potential the traditional cosmological constant and the kinetic term of the scalar field is shown to provide, from the conservation law of the energy momentum tensor, that the kinetic term dependence has a dust like behavior.

$$-\frac{1}{2}\nabla_\mu(\phi^{,\mu}\phi^{,\nu}) = 0 \quad \Rightarrow \quad \dot{\phi}^2 \sim \frac{1}{a^3} \tag{2}$$

This simple case refers to the classical ΛCDM model. The special advantage of this model is a unification of dark energy and dark matter from one scalar field and has an interesting possibility for exploring the coincidence problem.

The lack of an action principle for this model brought us to reformulate the unification between dark energy and dark matter idea put forward by Gao, Kunz, Liddle and Parkinson[12] in the framework of a Dynamical Space Time Theory[13,14] which forces a conservation of energy momentum tensor in addition to the covariant conservation of the stress energy momentum tensor that appears in Einstein equation. In the next chapter we explore the equations of motion for these theories. In the third chapter we solve analytically the theory for constant potentials which reproduce the ΛCDM model with a bounce, which gives a possibility to solve the initial big bang singularity. In the last chapter we solve the theory for an exponential potential which gives a good possibility for solving the coincidence problem.

2. Dynamical Space Time Theory

2.1. *A basic formulation*

One from the basic fatures in the standard approach to theories of gravity is the local conservation of an energy momentum tensor. In the field theory case it's derived as a result rather than a starting point. For example, the conservation of energy can be derived from the time translation invariance principle. The local conservation of an energy momentum tensor can be a starting point rather than a derived result. Let's consider a 4 dimensional case where a conservation of a symmetric energy

momentum tensor $T^{\mu\nu}_{(\chi)}$ is imposed by introducing the term in the action:

$$\mathcal{S}_{(\chi)} = \int d^4x\sqrt{-g}\chi_{\mu;\nu}T^{\mu\nu}_{(\chi)} \tag{3}$$

where $\chi_{\mu;\nu} = \partial_\nu\chi_\mu - \Gamma^\lambda_{\mu\nu}\chi_\lambda$. The vector field χ_μ called a dynamical space time vector, because of the energy density of $T^{\mu\nu}_{(\chi)}$ is a canonically conjugated variable to χ_0, which is what we expected from a dynamical time:

$$\pi_{\chi_0} = \frac{\partial\mathcal{L}}{\partial\dot{\chi}^0} = T^0_0(\chi) \tag{4}$$

If $T^{\mu\nu}_{(\chi)}$ is being independent of χ_μ and having $\Gamma^\lambda_{\mu\nu}$ being defined as the Christoffel connection coefficients (the second order Formalism), then the variation with respect to χ_μ gives a covariant conservation law:

$$\nabla_\mu T^{\mu\nu}_{(\chi)} = 0 \tag{5}$$

From the variation of the action with respect to the metric, we get a conserved stress energy tensor $G^{\mu\nu}$ (in appropriate units), which is well known from Einstein equation:

$$G^{\mu\nu} = \frac{2}{\sqrt{-g}}\frac{\delta\sqrt{-g}}{\delta g^{\mu\nu}}[\mathcal{L}_\chi + \mathcal{L}_m]\,, \quad \nabla_\mu G^{\mu\nu} = 0 \tag{6}$$

where $G^{\mu\nu}$ is Einstein tensor, $\mathcal{L}_\chi$ is the Lagrangian in (3) and $\mathcal{L}_m$ is an optional action that involve other contributions.

Some basic symmetries that holds for the dynamical space time theory are two independent shift symmetries:

$$\chi_\mu \to \chi_\mu + k_\mu\,, \quad T^{\mu\nu}_{(\chi)} \to T^{\mu\nu}_{(\chi)} + \Lambda g^{\mu\nu} \tag{7}$$

where Λ is some arbitrary constant and k_μ is a Killing vector of the solution. This transformation will not change the equations of motions, which means also that the process of redefinition of the energy momentum tensor in the action (3) will not change the equations of motion. Of course such type of redefinition of the energy momentum tensor is exactly what is done in the process of normal ordering in Quantum Field Theory for instance.

2.2. *A connection to modified measures*

A particular case of the stress energy tensor with the form $T^{\mu\nu}_{(\chi)} = \mathcal{L}_1 g^{\mu\nu}$ corresponds to a modified measure theory. By substituting this stress energy tensor into the action itself, the determinant of the metric is canceled:

$$\sqrt{-g}\chi^\mu_{;\mu}\mathcal{L}_1 = \partial_\mu(\sqrt{-g}\chi^\mu)\mathcal{L}_1 = \Phi\mathcal{L}_1 \tag{8}$$

where $\Phi = \partial_\mu(\sqrt{-g}\chi^\mu)$ is like a "modified measure". A variation with respect to the dynamical time vector field will give a constraint on $\mathcal{L}_1$ to be a constant:

$$\partial_\alpha\mathcal{L}_1 = 0 \quad \Rightarrow \quad \mathcal{L}_1 = M = Const \tag{9}$$

This situation corresponds to the "Two Measures Theory"[15,16] where in addition to the regular measure of integration in the action $\sqrt{-g}$ includes another measure of integration which is also a density and a total derivative. Notable effects that can be obtained in this way are the spontaneous breaking of the scale invariance, the see saw cosmological effects,[15] the resolution of the 5th force problem in quintessential cosmology[17] and a unified picture of both inflation and of slowly accelerated expansion of the present universe.[18,19] As we mentioned before in the introduction Two Measure Theory can serve to build unified models of dark energy and dark matter.

Usually the construction of this measure is from 4 scalar fields φ_a, where $a = 1, 2, 3, 4$.

$$\Phi = \frac{1}{4!}\varepsilon^{\alpha\beta\gamma\delta}\varepsilon_{abcd}\partial_\alpha\varphi^{(a)}\partial_\beta\varphi^{(b)}\partial_\gamma\varphi^{(c)}\partial_\delta\varphi^{(d)} \tag{10}$$

and then we can rewrite an action that uses both of these densities:

$$S = \int d^4x\Phi\mathcal{L}_1 + \int d^4x\sqrt{-g}\mathcal{L}_2\,. \tag{11}$$

As a consequence of the variation with respect to the scalar fields φ_a, assuming that $\mathcal{L}_1$ and $\mathcal{L}_2$ are independent of the scalar fields φ_a, we obtain that for $\Phi \neq 0$ it implies that $\mathcal{L}_1 = M = const$ as in the dynamical time theory with the case of (9).

3. DE-DM Unified Theory from Dynamical Space-Time

A suggestion of an action which can produce DE-DM unification takes the form:

$$\mathcal{L} = -\frac{1}{2}R + \chi_{\mu;\nu}T^{\mu\nu}_{(\chi)} - \frac{1}{2}g^{\alpha\beta}\phi_{,\alpha}\phi_{,\beta} - V(\phi) \tag{12}$$

Consisting of an Einstein Hilbert action ($8\pi G = 1$), quintessence and Dynamical space-time action, when the original stress energy tensor $T^{\mu\nu}_{(\chi)}$ is the same as the stress energy tensor (1) Gao and colleagues used:

$$T^{\mu\nu}_{(\chi)} = -\frac{1}{2}\phi^{,\mu}\phi^{,\nu} + U(\phi)g^{\mu\nu} \tag{13}$$

The action depends on three different variables: the scalar field ϕ, the dynamical space time vector χ_μ and the metric $g_{\mu\nu}$. Therefore there are 3 sets in for the equation of motions. For the solution we assume homogeneity and isotropy, therefore we solve our theory with a FLRW metric:

$$ds^2 = -dt^2 + a(t)^2\left(\frac{dr^2}{1-Kr^2} + r^2d\Omega^2\right) \tag{14}$$

According to this ansatz, the scalar field is just a function of time $\phi(t)$ and the dynamical vector field will be taken only with a time component $\chi_\mu = (\chi_0, 0, 0, 0)$, where χ_0 is also just a function of time. A variation with respect to the dynamical space time vector field χ_μ will force a conservation of the original stress energy tensor, which in FRWM gives the relation:

$$\ddot{\phi} + \frac{3}{2}\mathcal{H}\dot{\phi} + U'(\phi) = 0 \tag{15}$$

Compared with the equivalent equation which comes from quintessence model, this model gives a different and smaller friction term, as compared to the canonical scalar field. Therefore for increasing redshift, the densities for the scalar field will increase slower than in the standard quintessence.

The second variation with respect to the scalar field ϕ gives a non-conserved current:

$$\chi^{\lambda}_{;\lambda} U'(\phi) - V'(\phi) = \nabla_{\mu} j^{\mu} \tag{16a}$$

$$j^{\mu} = \frac{1}{2}\phi_{,\nu}(\chi^{\mu;\nu} + \chi^{\nu;\mu}) + \phi^{,\mu} \tag{16b}$$

and the derivatives of the potentials are the source of this current. For constant potentials the source becomes zero, and we get a covariant conservation of this current. In a FLRW metric this equation of motion takes the form:

$$\ddot{\phi}(\dot{\chi}_0 - 1) + \dot{\phi}[\ddot{\chi}_0 + 3\mathcal{H}(\dot{\chi}_0 - 1)] = U'(\phi)(\dot{\chi}_0 + 3\mathcal{H}\chi_0) - V'(\phi) \tag{17}$$

Substituting the term of the potential derivative $U'(\phi)$ from equation (15):

$$[1 - 2\dot{\chi}_0 - 3\mathcal{H}\chi_0]\ddot{\phi} - [\ddot{\chi}_0 - 3\mathcal{H} + \frac{9}{2}\mathcal{H}(\dot{\chi}_0 + \chi_0\mathcal{H})]\dot{\phi} + V'(\phi) = 0 \tag{18}$$

The last variation, with respect to the metric, gives the stress energy tensor that is defined by the value of the Einstein's tensor. For a spatially homogeneous, cosmological case, the energy density and the pressure of the scalar field are:

$$\rho = \dot{\phi}^2(\dot{\chi}_0(1 - \frac{3}{2}\mathcal{H}) - \frac{1}{2}) + V(\phi) - \dot{\phi}\dot{\chi}_0(U'(\phi) + \ddot{\phi}) \tag{19a}$$

$$p = \frac{1}{2}\dot{\phi}^2(\dot{\chi}_0 - 1) - V(\phi) - \chi_0\dot{\phi}U'(\phi) \tag{19b}$$

Substituting the potential derivative $U'(\phi)$ from Eq. (15) into the energy density term, makes the equation simpler:

$$\rho = (\dot{\chi}_0 - \frac{1}{2})\dot{\phi}^2 + V(\phi) \tag{20}$$

which has no longer dependence on the potential $U(\phi)$ or it's derivatives. Those three variations are sufficient for building a complete solution for the theory. Let's see a few simple cases.

4. The Evolution of the Homogeneous Solutions

4.1. *A bouncing ΛCDM solution*

In order to compute the evolution of the scalar field and to check whether it is compatible with observable universe, we have to specify a form for the potentials. Let's take a simplified case of constant potentials:

$$U(\phi) = C, \quad V(\phi) = \Omega_{\Lambda} \tag{21}$$

Overall, in the equations of motions only the derivative the potential $U(\phi)$ appears, not the potential itself. Therefore a constant part of the potential $U(\phi)$ does not contribute to the solution. However $V(\phi)$, as we shall see below, gives the cosmological constant. The conservation of the stress energy tensor from equation (15) gives:

$$\dot{\phi}^2 = \frac{2\Omega_m}{a^3} \tag{22}$$

where Ω_m is an integration constant which appears from the solution. From the second variation, with respect to the scalar field ϕ, a conserved current is obtained, which from equation (18) gives the exact solution of the dynamical time vector field:

$$\dot{\chi}_0 = 1 - \kappa\, a^{-1.5} \tag{23}$$

where κ is another integration of constant. Eventually, the densities and the pressure for this potentials are given by (20). By substituting the solutions for the scalar $\dot{\phi}$ and the vector $\dot{\chi}_0$ (in units with $\rho_c = \frac{8\pi G}{3H_0^2} = 1$) we get:

$$\rho = \Omega_\Lambda - \frac{\Omega_\kappa}{a^{4.5}} + \frac{\Omega_m}{a^3} \tag{24a}$$

$$p = -\Omega_\Lambda - \frac{1}{2}\frac{\Omega_\kappa}{a^{4.5}} \tag{24b}$$

where $\Omega_\kappa = \kappa\Omega_m$. Notice that Ω_m, Ω_κ are integration constants the solution contains and Ω_Λ is parameter from the action of the theory. We can separate the result into three different "dark fluids": dark energy ($\omega = -1$), dark matter ($\omega = 0$) and an exotic part ($\omega = \frac{1}{2}$), which is the responsible for the bounce (for $\kappa > 0$). From Eq. (22) the solution produces a positive Ω_m since it's proportional to $\dot{\phi}^2$. For Ω_Λ the measurements for the late universe forces the choice of this parameter to be positive. However for another solutions (in the context of Anti de-Sitter space, for instance) this parameter could be negative from the beginning.

In addition to those solutions, there is a strong correspondence between the zero component of the dynamical space time vector field and the cosmic time. For ΛCDM there is no bouncing solution $\kappa = 0$ and therefore from equation (23) we get $\chi_0 = t$ that implies that the dynamical time is exactly the cosmic time. For bouncing ΛCDM we obtain a relation between the dynamical and the cosmic time with some delay between the dynamical time and the cosmic time for the early universe (in the bouncing region). For the late universe the dynamical time returns back to run as fast as the cosmic time again. This relation between the dynamical and the cosmic time may have interesting application in the solution to "the problem of time" in quantum cosmology which will discussed elsewhere. Notice that the dynamical time is a field variable while the cosmic time is a coordinate.

In order to constrain our model, we use the Big Bang Nucleosynthesis (BBN) speed-up factor, defined as the ratio of the expansion rate predicted in a given model versus that of the ΛCDM model at the BBN epoch ($z_{BBN} \sim 10^9$). This amounts

to the limit[20] with $(\Delta H/H_{\Lambda CDM})^2 < 10\%$, where $H_{\Lambda CDM}$ is the Hubble rate for the ΛCDM model and the ΔH is the difference between the Dynamical Spacetime Hubble rate and the ΛCDM Hubble rate, $\Delta H = H - H_{\Lambda CDM}$. The bounds gives:

$$\Omega_\kappa < 6 \cdot 10^{-10}. \tag{25}$$

With this bound the model is consistent with the cosmological observations.[21]

5. Discussion and Future Work

In this paper the "unified dark energy and dark matter from a scalar field different from quintessence" is formulated through an action principle. Introducing the coupling of a dynamical space time vector field to an energy momentum tensor that appears in the action, determines the equation of motion of the scalar field from the variation of the dynamical space time vector field or effectively from the conservation law of an energy momentum tensor, as in.[12] The energy momentum tensor that is introduced in the action is related but not in general the same as the one that appears in the right hand side of the gravitational equations, as opposed to the non Lagrangian approach of,[12] so our approach and that of[12] are not equivalent. However in many situations the solutions studied in[12] can be also obtained here, but there are other solutions, in special non singular bounce solutions which are not present in.[12]

In those simple solutions, the dynamical time behaves very close to the cosmic time. In particular in solutions which are exactly ΛCDM, the cosmic time and the dynamical time exactly coincide with each other. If there is a bounce, the deviation of the dynamical time with respect to the cosmic time takes place only very close to the bounce region. The use of this dynamical time as the time in the Wheeler de-Witt equation should also a subject of interest.

In principle we can introduce two different scalar potentials: one coupled directly to $\sqrt{-g}$ and the other appearing in the original stress energy tensor $T^{\mu\nu}_{(\chi)}$. So far, for the purposes of starting the study of the theory, we have only introduced a scalar potential coupled directly to $\sqrt{-g}$ and shown that this already leads to an interacting Dark Energy — Dark Matter model, although the full possibilities of the theory will be revealed when the two independent potentials will be introduced.

Finally, another direction for research has been started by studying models of this type in the context of higher dimensional theories, where they can provide a useful framework to study the "inflation compactication" epoch and an exit from this era to the present LCDM epoch could be further explored.[22]

General Relativity is *a priori* a theory invariant under time reversal. Its integration with the laws of thermodynamics allows for a formulation of non-equilibrium phenomena in gravity and the introduction of an arrow of time, i.e. the the breaking of such invariance. Even though most of the evolution of the universe takes place in local thermal equilibrium, the effects of irreversible processes on the expansion via entropic forces may be phenomenologically relevant. We review our previous work on the covariant formulation of non-equilibrium thermodynamics in General Relativity and the proposal to explain the recent cosmic acceleration from it.

Keywords: General Relativity, thermodynamics, non-equilibrium phenomena, entropic forces, cosmic acceleration.

1. Introduction

General Relativity is an extremely successful physical theory. More than a century after its formulation, its predictions continue to be valid at all probed scales, albeit an extension at short scales will be required in order to obtain a UV-complete quantum theory of gravity and resolve space-time singularities.

Thermodynamics is an even older discipline. Its fundamental laws seem to resist the pass of time and are still of great relevance today. On the one hand, thermodynamics may help in building the bridge between classical and quantum gravity, as the laws of black hole thermodynamics points towards the existence of a microphysical description of gravity yet to be understood.

On the other hand, the second law of thermodynamics, i.e. the growth of entropy, dictates the sign of the arrow of time. Physical laws are usually invariant under time inversion. The increase in entropy with time in out-of-equilibrium phenomena, however, allows one to distinguish the future-directed from the past directed description of a physical process.

There lacks a consistent and rigorous integration between General Relativity and the laws of thermodynamics. Understanding the very notion of the arrow of time is of particular interest for cosmology. In section 2 we argue for the need of going beyond reversible cosmology. This can be achieved for any space-time metric using variational techniques.[1] We review our main results in this new approach to non-equilibrium thermodynamics in General Relativity and present them in sections 3 to 6.

The growth of entropy associated to the causal horizon in open inflation scenarios may explain the current accelerated expansion of the universe within the general relativistic entropic acceleration (GREA) theory.[2] We briefly describe how this mechanism works in section 7 and finish with our conclusions.

2. Reversible cosmology

Let us begin the study of the problem of reversibility in gravity and cosmology by reviewing a prototypic case of reversible gravitational system: a homogeneous and isotropic universe. It is described by the Friedmann-Lemaître-Robertson-Walker (FLRW) metric

$$ds^2 = -dt^2 + a(t)^2 \left(\frac{dr^2}{1-kr^2} + r^2 d\Omega_2^2 \right) , \tag{1}$$

where $a(t)$ is the scale factor, $k = -1, 0, 1$ is the curvature parameter corresponding to, respectively, an open, flat and closed universe; and $d\Omega_2^2$ is the solid angle element. This space-time is filled with a perfect fluid, described by the stress-energy tensor

$$T_{\mu\nu} = (\rho + p) u_\mu u_\nu + p g_{\mu\nu} , \tag{2}$$

where ρ and p are, respectively, the density and pressure of the fluid. The Einstein field equations for this metric and matter content deliver the dynamics for the scale factor, the well-known Friedmann equations

$$H^2 + \frac{k}{a^2} = \frac{8\pi G}{3}\rho \quad \frac{\ddot{a}}{a} = -\frac{4\pi G}{3}(\rho + 3p) , \tag{3}$$

where $H = \dot{a}/a$ is the Hubble parameter. There is a constraint on the stress-energy tensor due to the Einstein field equations and the Bianchi identities, namely its covariant conservation $D_\mu T^{\mu\nu} = 0$. From this constraint one can derive the continuity equation

$$\dot{\rho} + 3H(\rho + p) = 0 . \tag{4}$$

However, one can also derive this equation from the second law of thermodynamics. Indeed, changes in entropy are related to changes in internal energy and work $TdS = \delta U + \delta W$. If we apply this to a region of fixed comoving volume $a(t)^3$ we get

$$T\frac{dS}{dt} = \frac{d}{dt}\left(\rho a^3\right) + p\frac{d}{dt}\left(a^3\right) . \tag{5}$$

If the expansion of the universe is reversible, we can set the LHS to 0 and recover the continuity equation. However, this is only true in thermodynamical equilibrium and, in general, entropy is a monotonically increasing function of time. Most of the expansion history of the universe is indeed adiabatic. However, it is out-of-equilibrium at certain key points such as (p)reheating, phase transitions or gravitational collapse. Allowing for a time-varying entropy implies the addition of a term in the continuity equation

$$\dot{\rho} + 3H(\rho + p) = \frac{T\dot{S}}{a^3} . \tag{6}$$

Combining this with the first Friedmann equation we obtain a modified, non-equilibrium second Friedmann equation

$$\frac{\ddot{a}}{a} = -\frac{4\pi G}{3}\left(\rho + 3p - \frac{T\dot{S}}{a^3 H}\right) . \tag{7}$$

In principle, this evolution equation does not seem to be compatible with the Einstein field equations. In order to achieve that, the laws of thermodynamics need to be rigorously incorporated into the computation of the equations of motion. This can be achieved by applying the variational formalism of non-equilibrium thermodynamics, developed in another context by Gay-Balmaz and Yoshimura,[3,4] to General Relativity.

3. Entropic forces in mechanics and field theory

Entropic forces emerge naturally in any physical system out of equilibrium. They are a consequence of the coarse-graining of physical degrees of freedom and the laws of thermodynamics, which impose entropy to be a monotonically increasing function of time. This breaks time reversibility.

The dynamics of the coarse-grained degrees of freedom is unknown or ignored and so they do not appear in the action of the physical system. It would seem that a variational treatment of an out-of-equilibrium system is not possible. However, both the extremal-action principle and the second law of thermodynamics can be merged consistently by imposing the latter as a constrain on the variational problem defined by the action.[3,4] On the other hand, the first law of thermodynamics is obtained from the symmetries of the problem.

3.1. *Entropic forces in mechanics*

Let us start by reviewing the emergence of entropic forces in a mechanical system. Consider the action

$$\mathcal{S} = \int dt L(q, \dot{q}, S) , \tag{8}$$

where the Lagrangian depends on the generalized coordinate $q(t)$, its time derivative $\dot{q}(t)$ and the entropy $S(t)$. The variation of the action gives

$$\delta\mathcal{S} = \int dt \left(\frac{\delta L}{\delta q}\delta q + \frac{\partial L}{\partial S}\delta S\right) . \tag{9}$$

Setting $\delta\mathcal{S} = 0$ defines the variational problem. In order to enforce the second law of thermodynamics, we need to impose the variational constraint

$$\frac{\partial L}{\partial S}\delta S = f\delta q , \tag{10}$$

which simply states the relationship between variations of the entropy and the generalized coordinate. If we plug this in the variation of the action, then we can

readily obtain the equations of motion

$$\frac{\delta L}{\delta q} = \frac{\partial L}{\partial q} - \frac{d}{dt}\left(\frac{\partial L}{\partial \dot{q}}\right) = -f\,, \tag{11}$$

which is the Euler-Lagrange equation modified by the addition of the entropic force f. In order to know its precise form, we need to impose as well the phenomenological constraint, which is obtained by formally replacing the variations with time derivatives

$$\frac{\partial L}{\partial S}\dot{S} = f\dot{q}\,. \tag{12}$$

Note that usually temperature can be introduced as

$$T = -\frac{\partial L}{\partial S} > 0 \tag{13}$$

providing a clearer meaning to the variational and phenomenological constraint.

The imposition of the constraints and the emergence of an entropic force break the symmetry under time inversion. First, note that formally the Euler-Lagrange equation is invariant under the $t \to -t$ transformation, even with a non-vanishing entropic force. Next, the positiveness of the temperature and the change of entropy imposes $f\dot{q} < 0$. The entropic force has qualities of a generalized friction, as it opposes the coordinate velocity. Now, if one performs time inversion, this sign constraint becomes $f\dot{q} > 0$, as the temperature remains positive but entropy decreases with time. Before solving the equations of motion, $\dot{q}$ is still a degree of freedom and, thus, one must conclude a flip in the sign of f, which flips the overall sign of the Euler-Lagrange equation. Hence, one concludes that the emergence of an entropic force breaks symmetry under time reversion. The evolution of the system becomes irreversible.

3.2. *Entropic forces in classical field theory*

The extension of the variational formalism of non-equilibrium thermodynamics to the continuum is a bit involved. We present a short-cut derivation that relies on the introduction of an additional constraint. We refer the reader to the appendix of[1] to check its equivalence with the full variational derivation originally presented in.[4]

The action of a scalar field on Minkowski space-time contains now a dependency on a scalar function $s(t, \vec{x})$ that encodes information related to coarse-grained degrees of freedom

$$\mathcal{S} = \int d^4x \mathcal{L}\left(\phi, \partial_\mu \phi, s\right)\,. \tag{14}$$

In a similar fashion as before, the extremal-action principle needs to be supplemented by a variational constraint

$$\frac{\partial \mathcal{L}}{\partial s}\delta s = f\delta\phi\,, \tag{15}$$

so that the equation of motion becomes

$$\frac{\delta\mathcal{L}}{\delta\phi} = \frac{\partial\mathcal{L}}{\partial\phi} - \partial_\mu \frac{\partial\mathcal{L}}{\partial\partial_\mu\phi} = -f\,, \tag{16}$$

which is nothing but the Euler-Lagrange equation of a scalar field with a new term of entropic origin. As before, one can usually introduce a temperature as

$$T = -\frac{\partial\mathcal{L}}{\partial s} > 0 \tag{17}$$

and we would like to interpret s as the entropy density. However, due to spatial fluxes entropy need not necessarily increase locally and, thus, the constraint would not have a fixed sign. Before proceeding, we inspect the corresponding phenomenological constraint

$$\frac{\partial\mathcal{L}}{\partial s}\partial_0 s = f\partial_0\phi\,. \tag{18}$$

Instead, we interpret δs and $\partial_0 s$ as local entropy production and introduce a new function $s_{\rm tot}$ which is the actual entropy density and whose changes $\delta s_{\rm tot}$ and $\partial_0 s_{\rm tot}$ are indeed total local changes of the entropy density. Both are related as

$$\partial_0 s = \partial_0 s_{\rm tot} - \partial_i j_s^i\,, \tag{19}$$

where j_s^i is the entropy flux. This latter equation is an additional constraint we impose for the variational formalism to be consistent. Now one can check that $f\partial_0\phi < 0$ and time reversibility is broken by the same argument used in the mechanics example.

3.3. *Entropic forces in presence of additional symmetries*

The generalization of the above formalism to higher order tensors or to representations of some internal symmetry group is straightforward. Let us consider a field tensor z of contravariant rank r, which is also in some representation of an internal symmetry labelled by an index A. Then one builds the variational constraint as

$$\frac{\partial\mathcal{L}}{\partial s}\delta s = f_{A;\mu_1,\ldots\mu_r}\delta z_A^{\mu_1,\ldots\mu_r}\,, \tag{20}$$

which delivers the equation of motion

$$\frac{\delta\mathcal{L}}{\delta z_A^{\mu_1,\ldots\mu_r}}, = -f_{A;\mu_1,\ldots\mu_r}\,. \tag{21}$$

4. Entropic forces in General Relativity

The previous discussion makes us ready to study entropic forces in General Relativity. However, with the introduction of a dynamical space-time the very notion of time evolution becomes non-trivial. As we will see shortly, it is possible to obtain a modification of entropic origin to Einstein's field equation in the Lagrangian formulation of General Relativity. Its proper interpretation will require, nevertheless, the use of the Hamiltonian formalism.

4.1. *Lagrangian formulation*

Let us consider the Einstein-Hilbert action plus a matter term

$$\mathcal{S} = \frac{1}{2\kappa}\int d^4x\sqrt{-g}R + \int d^4x\mathcal{L}_m(g_{\mu\nu}, s)\,, \tag{22}$$

where $\kappa = 8\pi G$ is the gravitational coupling and we allow for the dependence of the matter Lagrangian on a function $s(t, \vec{x})$, which will have a similar interpretation to the one presented in the previous section. The extremal-action principle is supplemented by the variational constraint.

$$\frac{\partial\mathcal{L}_m}{\partial s} = \frac{1}{2}\sqrt{-g}f_{\mu\nu}\delta g^{\mu\nu}\,. \tag{23}$$

From the extremal-action principle and the variational constraint we obtain the modified Einstein's field equations

$$R_{\mu\nu} - \frac{1}{2}g_{\mu\nu}R = \kappa\left(T_{\mu\nu} - f_{\mu\nu}\right)\,, \tag{24}$$

where there is an additional term $f_{\mu\nu}$ of entropic origin. In order to obtain an expression for this term and to check the breaking of symmetry under time inversion we need to work in the Hamiltonian formulation of General Relativity.

4.2. *Hamiltonian formulation*

General Relativity admits a Hamiltonian formulation in the Arnowitt-Deser-Misner (ADM) formalism. Space-time is foliated in constant time hypersurfaces with normal unit vector n^μ, being the its 4-metric split as

$$g_{\mu\nu} = h_{\mu\nu} - n_\mu n_\nu\,, \tag{25}$$

where $h_{\mu\nu}$ is the 3-metric induced on the hypersurfaces. Analogously, one can parametrize the 4-metric in terms of the 3-metric h_{ij} and the lapse and shift functions N and N^i

$$ds^2 = -(Ndt)^2 + h_{ij}(dx^i + N^i dt)(dx^j + N^j dt)\,. \tag{26}$$

Greek indices run from 0 to 3, while Latin ones do from 1 to 3 and are raised and lowered by h_{ij}. The normal vector can be written as

$$n_\mu = (-N, 0, 0, 0)\,. \tag{27}$$

Note that h_{ij} is the purely spatial part of $h_{\mu\nu}$ and is also the pull-back of $g_{\mu\nu}$ onto the hypersurface.

The Einstein-Hilbert action for this parametrization of the metric is given by the following gravitational Lagrangian:

$$\mathcal{L}_G = \sqrt{-g}R = \frac{1}{2\kappa}N\sqrt{h}\left({}^{(3)}R + K_{ij}K^{ij} - K^2\right)\,, \tag{28}$$

where K_{ij} is the extrinsic curvature of the 3-hypersurface Σ and is given by the Lie derivative along the normal vector n:

$$K_{ij} = \frac{1}{2}\pounds_n h_{ij} = \frac{1}{2N}\left(\partial_0 h_{ij} - \nabla_i N_j - \nabla_j N_i\right) \tag{29}$$

where ∇ denotes the covariant derivative on Σ with respect to the 3-metric h_{ij}. Its trace and traceless part are:

$$\begin{aligned} K &= h^{ij}K_{ij} = \frac{1}{N}\left(\partial_0 \ln\sqrt{h} - \nabla_i N^i\right) \\ \bar{K}_{ij} &= K_{ij} - \frac{1}{3}K h_{ij}\,. \end{aligned} \tag{30}$$

Unlike the intrinsic curvature, described by the Riemann tensor $R^{\rho}_{\mu\nu\lambda}$ and its contractions, the extrinsic curvature is a quantity that depends on the embedding of a surface in a larger manifold.

We are now ready to introduce the Hamiltonian formulation of the theory. Note that the only quantity whose time derivative appears in the gravitational Lagrangian is the 3-spatial metric h_{ij} and, thus, it is the only dynamical or propagating d.o.f. Correspondingly, one defines its conjugate momentum as:

$$\Pi^{ij} = \frac{\partial \mathcal{L}_G}{\partial \dot{h}_{ij}} = \sqrt{h}\left(K^{ij} - K h^{ij}\right)\,. \tag{31}$$

With this, the gravitational Lagrangian can be rewritten as:

$$\begin{aligned} \mathcal{L}_G &= N\sqrt{h}^{(3)}R - \frac{N}{\sqrt{h}}\left(\Pi_{ij}\Pi^{ij} - \frac{1}{2}\Pi^2\right) - 2\Pi^{ij}\nabla_i N_j \\ &= \Pi^{ij}\dot{h}_{ij} - N\mathcal{H} - N_i\mathcal{H}^i - 2\nabla_i\left(\Pi^{ij}N_j\right)\,, \end{aligned} \tag{32}$$

where $\Pi = h_{ij}\Pi^{ij}$ and we introduced the functions:

$$\begin{aligned} \mathcal{H} &= -\sqrt{h}^{(3)}R + \frac{1}{\sqrt{h}}\left(\Pi_{ij}\Pi^{ij} - \frac{1}{2}\Pi^2\right) \\ \mathcal{H}^i &= -2\nabla_j\left(h^{-1/2}\Pi^{ij}\right)\,. \end{aligned} \tag{33}$$

Since N and N_i are not dynamical variables, they merely enter the gravitational Lagrangian as Lagrange multipliers. One defines the gravitational Hamiltonian as:

$$\begin{aligned} \mathcal{H}_G &= \Pi^{ij}\dot{h}_{ij} - \mathcal{L}_G \\ &= N\mathcal{H} + N_i\mathcal{H}^i + \nabla_i\left(\Pi^{ij}N_j\right)\,, \end{aligned} \tag{34}$$

with the Hamiltonian and momentum constraints:

$$\begin{aligned} \frac{\delta\mathcal{H}_G}{\delta N} &= \mathcal{H} = 0 \\ \frac{\delta\mathcal{H}_G}{\delta N_i} &= \mathcal{H}^i = 0\,. \end{aligned} \tag{35}$$

The Hamiltonian evolution equations are obtained from the variations of the action with respect to the metric and conjugate momentum

$$\delta\mathcal{S} = \int d^4x \left[\left(-\dot{\Pi}^{ij} - \frac{\delta\mathcal{H}_G}{\delta h_{ij}} - \kappa N\sqrt{h}\tilde{f}^{ij} + 2\kappa\frac{\partial\mathcal{L}_m}{\partial h_{ij}} \right)\delta h_{ij} + \left(\dot{h}_{ij} - \frac{\delta\mathcal{H}_G}{\delta\Pi^{ij}} \right)\delta\Pi^{ij} \right], \tag{36}$$

where the variational constraint

$$\frac{\partial\mathcal{L}_m}{\partial s}\delta s = -\frac{1}{2}N\sqrt{h}\tilde{f}^{ij}\delta h_{ij} \tag{37}$$

was already implemented. Note that the minus sign arises from

$$\frac{\partial h_{ij}}{\partial h^{kl}} = -\frac{1}{2}\left(h_{ik}h_{jl} + h_{il}h_{jk}\right) \tag{38}$$

and that $\tilde{f}_{ij}$ is the pull-back of $f_{\mu\nu}$ onto the hypersurfaces. By setting the variation to 0 we obtain the two Hamilton equations

$$\begin{aligned} \frac{\delta\mathcal{H}_G}{\delta h_{ij}} &= -\dot{\Pi}^{ij} - \kappa N\sqrt{h}f^{ij} + 2\kappa\frac{\partial\mathcal{L}_m}{\partial h_{ij}} \\ \frac{\delta\mathcal{H}_G}{\delta\Pi^{ij}} &= \dot{h}_{ij}\,, \end{aligned} \tag{39}$$

which completes the derivation of the entropic modification to the gravitational equations of motion in the Hamiltonian formulation.

The tensor $\tilde{f}_{ij}$ can be obtained from the phenomenological constraint, which can now be stated rigorously. In the ADM formalism, a well-defined notion of time evolution is given by the flow along the normal vector n^μ. Hence, the time derivative is generalized to the Lie derivative along n^μ. Then the phenomenological constraint is given by

$$\frac{\partial\mathcal{L}}{\partial s}\pounds_n s = \frac{1}{2}N\sqrt{h}\tilde{f}_{ij}\pounds_n h^{ij} \tag{40}$$

where growth in entropy by local processes is related to total entropy density growth by

$$\pounds_n s = \pounds_n s^{tot} - \nabla_i j_s^i\,. \tag{41}$$

Entropy produced locally is expected to grow over time, i.e. with the flow along the hypersurfaces, in compliance with the second law of thermodynamics. This completes the variational formulation of entropic forces in General Relativity.

4.3. *The Raychauduri equation*

Let us explore an immediate dynamical consequence of the inclusion of entropic forces, namely its effect on a congruence of worldlines with tangent vector n^μ. The congruence is then characterized by the tensor:

$$\Theta_{\mu\nu} = D_\nu n_\mu = \frac{1}{3}\Theta h_{\mu\nu} + \sigma_{\mu\nu} + \omega_{\mu\nu} - a_\mu n_\nu \tag{42}$$

where θ is the expansion rate of the congruence, $\sigma_{\mu\nu}$ is its shear or symmetric traceless part and $\omega_{\mu\nu}$ is its vorticity or antisymmetric part. If the worldline is not a geodesic, then the congruence suffers an acceleration given by:

$$a_\mu = n^\nu D_\nu n_\mu \,. \tag{43}$$

One can compute the Lie derivative of the expansion of the congruence along its tangent vector and find the Raychauduri equation:[5]

$$\pounds_n \Theta = -\frac{1}{3}\Theta^2 - \sigma_{\mu\nu}\sigma^{\mu\nu} + \omega_{\mu\nu}\omega^{\mu\nu} - R_{\mu\nu}n^\mu n^\nu + D_\mu a^\mu \,. \tag{44}$$

Let us perform the standard analysis of the sign of this equation. It is clear that $\sigma_{\mu\nu}\sigma^{\mu\nu} > 0$ and $\Theta^2 > 0$. On the other hand, if the congruence is chosen to be orthogonal to the spatial hypersurfaces, as we have been considering, then the vorticity vanishes $\omega_{\mu\nu} = 0$. Lastly, it is left to consider the term $R_{\mu\nu}n^\nu n^\nu$, which we can rewrite with the help of the field equations:

$$R_{\mu\nu}n^\mu n^\nu = 8\pi G\left(T_{\mu\nu}n^\mu n^\nu + \frac{1}{2}T - f_{\mu\nu}n^\mu n^\nu - \frac{1}{2}f\right). \tag{45}$$

If the strong energy condition is satisfied, then:

$$T_{\mu\nu}n^\mu n^\nu \geq -\frac{1}{2}T \tag{46}$$

and, in the absence of intrinsic acceleration, $a_\mu = 0$, we can establish the bound:

$$\pounds_n \Theta + \frac{1}{3}\Theta^2 \leq 8\pi G\left(f_{\mu\nu}n^\mu n^\nu + \frac{1}{2}f\right). \tag{47}$$

For a vanishing entropic force $f_{\mu\nu} = 0$, this means that an expanding congruence cannot indefinitely sustain its divergence and will eventually recollapse. On the contrary, a positive and sufficiently large entropic contribution can avoid such recollapse. This may become relevant for an expanding universe, but also to generic gravitational collapse and the singularity theorems.[6–8]

5. Sources of entropy

A main ingredient in the variational formulation of non-equilibrium thermodynamics in General Relativity is the inclusion of entropy at the Lagrangian level and the derivation of a notion of temperature from it. In this section we present two relevant examples: hydrodynamical matter, which is a prototypical case, and horizons.

5.1. *Entropy from hydrodynamical matter*

A classical fluid is the simplest matter content that can be considered in General Relativity and it is of particular relevance in Cosmology. Without paying attention to microphysical details, the Lagrangian of hydrodynamical matter can be written as

$$\mathcal{L}_m = -\sqrt{-g}\rho(g_{\mu\nu}, s)\,, \tag{48}$$

being then the temperature simply given by

$$T = -\frac{1}{\sqrt{-g}}\frac{\partial \mathcal{L}_m}{\partial s} = \frac{\partial \rho}{\partial s}\,. \tag{49}$$

This is analogous to the case of a mechanical system, where the Lagrangian is generically given by a kinetic and a potential energy

$$L = E_K(q, \dot{q}) - U(q, S) \tag{50}$$

and temperature can be defined as

$$T = \frac{\partial L}{\partial S} = -\frac{\partial U}{\partial S}\,. \tag{51}$$

Thus, the energy density of a fluid can be readily interpreted as the thermodynamic internal energy.

5.2. *Entropy from gravity and horizons*

Gravity itself has thermodynamical features. It is known since the discovery of the laws of black hole mechanics and their promotion to laws of black hole thermodynamics, allowed by the introduction of Bekenstein entropy and Hawking temperature. We propose to include the entropy associated with a horizon $\mathcal{H}$ by extending the Einstein-Hilbert actions with surface terms of Gibbons-Hawking-York (GHY) type

$$S_{GHY} = \frac{1}{8\pi G}\int_{\mathcal{H}} d^3y\sqrt{h}K\,, \tag{52}$$

where h is the determinant of the induced 3-metric on the horizon and K is the trace of its extrinsic curvature. Definitions are analogous to the ones used in the ADM formalism, but we stress that here the hypersurface of interest is a horizon and not constant-time hypersurfaces.

From the thermodynamic point of view, the GHY term contributes to the internal energy of the system. Hence, it can be rewritten as a function of the temperature and entropy of the horizon

$$S_{GHY} = -\int dt\, N(t)\, TS\,. \tag{53}$$

We have kept the lapse function $N(t)$, to indicate that the variation of the total action with respect to it will generate a Hamiltonian constraint with an entropy term together with the ordinary matter/energy terms. In order to illustrate this, let us now compute the GHY for the event horizon of a Schwarzschild black hole.

The space-time of a Schwarzschild black hole of mass M is described by the static metric

$$ds^2 = -\left(1 - \frac{2GM}{r}\right)dt^2 + \left(1 - \frac{2GM}{r}\right)^{-1} dr^2 + r^2 d\Omega_2^2\,. \tag{54}$$

We foliate it with spherical hypersurfaces, i.e. their intersection with constant time hypersurfaces is a 2-sphere around the origin of coordinates. The corresponding normal vector is

$$n = -\sqrt{1 - \frac{2GM}{r}}\partial_r \,. \tag{55}$$

With this, the trace of the extrinsic curvature for such a sphere scaled by the metric determinant is

$$\sqrt{h}K = (3GM - 2r)\sin\theta \,. \tag{56}$$

Integrating over the angular coordinates and setting the 2-sphere at the event horizon, i.e. $r = 2GM$, and restoring for a moment $\hbar$ and c, the GHY becomes

$$S_{GHY} = -\frac{1}{2}\int dt Mc^2 = -\int dt T_{BH} S_{BH} \,, \tag{57}$$

where T_{BH} is the Hawking temperature and S_{BH} is the Bekenstein entropy of the Schwarzschild black hole:

$$T_{BH} = \frac{\hbar c^3}{8\pi GM} \quad S_{BH} = \frac{Ac^3}{4G\hbar} = \frac{4\pi GM^2}{\hbar c} \,. \tag{58}$$

This favors the interpretation of the GHY term of a horizon as a contribution to the internal energy in the thermodynamic sense.

6. Irreversible cosmology

We derived in section 4 a powerful, generic tool to describe non-equilibrium thermodynamic effects in gravity. In the Hamiltonian formulation of General Relativity it is possible to obtain the modified equations of motion and rigorously impose the time-evolution of the entropy as dictated by the second law of thermodynamics.

In section 2 we motivated the study of these phenomena by our interest in understanding the dynamics of irreversible cosmology and justifying its equations of motion. One can obtain them using the Hamilton equations.[1] Here, however, we present a slightly different approach. Due to the symmetries of the FLRW universe, homogeneity and isotropy, there is a preferred slicing and time evolution is well-defined even at the Lagrangian level. Therefore, we can obtain the equations of non-equilibrium cosmology by imposing these symmetries, i.e. making an ansatz for the metric

$$ds^2 = -N(t)^2 dt^2 + a(t)^2 \left(\frac{dr^2}{1 - kr^2} + r^2 d\Omega_2^2 \,, \right) \tag{59}$$

where the lapse function $N(t)$ accounts for the freedom in choosing the time coordinate, i.e. the symmetry under $t \to f(t)$. The Ricci scalar associated to this metric is

$$R = \frac{6}{a^2}\left(\frac{a\ddot{a}}{N^2} + \frac{\dot{a}^2}{N^2} + k\right). \tag{60}$$

Let us stress that this result is imposed by symmetry, not dynamics. Without loss of generality, we can restrict the action to a region of comoving volume 1 and write it as

$$S = \int dtL = \frac{3}{8\pi G}\int dtNa\left(\frac{a\ddot{a}}{N^2} + \frac{\dot{a}^2}{N^2} + k\right) + \int dtNa^3\mathcal{L}_m(N,a,S)\,. \tag{61}$$

Effectively, this action describes a mechanical system, for the scale factor $a(t)$ has no spatial dependency and we got rid of the integral over spatial coordinates. The first term can be rewritten using integration by parts in order to get only terms with at most the first derivative of a

$$S = \frac{3}{8\pi G}\int dtNa\left(-\frac{\dot{a}^2}{N^2} + k\right) + \int dtNa^3\mathcal{L}_m(N,a,S)\,. \tag{62}$$

The variational constraint is here given by the usual expression for a mechanical system

$$\frac{\partial L}{\partial S}\delta S = f\delta a\,. \tag{63}$$

The Hamiltonian of the system is

$$H = \dot{a}\frac{\partial L}{\partial \dot{a}} - L = \frac{3}{8\pi G}\left(-\frac{\dot{a}^2 a}{N} - kaN\right) - Na^3\mathcal{L}_m\,. \tag{64}$$

For an arbitrary lapse function $N(t)$ this can be rewritten as

$$H = N^2a^3\frac{\partial \mathcal{L}_m}{\partial N}\,, \tag{65}$$

which gives the Hamiltonian constraint of the system. On the other hand, the dynamics is obtained from the equation of motion for a

$$\frac{\delta L}{\delta a} = -f\,. \tag{66}$$

Let us now consider the matter Lagrangian to be that of a perfect fluid, i.e.

$$\mathcal{L}_m = -\rho(a,S)\,. \tag{67}$$

Its stress-energy tensor is given in terms of the density ρ and pressure p by

$$T^{\mu\nu} = (\rho + p)u^{\mu\nu} + pg^{\mu\nu} \tag{68}$$

and $u^m u = (N,0,0,0)$ is the unit vector tangent to a comoving observer. Pressure is then obtained as

$$p = \frac{a^2}{3}T^{ij}\delta_{ij} = -\frac{1}{2a^4}\frac{\partial a^3\rho}{\partial a}\,. \tag{69}$$

Using the expressions for ρ and p and rearranging the terms in the Hamiltonian constraint and the equation of motion for $a(t)$ we arrive at the modified Friedmann

equations

$$\left(\frac{\dot{a}}{a}\right)^2 + \frac{k}{a^2} = \frac{8\pi G}{3}\rho$$
$$\frac{\ddot{a}}{a} = -\frac{4\pi G}{3}\left(\rho + 3p + \frac{f}{a^2}\right). \tag{70}$$

The expression for the entropic force F is obtained from the phenomenological constraint

$$\left(\frac{\partial L}{\partial S}\right)\dot{S} = -T\dot{S} = f\dot{a} < 0\,, \tag{71}$$

which determines the sign $f < 0$ whenever dealing with an expanding universe $\dot{a} > 0$. We express finally the second Friedmann equation as

$$\frac{\ddot{a}}{a} = -\frac{4\pi G}{3}\left(\rho + 3p - \frac{T\dot{S}}{a^2\dot{a}}\right). \tag{72}$$

From this equation we can conclude that entropic forces generally drive an acceleration of the expansion of the universe. Whether this can dominate the dynamics of the scale factor will depend on the particular thermodynamic process. Most of the expansion history of the universe takes place in equilibrium. Out of equilibrium processes, such as (p)reheating, phase transitions or gravitational collapse are short-lived. Should their associated entropic force dominate, we still only expect a short period of accelerated expansion.

Symmetry under time inversion is broken by the same arguments presented in section 3. Hence, the Friedmann equations together with the phenomenological constraint, i.e. the second law of thermodynamics, describe cosmic irreversible dynamics.

We currently live in a universe that is undergoing an accelerated expansion. The possibility of explaining this by means of an entropic force is fascinating. In the next section we review our proposal to achieve this by means of the sustained growth of the entropy associated to a causal horizon.

7. Cosmic acceleration as an entropic force

The growth of entropy associated to the cosmic horizon may be responsible for the current observed accelerated expansion of the universe. The choice of horizon is in principle not unique. The only available one which can be defined locally in time is the cosmic apparent horizon, but it fails to significantly affect the expansion.[2]

There is another option in the framework of eternal inflation, according to which we live in an open universe nucleated by quantum tunneling from a false to a true vacuum. After nucleation the bubble universe undergoes its own inflationary era, which renders the local metric almost flat. However, due to the presence of the bubble walls, the true causal horizon is located at a finite distance. It induces an

entropic fluid via GHY term with energy density

$$\rho_H\, a^2 = \frac{T_H S_H}{a} = \frac{x_0}{2G}\,\sinh(2a_0 H_0 \eta)\,, \quad x_0 \equiv \frac{1-\Omega_0}{\Omega_0} = e^{-2N}\left(\frac{T_{\rm rh}}{T_{\rm eq}}\right)^2 (1+z_{\rm eq})\,, \tag{73}$$

where η is the conformal time, Ω_0 is the density parameter, $T_{\rm rh}$ is the reheating temperature, $T_{\rm eq}$ and $z_{\rm eq}$ are, respectively, the temperature and redshift at matter-radiation equality. Introducing $\tau = a_0 H_0 \eta$ one can write the second Friedmann equation in conformal time as

$$\left(\frac{a'}{a_0}\right)^2 = \Omega_M \left(\frac{a}{a_0}\right) + \Omega_K \left(\frac{a}{a_0}\right)^2 + \frac{4\pi}{3}\Omega_K \left(\frac{a}{a_0}\right)^2 \sinh(2\tau)\,, \tag{74}$$

where Ω_M is the matter density paremeter and Ω_K is the curvature parameter. We call this the general relatvistic entropic acceleration (GREA) theory.

By solving this equation with cosmological parameters consistent with the CMB values (Planck 2018: $\Omega_M \simeq 0.31$, $\Omega_K \simeq 0.0006$, $h_0 \simeq 0.68$) and initial conditions deep in the matter era, $a_i(\tau) = a_0\,\Omega_M \tau^2/4$, we find generic accelerating behaviour beyond the scale factor $a \sim 1/2$ (*i.e.* $z \sim 1$), see Fig. 1. This is consistent with the current observed acceleration of the universe and may even resolve the Hubble tension,[9] providing a way to obtain from the CMB a present value of H_0 that is consistent with late-universe observations, see Fig. 2.

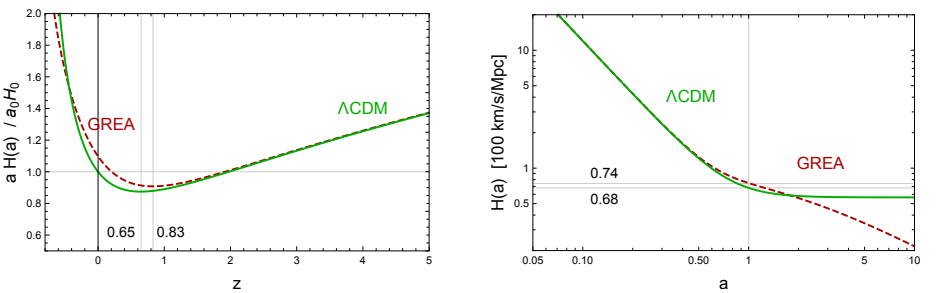

Fig. 1. The left plot shows the evolution of the inverse comoving horizon with the coasting point for each model, at $z \simeq 0.65$ for ΛCDM (in green) and $z \simeq 0.83$ for GREA (in red). The right plot shows the evolution of the rate of expansion. For GREA the present rate of expansion is approximately 74 km/s/Mpc, compared with the value of 68 km/s/Mpc predicted by ΛCDM, in agreement with the asymptotic value at the CMB.

8. Conclusions

The consistent inclusion of non-equilibrium phenomena in General Relativity leads to the modification of the Einstein field equations, as can be checked both in the Lagrangian and Hamiltonian formulations of the theory. This breaks symmetry under time inversion and allows for the introduction of an arrow of time.

In cosmology this implies the appearance of a term of entropic origin in the second Friedmann equation, which tends to accelerate the expansion of the universe as a result of the increase in entropy. Some physical processes such as (p)reheating, phase transitions or gravitational collapse may lead to phenomenologically relevant applications of this formalism. We look forward to further developments.

The sustained entropy growth associated to a causal horizon in the open universe scenario leads to an acceleration consistent with current observations and it may even solve the H_0 tension. Further research will be required to establish the full viability of the GREA theory.

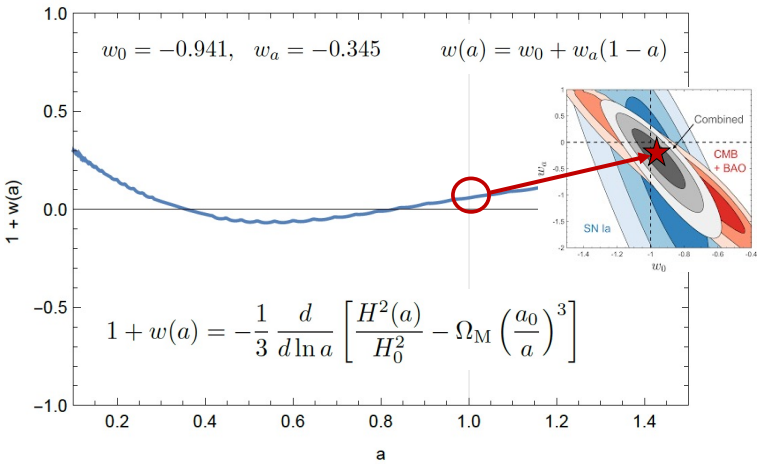

Fig. 2. The effective equation of state of the non-matter component of the GREA theory, as a function of thee sale factor. Note that the predicted effective PCL parameters (w_o, w_a) agree remarkably well with present observations.

LHC experiments for long-lived particles of the dark sector

Vasiliki A. Mitsou

Instituto de Física Corpuscular (IFIC), CSIC – Universitat de València, C/ Catedrático José Beltrán 2, E-46980 Paterna (Valencia), Spain
E-mail: vasiliki.mitsou@ific.uv.es
webific.ific.uv.es/web

Dark matter scenarios are being tested at the LHC in the general-purpose experiments through promptly decaying states. In parallel, new dedicated detectors have been proposed for the LHC to probe dark matter portal theories predicting long-lived particles that decay away from the interaction point: MoEDAL-MAPP, MoEDAL-MALL, FASER, SND@LHC, CODEX-b, MATHUSLA, AL3X, ANUBIS, FACET, milliQan, FORMOSA. In addition, the SHiP beam-dump experiment is planned to operate with the SPS beam to extend the discovery reach for such particles. The detector design and expected physics sensitivity of these experiments is presented with emphasis on scenarios explaining the nature of dark matter.

Keywords: Dark matter; Portal models; Long-lived particles; Displaced vertices; LHC.

1. Introduction

In collider physics, and in particular at the Large Hadron Collider (LHC),[1] there is a growing experimental interest in long-lived particles (LLPs),[2,3] which travel a macroscopic distance before either decaying within the detector or giving rise to anomalous ionisation. In theory, long lifetimes may be due to a symmetry (leading to stable particles), narrow mass splittings, small couplings, or a heavy mediator. In this arena, a class of LLPs called Feebly interacting Particles (FIPs)[4] is characterised by indirect interactions of FIPs with Standard Model (SM) particles through low-dimensional operators. These interactions, commonly referred to as *portals*, may predict dark photons (vector portal), a light dark Higgs boson (scalar portal), axion-like particles (pseudoscalar portal), or heavy neutral leptons (fermion portal).

Scenarios beyond-the-SM (BSM) that introduce a hidden sector in addition to the visible SM sector are required to explain a number of observed phenomena in particle physics, astrophysics and cosmology such as the non-zero neutrino masses, the dark matter (DM), the baryon asymmetry of the Universe and the cosmological inflation. The mystery of DM, in particular, is quite intriguing with around 25% of our Universe invisible (dark) that only interacts through gravity and remains unaccounted for in the SM. This review focuses on the possibility to explore DM with LLPs, as a complementary way to searches performed by the main experiments. ATLAS[5] and CMS[6] look for DM in mono-X final states, in associated production and in resonances via mediators,[7] while LHCb[8] has good prospects for probing DM-portal LLPs after its Phase-I upgrade.[9]

This review is organised as follows. After a brief introduction in Sec. 1, the specially designed LHC experiments to tackle LLPs are concisely presented in Sec. 2. The dark-scalar and dark-vector portals, proposing neutral LLPs that decay in the detector volumes to known particles, are reviewed in Sec. 3 and Sec. 4, respectively. Dark photons at the limit of zero mass, leading to fractionally charged particles, are discussed in Sec. 5. In Sec. 6, other BSM scenarios pertinent to LLPs are highlighted. Finally, possible measurements of new particle properties are outlined in Sec. 7, before summarising and giving an outlook in Sec. 8.

2. Dedicated LLP Experiments at the LHC

There is a constantly growing list of experiments planned for the LHC optimised for the detection of feebly interacting particles. Their projected added value stems mostly from their different operation and geometry parameters: angle w.r.t. the beam axis, the detector volume and distance from IP — probing different ranges of lifetime, couplings to SM and boost (mass) —, their time scale and the detector design.

Besides the detectors highlighted below, there are other, operating or future, non-LHC experiments with sensitivity to DM and other portal models. Such cases include BaBar,[10] existing CERN beam-dump experiments, like the NA48/2,[11] NA62[12] and NA64,[13] the Fermilab SeaQuest[14] and the reactor experiment SoLid.[15] Proposed experiments include the Search for Hidden Particles (SHiP)[16] at the CERN Beam Dump Facility, SHADOWS[17] at the CERN North Area, LUXE-NPOD[18] at DESY, HECATE[19] for the FCC-ee or CEPC, GAZELLE[20] in Bell II at SuperKEKB, SUBMET[21] at J-PARC and FerMINI[22] at Fermilab, among others.

2.1. *MAPP – MoEDAL Apparatus for Penetrating Particles*

The MoEDAL (Monopole and Exotics Detector at the LHC)[23] experiment is mainly dedicated to searches for manifestations of new physics through highly ionising particles in a manner complementary[24] to ATLAS and CMS. It is the first dedicated *search* LHC experiment. The principal motivation for MoEDAL is the quest for magnetic monopoles[25] and dyons, as well as for any massive, stable or long-lived, slow-moving particle[26] with single or multiple electric charge arising in various extensions of the SM.[27] The MoEDAL detector[28] is deployed around the region at interaction point 8 (IP8) of the LHC in the LHCb[8] vertex locator cavern.

It is a unique and, to a large extend, passive detector based on three different detection techniques: nuclear track detectors (NTDs), magnetic monopole trackers (MMTs) and TimePix pixel devices. MoEDAL has pioneered the quest for magnetic charges, by being the only contender in the high-charge regime[29–32] and by being first in constraining dyons[33] in colliders and in investigating the Schwinger thermal production of monopoles.[34] More analyses, also on electric charges,[35] are ongoing.[36]

The last few years, MoEDAL proposes to deploy MAPP[37,38] in a gallery near IP8 shielded by an overburden of approximately 100 m of limestone from cosmic

rays to extent its reach to the *low* ionisation regime. It is envisaged that the first-stage detector, MAPP-1 will be installed during LHC Long Shutdown 2 (LS2) and Run 3.[36] The purpose of the innermost detector, the MAPP-mQP, shown in Fig. 1, is to search for particles with fractional charge as small as $0.001e$, the so called *millicharged particles (mCP)*, using plastic scintillation bars. A prototype of the mQP detector (10% of the original system) is already in place since 2017 and the data analysis is ongoing.[39] The Phase-1 MAPP-mQP is going to be deployed in the UA82 gallery in a distance 100 m from IP8.

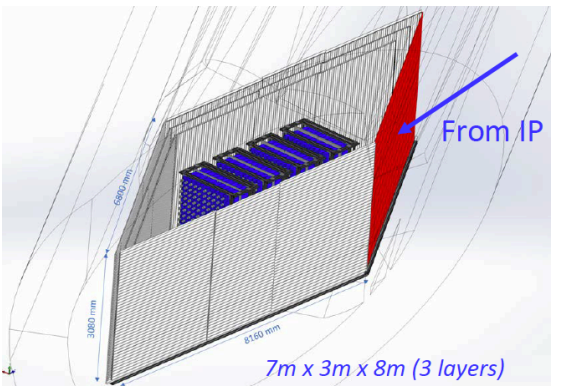

Fig. 1. Diagram of the MAPP-1 detector components: mQP at the centre and three layers of LLP around it.

Another part of the detector, the MAPP-LLP, is deployed as three nested boxes of scintillator hodoscope detectors, in a "Russian doll" configuration, following as far as possible the contours of the cavern as depicted in Fig. 1. It is designed to be sensitive to long-lived neutral particles from new physics scenarios via their interaction or decay in flight in a decay zone of size approximately 5 m (wide) $\times$ 10 m (deep) $\times$ 3 m (high). The MAPP detector can be deployed in a number of positions in the forward direction, at a distance of $\mathcal{O}(100$ m) from IP8. An upgrade plan for the MAPP-1 detector is envisaged for the High-Luminosity LHC (HL-LHC),[40] called MAPP-2, with considerably larger volume than MAPP-1.

Furthermore, the MoEDAL Apparatus for very Long Lived particles (MALL)[37] is intended to push the search for decays of new *electrically charged*, massive and *extremely* long-lived particles, with lifetimes well in excess of a year, by monitoring the exposed MMTs for decay products of trapped BSM particles.[37,38] Quite recently, an independent proposal has been presented to install such absorber volumes near the CMS IP.[41]

2.2. *FASER – ForwArd Search ExpeRiment*

FASER[42] is an approved small and inexpensive experiment designed to search for new particles produced in decays of light mesons copiously present at zero angle at the LHC in Run-3 and beyond. Such particles may be produced in large numbers and

travel for hundreds of meters without interacting, and then decay to SM particles. To search for such events, FASER will be located 480 m downstream of the ATLAS[5] IP in the unused service tunnel TI12 (cf. Fig. 12). It is planned to be constructed and installed in LS2 and collect data during Run 3.[43]

An overview of the different detector components is shown in Fig. 2.[44] The magnets are 0.55 T permanent dipole magnets based on the Halbach array design with a radius of 10 cm. There are three scintillator stations for timing, trigger and vetoing incoming charged particles. The electromagnetic calorimeter consists of four spare outer ECAL modules from LHCb. The tracker consists of three tracking stations, each containing three layers instrumented with spare ATLAS semiconductor-tracker barrel modules.

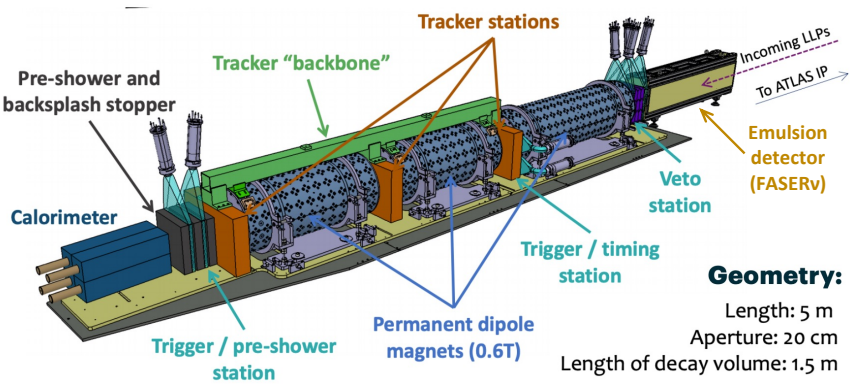

Fig. 2. Annotated schematic view of the FASER detector components.

Moreover, FASERν[45] is designed to directly detect collider neutrinos and study their cross sections at TeV energies. In 2018, a pilot detector employing emulsion films was installed in the far-forward region of ATLAS, also visible in Fig. 2, and collected 12.2 fb^{-1} of pp collision data at a $\sqrt{s} = 13$ TeV. The first candidate vertices consistent with neutrino interactions at the LHC were observed, an example of which is presented in Fig. 3, with a measured 2.7σ excess of neutrino-like signal above muon-induced backgrounds.[46]

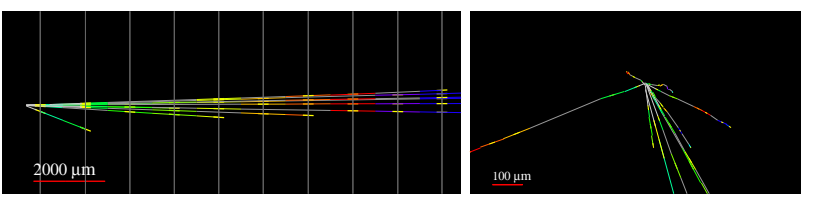

Fig. 3. FASERν event displays of a neutral vertex in the $y - z$ projection longitudinal to the beam direction (left) and in the view transverse to the beam direction (right).[46]

For the HL-LHC, FASER2,[43] a larger successor with roughly $R \sim 1$ m and $L \sim 5$ m is planned to be constructed during LS3 and installed in the LHC Forward Physics Facility (FPF) (cf. Fig. 12). Possible options for FPF locations are an expanded UJ12 cavern or a new cavern ~ 600 m downstream from IP1. Other experiments proposed to be housed in FPF include FASERν2,,[47] a detector with roughly ten times the mass of FASERν, as well as the Forward Liquid Argon Experiment (FLArE),[48] composed of a 10- or 100-tonne-scale liquid argon time projection chamber (LArTPC).

2.3. *SND@LHC – Scattering and Neutrino Detector at the LHC*

SND@LHC[49] is a recently approved, compact and stand-alone experiment designed to measure neutrinos produced at the LHC and search for FIPs in the unexplored range of $7.2 < \eta < 8.7$, where neutrinos are mostly produced from charm decay. It is a small-scale prototype of the SHiP[50] experiment Scattering and Neutrino Detector (SND). The proposed detector is hybrid, combining the nuclear emulsion technology and electronic detector; a schematic view is provided in Fig. 4. It will be installed in the TI18 tunnel, in a location off-axis with respect to the ATLAS[5] IP1.

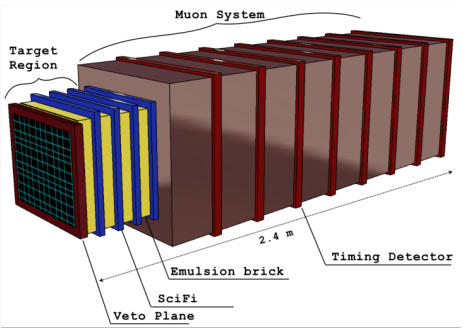

Fig. 4. Annotated schematic view of the SND@LHC detector components.[49]

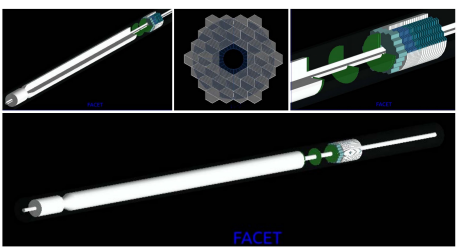

Fig. 5. Diagrams of the detector components of the FACET spectrometer.

2.4. *FACET – Forward-Aperture CMS ExTension*

FACET[51] is a multi-particle spectrometer to be located at $z \sim +100$ m from the CMS[6] IP5. The detector will have a radius of ~ 50 cm and coverage $6 < \eta < 8$, therefore it will be much closer to the IP and feature much larger decay volume than FASER. It is shielded by about $30 - 50$ m of steel in front of it, which corresponds to $190 - 300$ interaction lengths, λ_{int}. FACET will be fully integrated in CMS and can be used either a forward part of CMS or a standalone detector. Some GEANT4 modelling drawings of the FACET detector components are shown in Fig. 5. If approved, FACET will operate during HL-LHC.

2.5. *CODEX-b – COmpact Detector for EXotics at LHCb*

CODEX-b[52,53] is proposed as a cubic detector with a nominal fiducial volume of $10\ \text{m} \times 10\ \text{m} \times 10\ \text{m}$ to be situated in a transverse location ~ 25 m from the LHCb[8] IP8, as depicted in Fig. 6, corresponding to the pseudorapidity range $0.2 < \eta < 0.6$. It will be composed of six Resistive Plate Chamber (RPC) layers — being fast, precise and cheap for a large-area tracker — at 4 cm intervals on each box face with 1 cm granularity. An additional passive Pb shielding of $25\lambda_{\text{int}}$ with embedded active scintillator veto will reduce IP and secondary backgrounds. It is reminded that IP8 runs at a factor of ~ 10 less luminosity than IP1, IP2 and IP5.

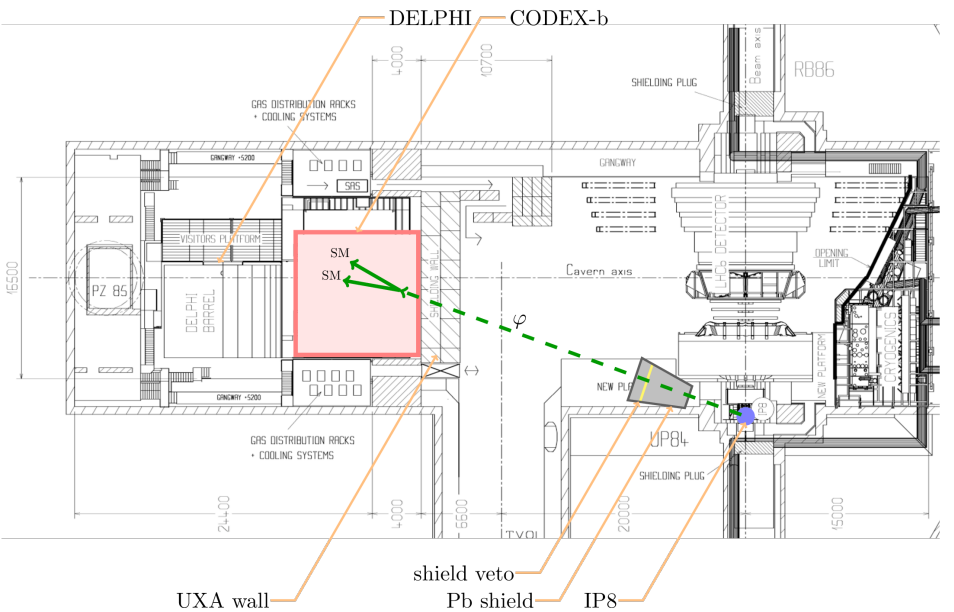

Fig. 6. Layout of the LHCb cavern UX85 at IP8, overlaid with the CODEX-b volume.[53]

CODEX-b will be interfaced with LHCb data acquisition, therefore there will have a unique trigger. Further additions to CODEX-b include calorimetry, which would significantly enhance the physics reach, e.g. photon signatures. Moreover, absorber or pre-shower layers can also perform particle identification, e.g. e/γ separation.

The CODEX-β demonstrator, with a volume of $2 \times 2 \times 2\ \text{m}^3$, is proposed to be operated during Run 3 to provide proof of concept. Its primary goal is to be integrate with LHCb online, reconstruct K_L^0 and measure background rates. It will provide competitive sensitivity to $b \to s\chi(\to \text{hadrons})$, as well.

2.6. *MATHUSLA – MAsive Timing Hodoscope for Ultra Stable neutraL pArticles*

MATHUSLA[54,55] is a proposed surface detector of a large footprint (area 100 × 100 m^2) and large decay volume (height 25 m) to be located above CMS,[6] as depicted in Fig. 7. The ∼ 90 m of rock between the IP5 and the detector decay volume provides enough shielding for MATHUSLA to work in a clean environment. The air-filled decay volume will be occupied by several detector layers for tracking in a modular way. RPCs and plastic scintillators are proven technologies that meet the specifications. Being a background-free experiment increases the sensitivity to LLPs up to decay lengths of 10^7 m and extends the sensitivity of the main detectors by orders of magnitude.

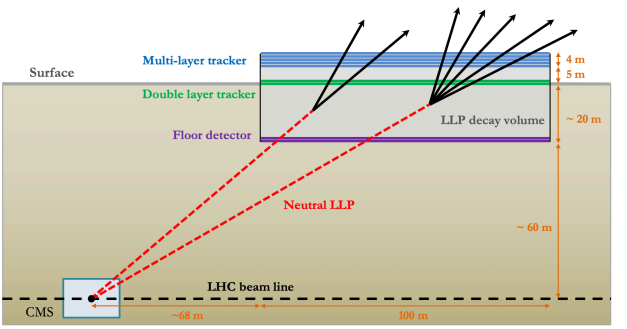

Fig. 7. The MATHUSLA detector layout positioned relative to CMS IP5.[55]

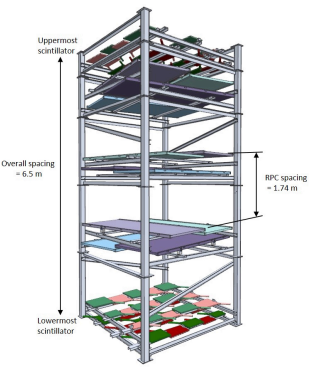

Fig. 8. The MATHUSLA test stand.[56]

A test stand following the concept of the full detector was installed in the surface area above the ATLAS[5] IP, taking data with different beam conditions during 2018.[56] The 2.5 × 2.5 × 6.5 m^3 unit detector is composed of one external layer of scintillators in the upper part and one in the lower part with six layers of RPCs between them, as shown in Fig. 8. The obtained results confirmed the background assumptions in the MATHUSLA proposal.

Moreover, MATHUSLA could act as a cosmic-ray (CR) telescope performing very precise measurements up to the PeV scale.[57,58] By integrating a device with the possibility to measure arrival times and particle densities of extensive air showers, such as an RPC, MATHUSLA can be employed as a CR detector and monitor a big portion of the sky above ($\theta < 80°$), without limitation to inclined events.

2.7. *ANUBIS – AN Underground Belayed In-Shaft*

ANUBIS[59] is an off-axis detector designed for neutral LLPs with $c\tau \gtrsim 5$ m, proposed to occupy the PX14 installation shaft of the ATLAS[5] experiment (cf. Fig. 9(left)),

which is not used during regular LHC operation. It will comprise four evenly spaced tracking stations (TS) with a cross-sectional area of 230 m^2 each, shown in Fig. 9(right). The tracking stations will use the same RPC technology as the new ATLAS layers and ATLAS can be used as an active veto of SM activity. The projective decay volume optimises the acceptance for different lifetimes. Two smaller TS prototypes are planned to be installed for Run 3 as a demonstrator.

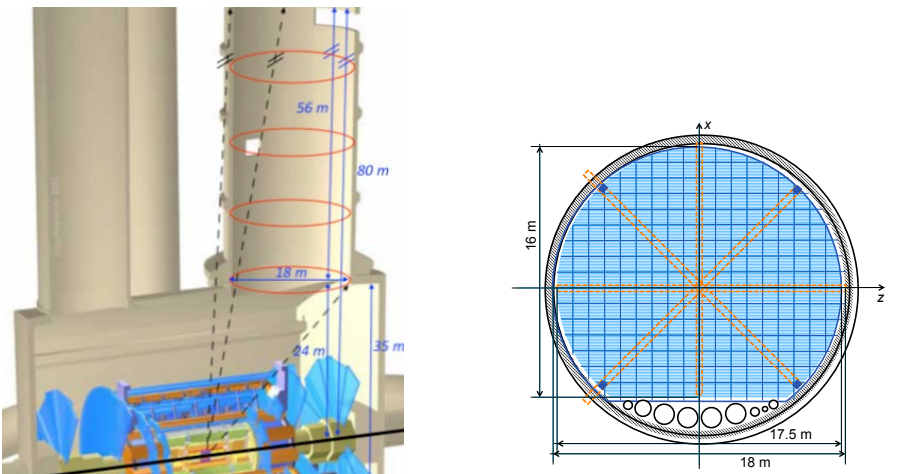

Fig. 9. Left: Location of the ANUBIS detector in the PX14 installation shaft of the ATLAS experiment. Above: One of the four ANUBIS tracking stations in the (x, z) plane. The shaft walls and the ATLAS cavern pipework are shown in gray, the TS in blue and the TS support structure in orange.[59]

2.8. *AL3X – A Laboratory for Long-Lived eXotics*

In the event that ALICE[60] finishes its physics program before the end of HL-LHC, it has been proposed[61] to reuse the L3 magnet at IP2 and the ALICE Time Projection Chamber (TPC) for LLP searches. This proposal requires to move the IP by 11.25 m outside the magnet, as shown in Fig. 10, to allow LLPs to travel before decaying. An additional thick shield and an active veto (D_1 and D_3) will reduce the background. The detector geometry corresponds to a pseudorapidity acceptance $0.9 < \eta < 3.7$. The AL3X configuration is in essence a tracking detector behind a heavy shield, which can be thought of as analogous to a calorimeter that is solely absorber. This permits AL3X to search for much rarer signals in a very low background environment compared to ATLAS and CMS, and in this sense AL3X would be complementary to the existing (and proposed upgraded) multi-purpose detectors.

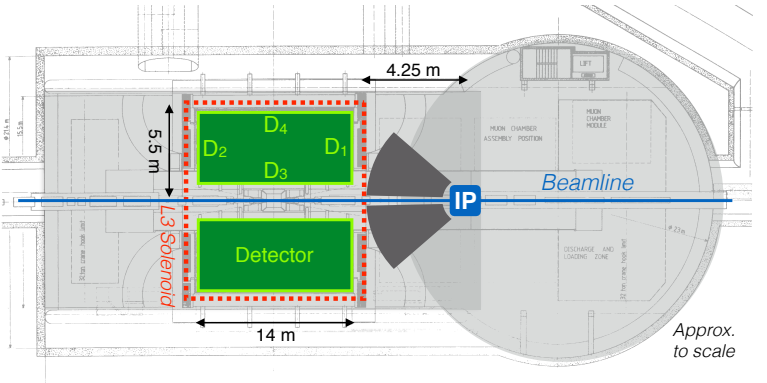

Fig. 10. Schematic view of the AL3X detector layout: the cylindrical TPC (dark green) and the veto and trigger layers D_i (light green). The current L3 magnet is shown (dashed red) for reference.[61]

2.9. *milliQan*

Just like MAPP-mQP, the milliQan detector,[62,63] to be installed near the CMS[6] IP5, will search for stable *millicharged* particles, unlike the majority of the aforementioned detectors which are sensitive to visible SM particles originating from *neutral* DM decays. The milliQan is located in an underground tunnel at a distance of 33 m from the CMS IP, with 17 m of rock between the IP and the detector that provides shielding from most particles produced in LHC collisions. In order to be sensitive to particles with charges as low as $0.001e$, a large active area of scintillator is required. For Run 3, two detector designs are planned for deployment. The bar detector is made of 0.2 m $\times$ 0.2 m $\times$ 3 m plastic scintillator bars surrounded by an active μ veto shield. The slab detector will increase the reach for heavier mCPs through 40 cm $\times$ 60 cm $\times$ 5 cm scintillator slabs.[64]

A small fraction of $\sim 1\%$ of the full detector, the *milliQan demonstrator,* shown in Fig. 11 was installed and operated to measure backgrounds and provide proof of principle. It allowed the first search for millicharged particles at a collider.[65] A data sample of 37.5 fb^{-1} pp collisions at $\sqrt{s} = 13$ TeV has been analysed and no excess over the background prediction observed. The results interpretation in terms dark photons is discussed later in Sec. 5.

2.10. *FORMOSA – FORward MicrOcharge SeArch*

FORMOSA[66] is also designed to discover millicharged particles, yet in the far-forward direction, close to the beam collision axis, where it can benefit from an enhanced mCP production cross section compared to the transverse direction. It is a scintillator-based detector to be hosted in the FPF, shown in Fig. 12. FORMOSA is proposed to start in Run 3 by moving the milliQan demonstrator to UJ12, as a phase called FORMOSA-I, with the full milliQan-type detector, FORMOSA-II, to be deployed at a later stage. The expected physics potential is discussed in Sec. 5.

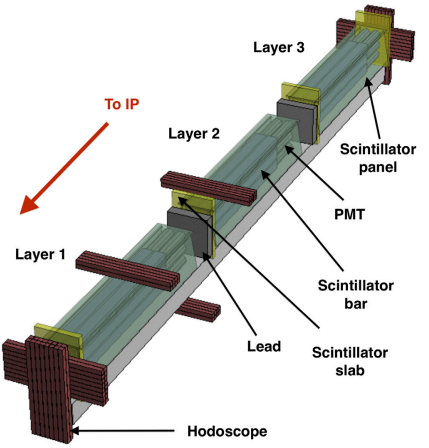

Fig. 11. Diagram of the milliQan demonstrator components.[65]

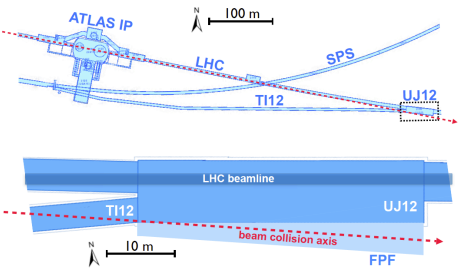

Fig. 12. Location of FORMOSA in the cavern UJ12 or side tunnel TI12 (blue) close to the beam collision axis (red). The FPF extension is shown as a light-blue area.[66]

3. The Higgs Portal

The so-called *scalar portal* involves a new dark scalar S, which mixes slightly with the SM-like Higgs, and provides a simple target for new physics searches.[67] The dark Higgs mixing portal admits exotic inclusive $B \to X\phi$ decays,[a] where ϕ is a light CP-even scalar that mixes with the SM Higgs, with a mixing angle of $\theta \ll 1$. The particle lifetime depends on the degree of mixing. One possible, simple Lagrangian which includes this new dark Higgs mixing is given by[68]

$$\mathcal{L} = \mathcal{L}_{\text{SM}} + \mathcal{L}_{\text{DS}} + \mu_S^2 S^2 - \frac{\lambda_S}{4} S^4 - \epsilon S^2 H^\dagger H, \tag{1}$$

where S is a real scalar field, H is a SM-like Higgs field, ϵ is the portal coupling, and λ_S is a free parameter. The quartic term contains the mixing between the SM Higgs and the new scalar, with the resulting physical fields: the SM Higgs h and the dark Higgs ϕ. Both fields acquire a non-zero VEV and the coupling between these two particles induces new Yukawa-like couplings between the dark Higgs and the SM fermions. In addition, there can appear a non-negligible trilinear interaction term between ϕ and h with the corresponding coupling denoted by λ, i.e. $\propto \lambda h\phi\phi$. Thus, the signal sought after in LLP experiments is two charged lepton tracks originating from dark Higgs decays $\phi \to \ell^+\ell^-$, in their fiducial volume.

Currently the best experimental limits on dark Higgs production at colliders come from CHARM[69] and LHCb,[70,71] shown in Fig. 13 in the $\sin^2\theta$-versus-m_S plane. If no trilinear coupling is assumed and the background is considered negligible, we derive the exclusion curves for MATHUSLA, SHiP, CODEX-b, MAPP-1

[a] D mesons and kaons have much smaller branching ratios into a Higgs-mixed scalar and are neglected.

and MAPP-2 that are shown in the same figure. MAPP-1 during Run 3 (30 fb^{-1}) is expected to provide considerable coverage, when the other experiments will be under construction; from the CODEX-b side, the CODEX-β demonstrator will be in operation. MAPP-2 extents significantly MAPP-1 sensitivity making it competitive with SHiP. As expected, MATHUSLA has better sensitivity in lower mixing angles, thus longer lifetimes, due to its large distance from the IP.

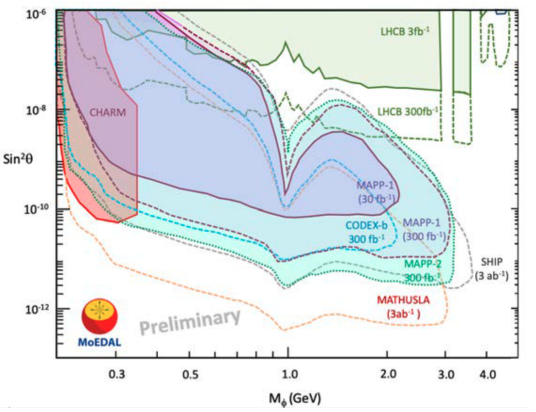

Fig. 13. 95% CL exclusion bounds Projected sensitivity of MoEDAL-MAPP and other experiments for dark Higgs bosons produced in rare B decays at $\sqrt{s} = 14$ TeV. Adopted from Ref. 61.

Assuming now a non-vanishing trilinear coupling λ, the expected sensitivity from the experiments presented in Sec. 2 is shown in Fig. 14. This time, a larger fraction of the parameters space is covered due to the contributions arising from a Higgs in the decay cascade, either virtual, e.g. the $B \to KSS$ mode, or real, e.g. the $h \to SS$. The branching fraction $BR(h \to SS) \sim 10^{-2}$ is considered to remain compatible with the LHC searches for the Higgs to invisible channels. The larger impact is provided by the bigger experiments, MATHUSLA,[72] SHiP,[73] FASER2[68] and CODEX-b,[74] which can explore the region well above the GeV mass scale in a fully uncharted range of couplings.

Dark scalar portals may have cosmological implications, contributing to the observed DM abundance. Dark Higgs bosons may mediate interactions with hidden dark matter that has the correct thermal relic density or resolves small-scale-structure discrepancies. Indeed, there are models with a dark Higgs inflaton strongly favoured by cosmological Planck[75] and BICEP/Keck Array[76] data that constrain the energy scale of inflation. One of these is expected to leave imprints on LHC experiments, such as FASER and MAPP-1.[77]

4. Dark Photons: Neutral Metastable States

A large class of BSM models includes interactions with light new *vector* particles. Such particles can result from additional gauge symmetries of BSM physics. New vector states can mediate interactions between the SM fields and extra dark-sector fields that may eventually play the role of the DM states.

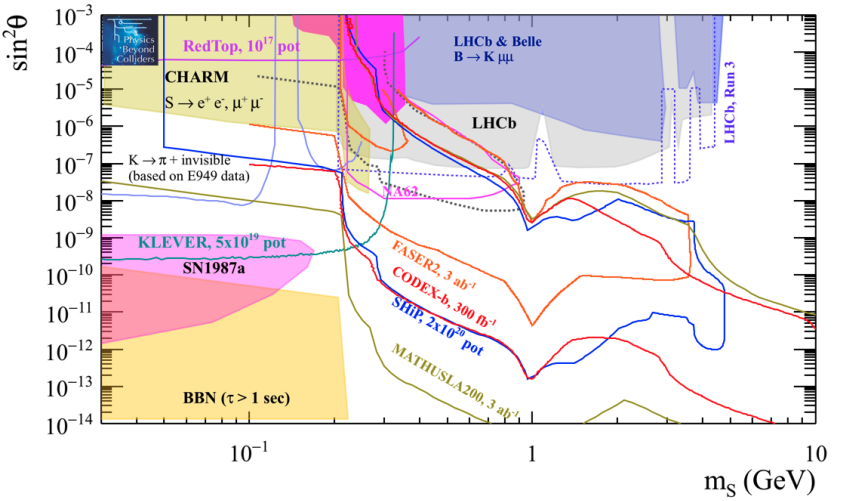

Fig. 14. Prospects on 10-15 year timescale for dark-scalar mixing with Higgs in the $(m_S, \sin^2\theta)$ plane with trilinear coupling $\lambda \neq 0$ and assuming $BR(h \to SS) = 10^{-2}$. The NA62^{++} and KLEVER curves correspond to $\lambda = 0$, so they are conservative.[74]

The most minimal vector portal interaction can be written as

$$\mathcal{L}_{\text{vector}} = \mathcal{L}_{\text{SM}} + \mathcal{L}_{\text{DS}} - \frac{\epsilon}{2\cos\theta_W} F'_{\mu\nu} B^{\mu\nu}, \tag{2}$$

where $\mathcal{L}_{\text{SM}}$ is the SM Lagrangian, $B_{\mu\nu}$ and $F'_{\mu\nu}$ are the field stengths of hypercharge and new $U'(1)$ gauge groups, ϵ is the so-called *kinetic mixing* parameter,[78] and $\mathcal{L}_{\text{DS}}$ stands for the dark sector Lagrangian that may include new matter fields χ charged under $U'(1)$,

$$\mathcal{L}_{\text{DS}} = -\frac{1}{4} F'_{\mu\nu} F'^{\mu\nu} + \frac{1}{2} m^2_{A'} A'_\mu A'^\mu + |(\partial_\mu + i g_D A'_\mu)\chi|^2 + \ldots \tag{3}$$

If χ is (meta)stable, it may constitute a fraction or entirety of dark matter. At low energy this theory contains a new massive vector particle, a *dark photon* state, coupled to the electromagnetic current with ϵ-proportional strength, $\epsilon A'_\mu J^\mu_{\text{EM}}$.

In the minimal dark photon model, DM is assumed to be either heavy or contained in a different sector. The dark photon, γ_{d}, decays into SM states (visible decays). The physics potential of the proposed LLP experiments as a function of the dark photon mass $m_{A'}$ and the coupling of dark photon with the SM photon ϵ is shown in Fig. 15, compared with existing bounds from several beam-dump data, e.g. Refs. 79, 80. The sensitivity for dark photons decaying into visible final states is expected to be dominated by SHiP,[73] while FASER2,[68] LDMX[81] and AWAKE[82] will be directly competing with SeaQuest, LHCb, Heavy Photon Search (HPS)[83] experiment, and others. MATHUSLA in this scenario is however not competitive, mostly due to the fact that the dark photon is produced in the forward direction.

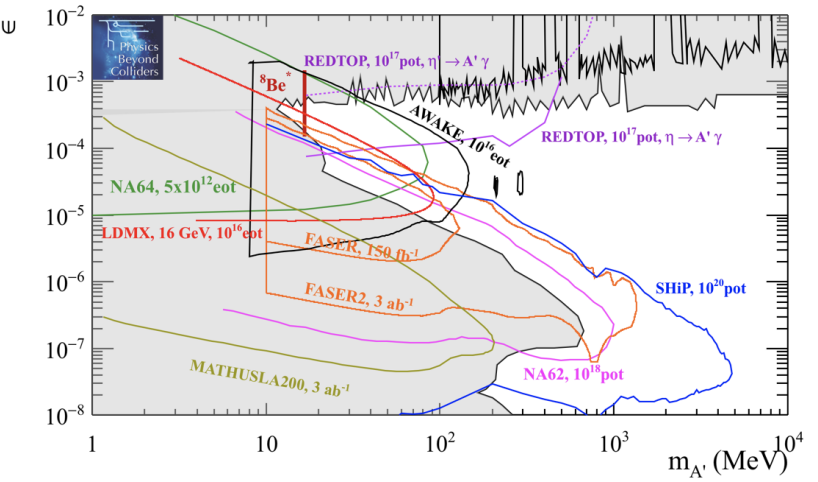

Fig. 15. Future upper limits at 90% CL for a minimal dark-photon model with visible decays in the plane mixing strength ϵ versus mass $m_{A'}$ for various projects on a ∼10–15 year timescale.[74]

In a different scenario, light (sub-GeV) DM, χ, may be coupled to a dark photon, constituting a minimally coupled weakly interacting massive particle (WIMP) model. The preferred values of the coupling g_D are such that $A' \to \chi\chi$, with χ potentially scattering further on electrons and nuclei, while $m_{A'}/m_\chi = 3$ is assumed for the masses. Recent studies on DM scattering off electrons[48] and off nuclei[84] in an emulsion detector (FASERν2) and a LArTPC (FLArE) in the FPF showed very interesting sensitivity, probing the thermal-relic region. Neutrino background may be separated from DM signal using energy and angle selection criteria. Such forward detectors open the possibility for performing a direct-detection-type DM search at the LHC.

In inelastic DM, which constitutes a viable and compelling paradigm for light thermal DM, DM couples to the SM only by interacting with a nearly degenerate dark-photon mediator heavier than $\sim$ 10 GeV. For relative mass-splittings larger than $\mathcal{O}(10^{-6})$, DM-nucleon/electron scattering at direct detection experiments is kinematically suppressed. However, at the LHC, where the DM and excited state can be directly produced, for mass-splittings above a few MeV, the excited state can decay back to DM and a pair of SM fermions, often on collider timescales. giving rise to visible displaced vertices. ATLAS, CMS, LHCb, CODEX-b, FASER, and MATHUSLA can detect such DM signals in the cosmologically motivated mass range of $\sim 1 - 100$ GeV.[85]

5. Dark Photons: Stable Millicharged Particles

Millicharged particles have been discussed in connection with the mechanism of electric charge quantisation and possible non-conservation of electric charge.[86] There are three experiments planned to run at the LHC that are sensitive to the detection

of the low ionisation coming from an mCP: milliQan (Sec. 2.9), the MAPP-mQP sub-detector (Sec. 2.1) and, the recently proposed, FORMOSA (Sec. 2.10).

A well-motivated mechanism that predicts mCPs is the introduction of a new massless $U'(1)$ gauge field, the dark photon, $A'_{\mu\nu}$, which is coupled to the SM photon field, $B^{\mu\nu}$. A new massive dark fermion ψ *(dark QED)* of mass M_{mCP}, is predicted, which is charged under the new $U'(1)$ field A' with charge e'. The Lagrangian for the model is given by[62]

$$\mathcal{L} = \mathcal{L}_{\mathrm{SM}} - \frac{1}{4}A'_{\mu\nu}A'^{\mu\nu} + i\bar{\psi}(\partial\!\!\!/ + ie'A\!\!\!/' + iM_{\mathrm{mCP}})\psi - \frac{\kappa}{2}A'_{\mu\nu}B^{\mu\nu}. \tag{4}$$

The last term contains the kinetic mixing, which one can eliminate by expressing the new gauge boson as, $A'_\mu \to A'_\mu + \kappa B_\mu$. Applying this field redefinition reveals a coupling between the charged matter field ψ to the SM hypercharge. The Lagrangian (4) then becomes:

$$\mathcal{L} = \mathcal{L}_{\mathrm{SM}} - \frac{1}{4}A'_{\mu\nu}A'^{\mu\nu} + i\bar{\psi}(\partial\!\!\!/ + ie'A\!\!\!/' - i\kappa e'B\!\!\!/ + iM_{\mathrm{mCP}})\psi. \tag{5}$$

It is now apparent that the field ψ acts as a field charged under hypercharge with a millicharge $\kappa e'$, which couples to the photon and Z^0 boson with a charge $\kappa e' \cos\theta_W$ and $-\kappa e' \sin\theta_W$, respectively. Expressing the fractional charge in terms of electric charge thus gives $\epsilon = \kappa e' cos\theta_W / e$.

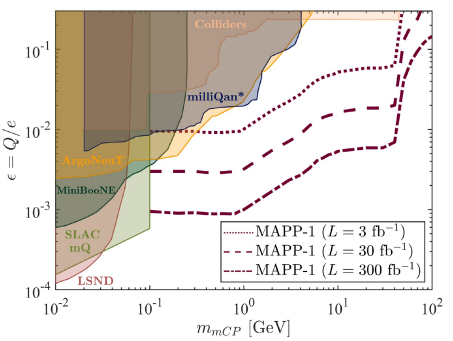

Fig. 16. 95% CL exclusion limits for dark fermion mCPs in the mass vs. charge plane obtained by the milliQan demonstator[65] compared to previous constraints and to the MAPP-mQP sensitivity for various integrated luminosity assumptions.[87]

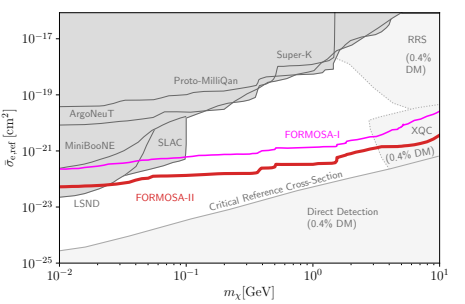

Fig. 17. Sensitivity reaches of FORMOSA in the millicharged SIDM window in terms of the reference cross-section $\bar{\sigma}_{\mathrm{e,ref}}$. In addition to accelerator constraints, constraints from direct-detection experiments (assuming 0.4% DM abundance for the direct-detection experiments) are drawn.[66]

The milliQan 1% scale demonstrator discussed in Sec. 2.9 and shown in Fig. 11 provided the first constraints on mCPs at LHC, as shown in Fig. 16. Pair-production of millicharged particles at 13 TeV is considered through the Drell-Yan process, as well as from Υ, J/ψ, $\psi(2S)$, ϕ, ρ, and ω decays into mCP pairs, and from Dalitz decays of π^0, η, η', and ω. This search excluded mCP masses of $20 - 4700$ MeV

for charges varying between $0.006e$ and $0.3e$ depending on mass.[65] MAPP-mQP, on the other hand, can extend these limits especially towards higher masses, while the reach in terms of low charges depends on the integrated luminosity; charges as low as $10^{-3}e$ will need the HL-LHC,[87] as evident from Fig. 16. Similar sensitivity is expected by the full milliQan detector during the HL-LHC run.[64]

When considering DM abundance, mCPs can account for a fraction of it that cannot be detected by direct-detection experiments due to attenuation effects, when the ambient DM has substantial cross section with SM particles making it to lose most of its kinetic energy. For some model parameters,[88,89] the DM particles cannot be detected by ground-based direct detection experiments after interacting with the atmospheric particles and the crust. These DM particles are generally referred to as strongly interacting DM (SIDM). In general, mCP-hunting experiments constrain the larger cross sections, leaving a gap, that can be filled by FORMOSA.[66] This is shown in Fig. 17, where the accessible *reference cross section* versus mCP mass is drawn for accelerator and for direct-detection experiments, together with the FORMOSA expected reach.

In addition to DM, apparent fractionally charged particles may arise as heavy neutrinos with a large enough electric dipole moment (EDM) to yield ionisation in mCP-sensitive detectors. It has been demonstrated that milliQan and MAPP-mQP have very good sensitivity in a scenario where the heavy neutrino is considered to be a member of a fourth generation lepton doublet with the EDM introduced within a dimension-five operator.[90,91]

6. More Portals and Beyond

As highlighted in the introduction in Sec. 1, besides the hidden sectors directly related to DM, namely the dark Higgs and dark photons, there are other portals, such as those predicting heavy neutral leptons and axion-like particles (ALPs). The quest for these objects is of equal interest to Particle Physics open questions, they are often related to dark matter and are similarly relevant to the above mentioned LLP experiments, as those discussed in Secs. 3, 4 and 5. Besides the portal connection to DM, LLPs can probe specific DM models, such as the case of MATHUSLA and dynamical dark matter.[92]

6.1. *Extended neutrino sector*

In the so-called *fermion portal*, new heavy neutral leptons (HNLs) are added to the SM to provide an elegant way to generate non-zero neutrino masses via the seesaw mechanism.[93–95] In type-I seesaw models, one extends the SM by adding neutral right-handed fermions (identified with HNLs) that couple to the SM neutrinos similarly to the coupling between left- and right-handed components of the charged leptons. In a considerable class of these models, the HNLs become long lived and the LLP experiments have good prospects to detect them.[74,96–100]

To highlight an example, in the case of right-handed neutrinos being produced in the decay of an additional Z' boson in the gauged $B-L$ model, which also contains a singlet Higgs that spontaneously breaks the extra $U(1)_{B-L}$ gauge symmetry, MAPP-2 will fill the gap left by CMS, LHCb, MATHUSLA, FASER2 and CODEX-b.[101]

Light sterile neutrinos can account for dark matter,[102–104] while sterile neutrinos with a broad range of masses can account for the baryon asymmetry of the Universe through leptogenesis.[105] Sterile neutrinos may be long-lived in simplified models where the SM is extended with one sterile neutrino[106] or in neutrino-extended SM Effective Field Theories, νSMEFT. Intermediate-mass can be produced in leptonic and semi-leptonic decays of charmed and bottomed mesons, decaying to leptons via neutral and charged weak currents, thus becoming detectable in LHC LLP experiments.[107]

6.2. *Axions & axion-like particles*

Axions, or more generally ALPs, are pseudoscalar pseudo-Nambu-Goldstone bosons arising from approximate Abelian global symmetries beyond the SM which are broken spontaneously at a scale much greater than the electroweak scale. Axions, in particular, were postulated by the Peccei-Quinn theory to resolve the strong CP problem in quantum chromodynamics. ALPs also provide an interesting connection to the puzzle of dark matter, because they can mediate the interactions between the DM particle and SM states and allow for additional annihilation channels relevant for the thermal freeze-out of DM. Prospects for searches for ALPs in LLP experiments are reviewed in Refs. 2, 4, 43, 53, 57, 73, 74, 108.

6.3. *Supersymmetry*

Going even further, supersymmetry (SUSY), a theoretical framework that provides a natural DM candidate, predicts the existence of LLPs. For instance, sleptons, charginos and R-hadrons (namely gluinos, top- or bottom-squarks) with unit electric charge may be detected in the MoEDAL NTDs, in the case they are sufficiently long lived to reach the detector.[109–111]

R-parity violating SUSY also predicts LLPs, such as light long-lived neutralinos $\tilde{\chi}_1^0$ decaying via λ'_{ijk} couplings to charged particles. Benchmark scenarios related to either charm or bottom mesons decaying into $\tilde{\chi}_1^0$ have been considered, in similar fashion as in sterile neutrinos, showing that these experiments can cover various meson production and decay modes and $\tilde{\chi}_1^0$ lifetimes.[53, 98, 112, 113]

7. Post-Discovery Matters

The variety of BSM scenarios predicting LLPs and the sensitivity to those by dedicated LLP experiments — and main detectors equally — begs the question regarding the power to provide qualitative and even quantitative information about the *nature*

of these LLPs in the post-discovery phase. The definition of *LLP simplified models*[2] serves as a bridge between specific theoretical models and particular experimental signatures.

The geometry of two-body γ_d/ϕ decays to massless final states can provide information about their velocity and the ability to discriminate between different γ_d/ϕ masses. CODEX-b can reconstruct the γ_d/ϕ velocity to better than 1% using spacial tracking information. If RPC timing information is used in a complementary way to discriminate between slow-moving new states, it is possible to separate between ϕ masses of 0.5 GeV and 2.0 GeV.[52]

If the LLP is pair-produced in Higgs boson decays, it is possible to measure the mass of this particle and determine the dominant decay mode with less than 100 observed events in MATHUSLA. In more general cases, the latter should be able to distinguish the production mode of the LLP and to determine its mass and spin based on the decay products of the long-lived particle.[114]

Moreover, if information from the LLP and the main experiment of the same IP, e.g. MATHUSLA and CMS, is combined, the LLP production mode topology could be determined with as few as ~ 100 observed LLP decays. Underlying theory parameters, like the LLP and parent particle masses, can also be measured with $\lesssim 10\%$ precision.[115]

8. Summary and Outlook

There is an ever increasing interest in long-lived particle searches at the LHC (and not only) to exlore the dark sector besides other unanswered questions in Particle Physics today. Besides the efforts in the main experiments ATLAS, CMS and LHCb, additional complementary experiments have been approved (MoEDAL, FASER, SND@LHC), aiming at data taking in Run 3, or have been proposed (MATHUSLA, CODEX-b, milliQan, ANUBIS, AL3X and others). In addition to these LHC detectors, the SHiP experiment at the SPS is also planned to explore hidden (dark) sectors. Several of these experiments have constructed, operated and analysed the data from small-scale demonstrators that proved the detector concept and provided the first encouraging (physics) results. Others plan to install such prototype for (part of) Run 3, before preparing a complete detector for the HL-LHC operation. The enigma of dark matter is challenged in a different perspective — the lifetime frontier — at the LHC Run 3 and beyond.

Constraining the interactions in the dark sector with cosmological data

Adrià Gómez-Valent[1,*], Valeria Pettorino[2] and Luca Amendola[1]

We provide constraints on coupled dark energy (CDE) cosmology with Peebles-Ratra (PR) potential, $V(\phi) = V_0\phi^{-\alpha}$, and constant coupling strength β. This modified gravity scenario introduces a fifth force between dark matter particles, mediated by a scalar field that plays the role of dark energy. The mass of the dark matter particles does not remain constant, but changes with time as a function of the scalar field. Here we assess the ability of the model to describe updated cosmological data sets that include the *Planck* 2018 cosmic microwave background (CMB) temperature, polarization and lensing, baryon acoustic oscillations, the Pantheon compilation of supernovae of Type Ia, data on $H(z)$ from cosmic chronometers, and redshift-space distortions. We also study the impact of the local measurement of H_0 from SH0ES and the strong-lensing time delay data from the H0LICOW collaboration on β. We find a peak corresponding to a coupling $\beta > 0$ and to a potential parameter $\alpha > 0$, more or less evident depending on the data set combination. We show separately the impact of each data set and remark that it is especially CMB lensing the one data set that shifts the peak the most towards ΛCDM. When a model selection criterion based on the full Bayesian evidence is applied, however, ΛCDM is still preferred in all cases, due to the additional parameters introduced in the CDE model. The model is not able to loosen significantly the H_0 tension. This contribution to the proceedings of the DM1 parallel session of the 16th Marcel Grossmann virtual Conference: "Interacting dark matter" is based on the paper 2004.00610.[1]

Keywords: Cosmology: observations; Cosmology: theory; cosmological parameters; dark energy; dark matter.

1. Introduction

Important observational hints in favor of the positive acceleration of the Universe appeared already more than twenty years ago, thanks to the detection of standardizable high-redshift supernovae of Type Ia (SNIa) and the measurement of their light-curves and redshifts.[2,3] Since then, many other probes have contributed to increase the evidence in favor of the late-time accelerated phase. They range e.g. from the detection of the baryon acoustic peak in the two-point correlation function of matter density fluctuations[4,5] to the very accurate measurement of the cosmic microwave background (CMB) temperature anisotropies by WMAP[6] and *Planck*.[7–9]

*Speaker. E-mail: gomez-valent@thphys.uni-heidelberg.de

At the phenomenological level, the easiest explanation for such acceleration is given by the presence of a very tiny cosmological constant in Einstein's field equations, with an associated energy density which is orders of magnitude lower than the quantum field theoretical estimates made for the vacuum energy density. Protecting such low value from radiative corrections is extremely difficult and constitutes the core of the so-called "old" cosmological constant problem, cf. e.g.[10–12] In addition, explaining why the current value of this energy density is of the same order of magnitude as the matter energy density, the so-called "coincidence problem", is considered by part of the cosmological community as another problem that needs to be addressed. The cosmological constant is a pivotal ingredient of the standard cosmological model, also known as ΛCDM or concordance model (cf. e.g. the reviews[13,14]), which can explain most of the cosmological observations with high proficiency. Nevertheless, the aforementioned theoretical conundrums, together with few persistent tensions in some relevant parameters of the model as the Hubble parameter H_0[9,15] and the root-mean-square (*rms*) of mass fluctuations at scales of $8h^{-1}$ Mpc,[16] σ_8 (or $S_8 = \sigma_8(\Omega_m^{(0)}/0.3)^{0.5}$ [a17]), with h being the reduced Hubble parameter, motivate theoretical cosmologists to look for alternative scenarios in which these problems can be solved or, at least, alleviated, see[18,19] and references therein. Wherever the solution comes from, i.e. a departure from General Relativity or some sort of new field describing dark energy (DE), it must mimic very well the behavior of a cosmological constant at low redshifts, meaning that the corresponding effective equation of state (EoS) parameter must be very close to -1, and that the new component must not be able to cluster efficiently at low scales.

In this paper we consider a scenario in which dark matter (DM) particles interact via a force mediated by a scalar field, which in turn drives cosmic acceleration. This scenario is referred to as *coupled dark energy* (CDE). It was originally proposed as a means of alleviating the coincidence problem,[20,21] considering not only a potential energy density for quintessence to generate its dynamics, but also allowing an interaction with other sectors of the theory. These interactions extended the original quintessence models.[22–25] They cannot be ruled out *a priori* and, hence, they must be duly constrained by experiments and observations.

Some works already set constraints on this model, but using older cosmological data sets, for instance CMB data from the WMAP satellite and the South Pole Telescope,[26] or considering past (2013, 2015) releases of *Planck* CMB data in combination with other data sets, as e.g. from baryon acoustic oscillations (BAO) and SNIa,[27,28] Intriguingly, these works detected a likelihood peak at a non-vanishing value of the coupling constant. One of our main goals is then to critically revisit and update these results in the light of the recent strengthening of the H_0 tension and of the rich amount of currently available data at our disposal, in particular the *Planck* 2018 CMB temperature, polarization and lensing data, but also other new cosmological data, for instance Refs.[29,30]. For constraints on other models with DM-DE

[a]The superscripts (0) will denote from now on quantities evaluated at present, i.e. at $a = 1$.

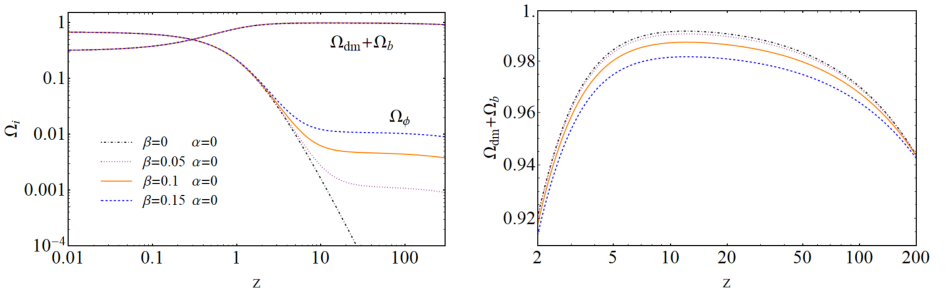

Fig. 1. *Left plot:* Normalized densities $\Omega_{dm}(z)+\Omega_b(z)$ and $\Omega_\phi(z)$ for four alternative values of β and considering a constant potential. The other parameters (including the current energy densities) have been set to the best-fit ΛCDM values from the TTTEEE+lowE *Planck* 2018 analysis.[9] *Right plot:* Here we zoom in the range $z=[2,200]$ of the $\Omega_{dm}+\Omega_b$ curves in order to better visualize their evolution during the matter-dominated epoch, when the system is near the ϕMDE fixed point. See the text for details.

interactions see e.g.,[31–44] and when the interaction is motivated in the context of the running vacuum models.[40,41,45–48]

2. Coupled dark energy

We consider a CDE scenario, as studied in,[21,49,50] to which we refer for a detailed description. We here briefly recall the main equations. This CDE model is formulated in the so-called Einstein or observational frame.[51] Apart from the Standard Model of Particle Physics and a potential extension accounting for the origin of the neutrino masses, we consider a dark sector described by the following Lagrangian density:

$$\mathcal{L}_{\rm dark}=-\partial_\mu\phi\partial^\mu\phi-V(\phi)-m(\phi)\bar{\psi}\psi+\mathcal{L}_{\rm kin}[\psi]\,, \tag{1}$$

where ϕ is the scalar field that plays the role of DE, with potential $V(\phi)$, and ψ is the DM field, considered here to be of fermionic nature, just for illustrative purposes. The DM particles interact with the DE due to the ϕ-dependent mass term appearing in (1). Such interaction introduces a fifth force that alters the trajectory in spacetime of the DM with respect to the one found in the uncoupled case. As we do not couple ϕ to the standard model sector we avoid the stringent local (Solar System) constraints on the violation of the weak equivalence principle,[52] and also on screened fifth forces that couple ϕ to non-dark matter, e.g. from Casimir experiments,[53] precision measurements of the electron magnetic moment,[54] or measurements of the Eötvös parameter.[55] They have no impact on the CDE model under study.

The variation of the total action with respect to the metric leads as usual to Einstein's equations, and the covariant energy of the joint system DM-DE is conserved. Hence, $\nabla^\mu T^\phi_{\mu\nu}=+Q_\nu$ and $\nabla^\mu T^{dm}_{\mu\nu}=-Q_\nu$, with Q_ν defined as

$$Q_\nu=\beta\kappa T^{dm}\nabla_\nu\phi\,, \tag{2}$$

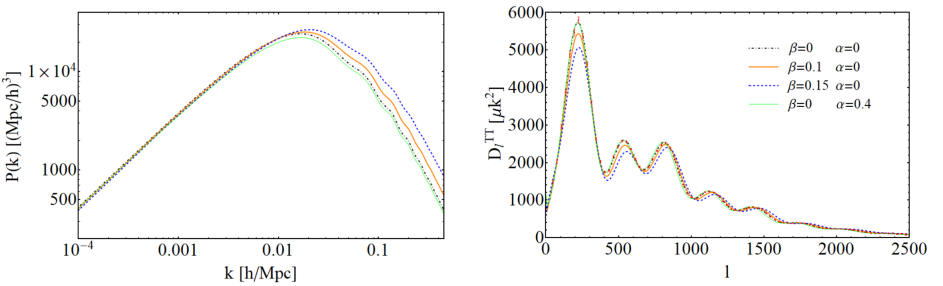

Fig. 2. Theoretical curves of the current matter power spectrum (left plot) and CMB temperature anisotropies (right plot) for the ΛCDM, two CDE models with $\beta = 0.1$, 0.15 and flat potential, and also for the uncoupled Peebles-Ratra model with $\alpha = 0.4$. We set the other parameters as in Fig. 1. In the right plot we also include the observational data from[9] (in red). These figures show: (i) the enhancement of the growth of matter perturbations caused by $\beta > 0$, and the opposite effect produced by $\alpha > 0$; and (ii) the shift to larger multipoles and the amplitude suppression of the acoustic peaks induced by increasing values of β. See the text for further details.

where $\kappa = \sqrt{8\pi G}$, T^{dm} is the trace of the DM energy-momentum tensor, and β controls the strength of the interaction and is in general a function of ϕ. If set to zero, we recover the equations of uncoupled quintessence. In this work we consider β to be a positive constant.

We assume that the Universe is spatially flat, as supported by CMB information from *Planck* 2018 when combined with BAO[9] and/or SNIa,[56] with the curvature parameter $\Omega_K^{(0)}$ constrained to be lower than $\sim 2\%$ at 68% c.l. in ΛCDM. Thus, we can make use of the Friedmann-Lemaître-Robertson-Walker metric, which at the background level reads $ds^2 = a^2(\tau)\left[-d\tau^2 + \delta_{ij}dx^i dx^j\right]$, with a being the scale factor, τ the conformal time, and x^i for $i = 1, 2, 3$ the spatial comoving coordinates. In addition, we treat DM as a pressureless perfect fluid, so the conservation equations for DE and DM can be written, respectively,

$$\beta\kappa a^2 \rho_{dm} = \phi'' + 2\mathcal{H}\phi' + a^2 \frac{\partial V}{\partial \phi}\,, \tag{3}$$

$$\rho'_{dm} + 3\mathcal{H}\rho_{dm} = -\beta\kappa\rho_{dm}\phi'\,, \tag{4}$$

with ρ_{dm} the DM energy density, $\mathcal{H} = a'/a$, and the primes denoting derivatives *w.r.t.* the conformal time. All the functions entering these equations are background quantities. If we assume the conservation of the number density of DM particles then their mass evolves as $m(\phi) = m^{(0)} e^{\beta\kappa(\phi^{(0)} - \phi)}$.

A feature of the model is that for $\beta^2 < 3/2$ it has an unstable (saddle) fixed point at $(\Omega_{dm}, \Omega_\phi) = (1 - 2\beta^2/3, 2\beta^2/3)$, where $\Omega_i = \rho_i/\rho_c$, with ρ_c the critical energy density. This fixed point (dubbed ϕMDE in[21]) cannot be reached exactly, since there is also a non-null fraction of baryons, but the system can be quite close to it, since the DM energy density is much larger than the baryonic one (cf. Fig. 1). During this phase the effective EoS parameter, i.e. the ratio of the total pressure

and the critical energy density in the Universe, is given by $w_{\rm eff} = \Omega_\phi$, and hence the deceleration parameter reads $q = \frac{1}{2}(1+3\,w_{\rm eff}) = \frac{1}{2}+\beta^2$. Thus, the coupling between DM and DE makes the Universe more decelerated with respect to the uncoupled quintessence case during the matter-dominated epoch (MDE). This fact together with the fifth force that enters now as a new source term in the Poisson equation help matter inhomogeneities to grow faster for larger values of β. We also remark that for fixed values of the present energy densities, matter becomes dominant over radiation earlier in time when $\beta > 0$, with respect to the uncoupled case. In the CDE scenario, the equation for the DM density contrast $\delta_{dm} = \delta\rho_{dm}/\rho_{dm}$ at deep subhorizon scales ($k \gg \mathcal{H}$) and when non-linear processes are unimportant, reads,

$$\delta''_{dm} + (\mathcal{H} - \ \beta\kappa\phi')\delta'_{dm} - 4\pi G a^2[\rho_b\delta_b + \rho_{dm}\delta_{dm}(1+2\beta^2)] = 0\,. \tag{5}$$

If we neglect the contribution of baryons, $\delta_m(a) \sim a^{1+2\beta^2}$. Hence, larger values of β enhance the matter power spectrum (see the left plot of Fig. 2) and leave an imprint on the CMB temperature anisotropies. First, the integrated Sachs-Wolfe effect[57] is enhanced during the MDE earlier than in the uncoupled scenario, in which such effect is only relevant after matter-domination; second, the coupling affects lensing of CMB by large scale structure; the interaction also shifts the position of the acoustic peaks to larger multipoles due to the decrease of the sound horizon at the baryon-drag epoch, which is caused by the increase of the mass of the DM particles. Finally, the amplitude is suppressed, because of the decrease of ρ_b/ρ_{dm} at recombination. These two effects explain why the coupling strength is degenerate with the Hubble parameter today,[27] whose value is related to the position and overall amplitude of the first peak. These and other aspects of the structure formation were already discussed in.[50,58–60] See therein for further details, and also the plots in Fig. 2.

The quintessence potential only rules the dynamics of ϕ in the late-time universe, after the MDE, when the interaction term appearing in the *l.h.s.* of (3) becomes subdominant. It helps to slow down structure formation processes *w.r.t.* the flat-potential scenario (for a fixed value of the current DE density). Hence, it can compensate in lesser or greater extent (depending on its steepness) the enhancement of power generated by the fifth force during the MDE (cf. the left plot of Fig. 2 and its caption).

We employ the Peebles-Ratra (PR) potential,[24,25]

$$V(\phi) = V_0\phi^{-\alpha}\,, \tag{6}$$

with V_0 and $\alpha > 0$ being constants, and the former having dimensions of mass$^{4+\alpha}$ in natural units, since ϕ has dimensions of mass. We want to update the constraints on the parameters of the CDE model with PR potential that were obtained in some past works using older CMB data, from WMAP and/or past releases of *Planck* (cf.[26–28,61]), so it is natural to stick to (6) here. Also because it has proved to be capable of improving the description of some cosmological data sets with respect to the ΛCDM model in the non-interactive case.[62–64]

The CDE model we are considering (i.e. CDE with PR potential) has three nested models, namely the ΛCDM, the PR model, and the CDE model with flat potential. They are obtained from the full CDE model with (6) in the limits $(\alpha, \beta) \to (0, 0)$, $\beta \to 0$ and $\alpha \to 0$, respectively. For constraints on these scenarios cf. appendix B of Ref.[1].

For recent studies on CDE with an exponential potential, see[31,33,34,43] and appendix C of Ref.[1]. The results are very similar to the ones obtained with the PR potential.

3. Methodology and data

We have implemented the CDE model described in Sec. 2 in our own modified version of the Einstein-Boltzmann system solver `CLASS`.[65] The Bayesian exploration of the parameter space of the model in the light of the various data sets has been carried out with the Monte Carlo sampler `Montepython`.[66] We have also used the `Python` package `GetDist`[67] to process the chains and obtain the mean values and uncertainties of the parameters reported in Table 1, as well as the contours of Figs. 3-4. Finally, we have computed the full Bayesian evidences for all the models and under the various data sets, by processing the corresponding Markov chains with the code `MCEvidence`.[68] This has allowed us to carry out a rigorous model comparison analysis, which we present in Sec. 4.

Our data set is very similar to the one used by the *Planck* collaboration in their 2018 analysis of the ΛCDM and minimal extensions of it.[9] There are some differences, though, e.g. we analyze here the effect of cosmic chronometers and the H0LICOW data, something that was not done there. We refer the reader to Sec. 3 and reference[9] for details.

This is the list of individual data sets that we employ in this work to constrain the CDE model presented in Sec. 2:

- CMB: The main results of this paper are derived making use of the full TTTEEE+lowE CMB likelihood from *Planck* 2018.[9] We also study what is the impact of also including the CMB lensing likelihood.[69]
- BAO: We use the data points reported in[30,70–75]
- SNIa: We consider 6 effective points on the Hubble rate, i.e. $E(z) \equiv H(z)/H_0$, and the associated covariance matrix. They compress the information of 1048 SNIa contained in the Pantheon compilation[76] and the 15 SNIa at $z > 1$ from the Hubble Space Telescope Multi-Cycle Treasury programs.[77]
- Cosmic chronometers (CCH): We have employed the 31 data points on $H(z_i)$ at various redshifts provided in.[78–85] More concretely, we make use of the *processed* sample provided in Table 2 of,[86] which is more conservative, since it introduces corrections accounting for the systematic errors mentioned above.

Table 1. Constraints obtained using the data set combinations described in Sec. 3 on the following parameters of the CDE model: the reduced DM and baryon energy densities, $\Omega_{dm}^{(0)}h^2$ and $\Omega_b^{(0)}h^2$; the reionization optical depth, τ; the Hubble parameter, H_0 (in units of km/s/Mpc); the power of the primordial power spectrum, n_s; the current amplitude of mass fluctuations at $8h^{-1}$ Mpc, σ_8; the coupling strength β; and the power of the PR potential (6). We provide the mean values and 68% confidence intervals for each of them. We also show the differences *w.r.t.* the ΛCDM of the minimum values of the χ^2-function, and the natural logarithm of the Bayes ratio $B_{\rm CDE,\Lambda}$, as defined in (9)-(10). The (small) negative values of $\chi^2_{min.\rm CDE} - \chi^2_{min,\Lambda}$ tell us that CDE is able to fit slightly better the data than the ΛCDM; if we use as an alternative estimator the Bayes factor, we find negative values of $\ln(B_{\rm CDE,\Lambda})$, indicating a preference for the ΛCDM model. See Sec. 4 for a thorough discussion.

- Redshift-spcae distortions (RSD): We also use large-scale structure measurements from the anisotropic clustering of galaxies in redshift space. Galaxy redshift surveys provide constraints on the product of the growth rate of structure, $f(z) = \frac{d \ln \delta_m(a)}{d \ln a}$, and the *rms* of mass fluctuations at scales of $8h^{-1}$ Mpc, $\sigma_8(z)$. The data points employed in this work are found in Refs.[30,71,87–95]. The internal correlations between the BAO and RSD data from[71] and[30] have been duly taken into account through the corresponding covariance matrices provided in these two references.
- SH0ES: In some of our data set combinations we include the prior on the Hubble parameter, $H_{0,\mathrm{SH0ES}} = (74.03 \pm 1.42)$ km/s/Mpc obtained by the SH0ES Team with the cosmic distance ladder method.[15] This value of the Hubble parameter is in 4.4σ tension with the TTTEEE+lowE+lensing best-fit ΛCDM model of *Planck* 2018,[9] $H_0 = 67.36 \pm 0.54$ km/s/Mpc.
- H0LICOW: In combination with the prior on H_0 from SH0ES we also use the angular diameter distances reported by the H0LICOW collaboration. They analyze six gravitationally lensed quasars of variable luminosity. After measuring the time delay between the deflected light rays and modeling the lenses they are able to measure the so-called time-delay distances $D_{\Delta t}$ (cf.[29] and references therein). We use their reported six time-delay distances (one for each lensed system), and one distance to the deflector B1608+656, which according to the authors of[29] is uncorrelated with the corresponding $D_{\Delta t}$. The relevant information for building the likelihood can be found in Tables 1 and 2 of,[29] and their captions. Assuming the concordance model, these distances lead to a value of $H_0 = (73.3^{+1.7}_{-1.8})$ km/s/Mpc, which is in 3.2σ tension with the one obtained from the TTTEEE+lowE+lensing analysis by *Planck*.[9]

For more detailed information about these data sets see Ref.[1] and the original observational works.

We proceed now to describe the data set combinations under which we have obtained the main results of this work. They are discussed in detail in Sec. 4. We put constraints using the following combinations: (i) TTTEEE+lowE CMB data from *Planck* 2018,[9] in order to see the constraining power of the CMB when used alone, and also to check whether these data lead to a higher value of H_0 than in the ΛCDM. For simplicity, we will refer to this data set as P18 throughout the paper; (ii) P18+BSC, with BSC denoting the background data set BAO+SNIa+CCH; (iii) We add on top of the latter the linear structure formation information contained in the RSD data, P18+BSC+RSD; (iv) We study the impact of the CMB lensing by also adding the corresponding likelihood, P18lens+BSC+RSD; (v) Finally, we analyze the impact of the prior on H_0 from SH0ES[15] and the H0LICOW angular diameter distances[29] by using the data sets P18+SH0ES+H0LICOW, P18lens+SH0ES+H0LICOW and P18+BSC+SH0ES+H0LICOW. The distance ladder and strong-lensing time delay measurements of the Hubble constant are

completely independent (see e.g. the reviews[96, 97]). When combined, they lead to

$$H_{0,comb} = (73.74 \pm 1.10)\,\mathrm{km/s/Mpc}\,, \tag{7}$$

in 5.2σ tension with the best-fit ΛCDM value reported by *Planck* 2018.[9] Hence, it is interesting to check what is the response of the CDE model under these concrete data sets, and to compare the results with those obtained using only the CMB likelihood.

4. Results

Our main results are presented in Table 1 and Figs. 3-4. When we only employ the CMB temperature and polarization data from *Planck* 2018[9] (i.e. the P18 data set) to constrain the CDE model, the fitting values obtained for α and β are compatible at 1σ c.l. with 0, i.e. with a cosmological constant and no interaction in the dark sector (cf. the first row, first column in Table 1). The value of H_0 remains low, roughly 4.1σ below the cosmic distance ladder measurement of.[15] Similarly, when we combine *Planck* with BSC background data or with BSC+RSD, we get a value of H_0 which is 3.8σ and 3.7σ away from the SH0ES value, respectively.

As we have explained in Sec. 2, there is a degeneracy between the strength of the fifth force, i.e. the parameter β, and the Hubble parameter. CDE is in principle able to lower the value of the sound horizon at the decoupling time, r_s, and the amplitude of the first peak of the $\mathcal{D}_l^{TT}$'s. The CMB data fix with high precision the angle $\theta_* = r_s/D_A^{(c)}(z_{dec})$, with $D_A^{(c)}(z_{dec})$ the comoving angular diameter distance to the CMB last scattering surface. This means that in order to keep this ratio constant, H_0 will tend to grow for increasing values of the coupling strength, so that $D_A^{(c)}(z_{dec})$ decreases and compensates in this way the lowering of r_s, while keeping the height of the first peak compatible with data. This positive correlation between H_0 and β can be appreciated in the left-most contour plot of Fig. 3. The latter shows 1 and 2σ posterior probabilities for a selection of cosmological parameters. As discussed, we confirm from the first plot a mild degeneracy between H_0 and β. The strength of the fifth force does not seem to be very degenerate with σ_8 nor with the potential parameter α.

The impact of adding background data on top of P18 can be grasped by looking at the one-dimensional posterior distributions of Fig. 3 (in blue), and also at the numbers of the first row/second column of Table 1. Using the P18+BSC combined data set we find that β and α are now ~ 2.5 and $\sim 3.1\sigma$ away from 0, respectively. The values of H_0 and σ_8, are however compatible at 1σ with the ones obtained using only the P18 data set. They are also fully compatible with those obtained with the ΛCDM under the same data set, which read: $H_0 = (68.29 \pm 0.37)$ km/s/Mpc, $\sigma_8 = 0.812^{+0.006}_{-0.008}$. The peaks in β and α may indicate a mild preference of low-redshift data, when combined with the CMB, for a non-null interaction in the dark sector and a running quintessence potential. As noted already in,[28] we remark that this preference does not seem to correspond to a large improvement in the minimum

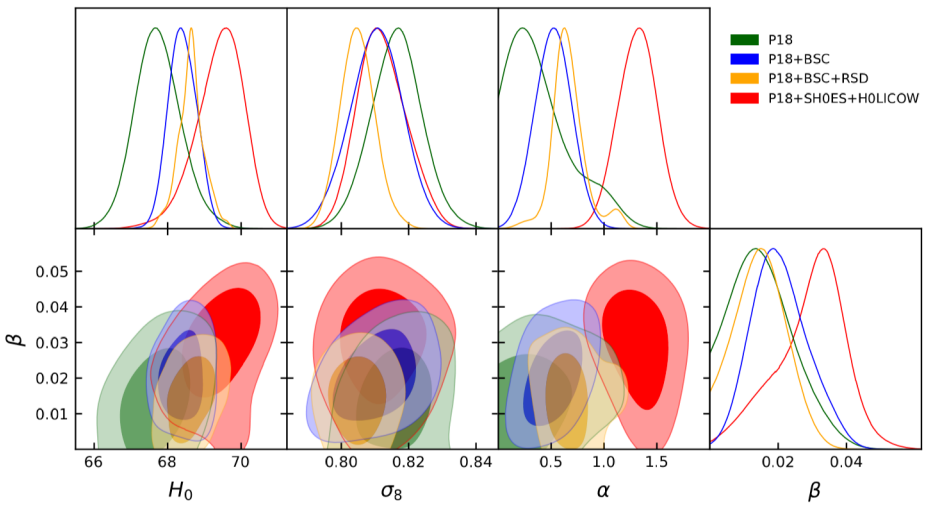

Fig. 3. 1 and 2σ confidence contours obtained using some of the combined data sets described in Sec. 3 in the (H_0, β), (σ_8, β), and (α, β) planes, together with the marginalized one-dimensional posterior distributions for these parameters. See the discussion of these results in Sec. 4.

value of χ^2 with respect to the ΛCDM: under the P18+BSC data set, $\chi^2_{min,\mathrm{CDE}} - \chi^2_{min,\Lambda}$ is negative, but very close to 0, which means that the CDE model only is able to improve the description of the data in a very marginal way.

The addition of the RSD data to the P18+BSC combined data set doesn't change much the result: there is a very small shift in the peak of the one-dimensional posterior distribution for α to larger values and the one for β to lower ones (see the yellow curves in Fig. 3). These two facts reduce a little bit the value of σ_8. The aforesaid peaks are now ~ 5 and $\sim 2\sigma$ away from 0, respectively, with a reduction of χ^2_{min} *w.r.t.* the ΛCDM of 1.56 units (cf. Table 1, second row/second column), i.e. pointing to a very small preference for CDE. The value of H_0 is almost unchanged.

We find important to highlight the specific impact of CMB lensing data with respect to the P18+BSC+RSD data set. If we include also the CMB lensing information, i.e. if we consider the P18lens+BSC+RSD combined data set, posterior probabilities squeeze, as expected, towards the ΛCDM values. This can be seen in Fig. 4, and also in the third row/first column of Table 1.

In order to further evaluate the level at which the degeneracy observed in the (H_0,β)-plane can alleviate the tension in the Hubble parameter between *Planck* and {SH0ES, H0LICOW} data, we perform a Monte Carlo analysis combining those data within the CDE model: results are shown in the second row/first column in Table 1 and correspond to red contours in Fig. 3. In this case, the best fit corresponds to a value of $\beta = 0.0294^{+0.0120}_{-0.0076}$, i.e. at 3σ from zero coupling, a value of $\alpha = 1.32 \pm 0.18$, with $\alpha > 0$ at $\sim 7\sigma$ c.l., and $H_0 = (69.43^{+0.72}_{-0.53})$ km/s/Mpc. The raise of H_0 is

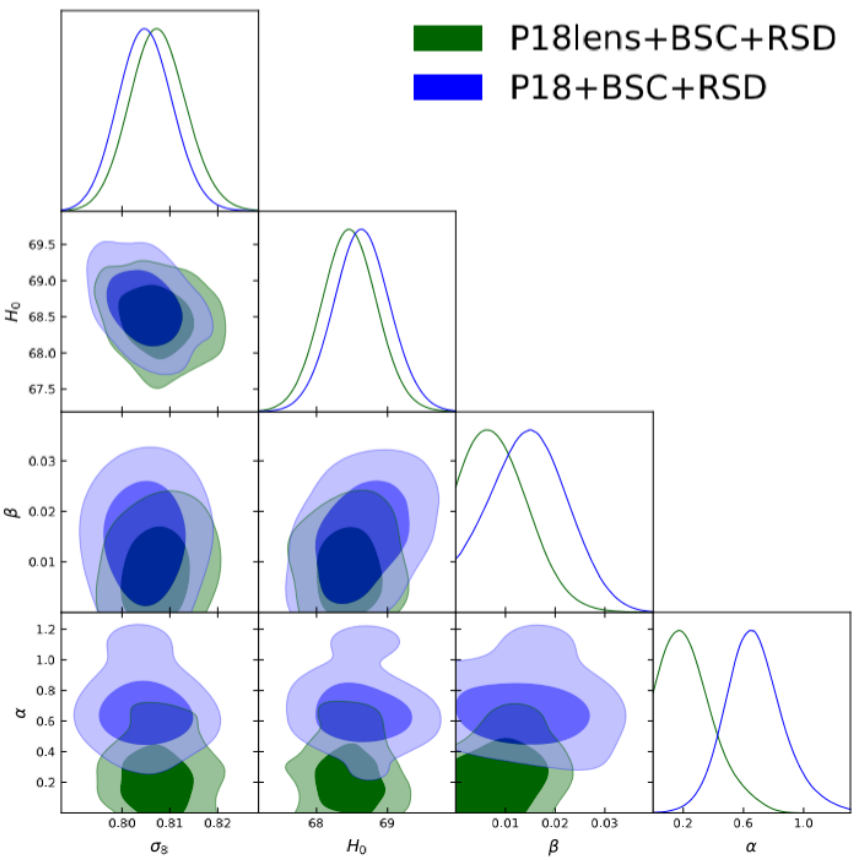

Fig. 4. 1 and 2σ confidence contours obtained with the P18+BSC+RSD and P18lens+BSC+RSD data sets in the most relevant two-dimensional planes of the CDE model parameter space. They allow us to see what is the impact of the CMB lensing on our results. We also show the corresponding marginalized one-dimensional posterior distributions for all the parameters. See the related comments in Sec. 4.

possible thanks to the increase of β, which in turn needs also larger values of α. The tension with the SH0ES+H0LICOW measurement (7) is slightly reduced from 4.8σ (when only P18 is used to constrain the model, cf. the first row/first column of Table 1) to 3.5σ (when also the SH0ES+H0LICOW data are considered). This shifts the H_0 value 1.9σ higher than the best fit using the P18 data set alone, within CDE. Combining also with background data, such as BSC, can partially break degeneracies and leads to $\alpha = 0.73^{+0.11}_{-0.27}$, with $\alpha > 0$ at 3.8σ and $H_0 = (68.79^{+0.35}_{-0.40})$ km/s/Mpc at 4.3σ from the SH0ES+H0LICOW value (7), reducing the chance of CDE to alleviate the tension, as shown in the third row/second column of the table. Finally, the impact of adding CMB lensing is shown in the last row, where now $\beta = 0.0197^{+0.0094}_{-0.0084}$ and $\alpha = 0.33^{+0.19}_{-0.23}$, with $\beta > 0$ and $\alpha > 0$ at 2.2σ and 1.6σ,

respectively, i.e. shifting back towards ΛCDM. In this case $H_0 = (68.99 \pm 0.51)$ km/s/Mpc, 3.9σ away from the SH0ES+H0LICOW value (7) and even more had we included also BSC.

Finally, we can further quantify the relative ability of the CDE model to describe the various data sets *w.r.t.* the ΛCDM cosmology using the Bayes ratio, in alternative to the more approximate χ^2 estimate we mentioned so far. Given a data set $\mathcal{D}$, the probability of a certain model M_i to be the best one among a given set of models $\{M\}$ reads,

$$P(M_i|\mathcal{D}) = \frac{P(M_i)\mathcal{E}(\mathcal{D}|M_i)}{P(\mathcal{D})}\,, \tag{8}$$

where $P(M_i)$ is the prior probability of the model M_i and $P(\mathcal{D})$ the probability of having the data set $\mathcal{D}$. Obviously, the normalization condition $\sum_{j\in\{M\}} P(M_j) = 1$ must be fulfilled. The quantity $\mathcal{E}(\mathcal{D}|M_i)$ is the so-called marginal likelihood or evidence. If the model M_i has n parameters $p_1^{M_i}, p_2^{M_i}, ..., p_n^{M_i}$, the evidence takes the following form,

$$\mathcal{E}(\mathcal{D}|M_i) = \int \mathcal{L}(\mathcal{D}|\vec{p}^{M_i}, M_i)\pi(\vec{p}^{M_i})d^n p^{M_i}\,, \tag{9}$$

with $\mathcal{L}(\mathcal{D}|\vec{p}^{M_i}, M_i)$ being the likelihood and $\pi(\vec{p}^{M_i})$ the prior of the parameters entering the model M_i. The evidence is larger for those models that have more overlapping volume between the likelihood and the prior distributions, but penalizes the use of additional parameters having a non-null impact on the likelihood. Hence, the evidence constitutes a good way of quantifying the performance of the model by implementing in practice the Occam razor principle. If we compare the CDE and ΛCDM models by assuming equal prior probability for both of them, i.e. $P(\text{CDE}) = P(\Lambda\text{CDM})$, then we find that the ratio of their associated probabilities is directly given by the ratio of their corresponding evidences, i.e.

$$\frac{P(\text{CDE}|\mathcal{D})}{P(\Lambda\text{CDM}|\mathcal{D})} = \frac{\mathcal{E}(\mathcal{D}|\text{CDE})}{\mathcal{E}(\mathcal{D}|\Lambda\text{CDM})} \equiv B_{\text{CDE},\Lambda}\,. \tag{10}$$

This is known as Bayes ratio and is the quantity we are interested in. For more details we refer the reader to.[18,98,99] Notice that the computation of (10) is not an easy task in general, since we usually work with models with a high number of (mostly nuisance) parameters, so the integrals under consideration becomes quite involved. We have computed the evidences numerically using the Markov chains obtained from the Monte Carlo analyses and with the aid of the numerical code `MCEvidence`,[68] which is publicly available (cf. Sec. 3). We report the values obtained for the natural logarithm of the Bayes ratio (10) in the last row of Table 1. For all the data sets under study we find values of $\ln(B_{\text{CDE},\Lambda}) < -5$, which point to a preference of the ΛCDM over the CDE model according to Jeffreys' scale.[18,98,99] Although the CDE model we are studying here is able to reduce slightly the value of χ^2_{min} *w.r.t.* the ΛCDM, it has two additional parameters, namely α and β. Moreover, the initial value of the scalar field, ϕ_{ini}, is also left free in the Monte Carlo analysis,

cf. Appendix A of Ref.[1] for details[b]. It turns out that the decrease in χ^2_{min} is insufficient to compensate the penalization introduced by the use of these extra parameters. If instead of using the evidences (9) and the Bayes ratio (10) to perform the model comparison we make use of e.g. the Akaike,[100] Bayesian[101] or Deviance[102] information criteria, we reach similar conclusions[c]. We want to note, though, that all these information criteria are approximations of the exact Bayesian approach. Although they allow to skip the demanding computation of the evidence (9), they are only reliable when the posterior distribution is close to a multivariate Gaussian (which is not the case under study), and the Akaike and Bayesian criteria do not take into account the impact of priors nor the existing correlations between the parameters.

Similar results and conclusions are reached using an exponential potential for the scalar field, instead of (6). See appendix C of Ref.[1].

Finally, it is worth to mention that our results are compatible with the ones obtained in the context of the Ricci running vacuum models (RVMs) of type I recently studied in Ref.[48], in which there is also an interaction in the dark sector between dark matter and a dynamical vacuum component with $p_{\rm vac} = -\rho_{\rm vac}$ and $\rho_{\rm vac}(\mathcal{R}) = \frac{3}{8\pi G_N}\left(c_0 + \frac{\nu}{12}\mathcal{R}\right)$, where $\mathcal{R} = 12H^2 + 6\dot{H}$ is the Ricci scalar. These models can be motivated using renormalization group arguments in QFT in curved space-time, see Refs.[12,103] and references therein. In Ref.[48] the authors show that these RVMs are also unable to alleviate the cosmological tensions significantly when the interaction is active around the CMB decoupling time. Allowing for a late-time activation of the interaction around $z \sim 1$, with an energy transfer from the vacuum to the matter sectors, it is possible to mitigate the σ_8 tension due to the increase of the relative amount of vacuum energy with respect to dark matter in the past. Nevertheless, the H_0 tension persists. Other Ricci RVMs (those of Type II) are able to soften both tensions at a time, see[48] for further details.

5. Conclusions

Cosmological observations help to test the dark sector, and in particular interactions between dark matter particles, mediated by a dark energy scalar field, as in CDE cosmologies. Up to a conformal transformation, this is another way of testing gravity at large scales. In this paper we carried out this task in one of the simplest and most studied models, namely, a dark energy-dark matter conformal coupling with a

[b]In the computation of the evidence (9) for the CDE model we have employed the following flat priors for the extra parameters: $0 < \beta < 0.1$, $0 < \alpha < 2$, and $0 < \kappa\phi_{ini} < 50$. Slightly broader or tighter priors can be considered, but $\ln(B_{\rm CDE,\Lambda})$ only changes logarithmically, so our conclusions are not very sensitive to them.

[c]For instance, Akaike criterion[100] is given by $\mathrm{AIC} = \chi^2_{min} + 2n$, where n is the number of parameters in the model (the degree of correlation between them is not taken into account). Considering that CDE with PR potential has an effective number of parameters between 2 and 3 we find $2.5 < \mathrm{AIC}_{\rm CDE} - \mathrm{AIC}_\Lambda < 6$ for the scenarios explored in Table 1, which leads to a positive preference for ΛCDM, again using Jeffreys' scale.[18,98,99]

Peebles-Ratra potential. CDE might probe helpful to explain the well-known tension between local and cosmological values of H_0. Any detection of a varying dark energy potential or interaction would clearly constitute a major result and it is therefore important to monitor the constraints that newer data impose. This is particularly true in view of earlier results that detected a non-zero value of the coupling β.[27,28]

We confirm the existence of a peak in the marginalized posterior distribution for β and α, more or less evident depending on the data set combination. While for P18 + SH0ES + H0LICOW $\beta > 0$ at 3σ and $\alpha > 0$ at nearly 7σ, inclusion of background data reduces the evidence to $\beta > 0$ at 2.3σ and $\alpha > 0$ at nearly 3.8σ. Inclusion of CMB lensing shifts both values to be compatible with ΛCDM within 2σ. We find it important to stress that specifically CMB lensing prefers ΛCDM. In all cases, we find that, overall, the peak does not correspond to a better Bayes ratio and ΛCDM remains the favored model when employing Bayesian model comparison, given the extra parameters introduced within the model. With regard to H_0, we find that under the P18+SH0ES+H0LICOW combined data set the simple coupled model with constant coupling investigated in this work leads to a value in 3.5σ tension with (7), or in 4.3σ tension when including further background data. The values of σ_8 are also similar to those found in the ΛCDM (i.e. $\sigma_8 \sim 0.80 - 0.82$), even when RSD data are considered together with CMB and background data. In this case we find $\beta = 0.010^{+0.003}_{-0.009}$ and $\beta = 0.015^{+0.007}_{-0.008}$, with and without CMB lensing, respectively. For the values of the coupling strength preferred by the data we find the typical increase of the mass of the DM particles to be $m(\phi_{ini})/m^{(0)} - 1 \lesssim \mathcal{O}(1)\%$.

The question that naturally arises is then, which modification of CDE can help alleviating the tensions? One can immediately suppose that a varying β can go some way towards this. Or, it could be that a model with both energy- and momentum-couplings (see e.g.[104]), which can introduce a weaker gravity, helps with the tensions. These issues will be investigated in future publications.

Acknowledgments

I want to express my most sincere gratitude to Prof. Mavromatos for his invitation to give my talk at the very interesting DM1 parallel session of the MG16 Meeting. I also want to thank Prof. Luca Amendola and Valeria Pettorino for their collaboration in the work my presentation of July 5th 2021 was based on, namely arXiv:2004.00610.[1]

The cosmological term, Λ, in Einstein's equations is an essential ingredient of the 'concordance' ΛCDM model of cosmology. In this mini-review presentation, we assess the possibility that Λ can be a dynamical quantity, more specifically a 'running quantity' in quantum field theory in curved spacetime. A great deal of phenomenological works have shown in the last few years that this option (sometimes accompanied with a running gravitational coupling) may cure some of the tensions afflicting the ΛCDM. The 'running vacuum models' (RVM's) are characterized by the vacuum energy density, $\rho_{\rm vac}$, being a series of (even) powers of the Hubble rate and its time derivatives. Here we describe the technical quantum field theoretical origin of the RVM structure in FLRW spacetime, which goes well-beyond the original semi-qualitative renormalization group arguments. In particular, we compute the renormalized energy-momentum tensor using the adiabatic regularization procedure and show that it leads to the RVM form. In other words, we find that the renormalized vacuum energy density, $\rho_{\rm vac}(H)$ evolves as a (constant) additive term plus leading dynamical components $\mathcal{O}(H^2)$. There are also $\mathcal{O}(H^4)$ contributions, which can be relevant for the early universe. Remarkably enough, the renormalized $\rho_{\rm vac}(H)$ does not exhibit dangerous terms proportional to the quartic power of the masses ($\sim m^4$) of the fields. It is well-known that these terms have been the main source of trouble since they are responsible for the extreme fine tuning and ultimately for the cosmological constant problem. In its canonical form, the current $\rho_{\rm vac}(H)$ is dominated by a constant term, as it should be, but it acquires a mild dynamical component $\sim \nu H^2$ $(0 < \nu \ll 1)$ which makes the RVM to mimic quintessence.

Keywords: Running Vacuum, Dynamical Dark Energy, Inflation, Dark Matter

1. Introduction

The standard or concordance model of cosmology, the so-called ΛCDM, is a very successful theoretical framework for the description of the Universe.[1] Crucial ingredients of it are left, though, without direct observational evidence and/or a proper theoretical interpretation based on fundamental principles. Such is the situation with dark matter, but also with the cosmological term, Λ, which has been traditionally associated with the vacuum energy density (VED) of the Universe, $\rho_{\rm vac}$. In fact, the notion of VED in cosmology is a most subtle concept, which is challenging theoretical physicists and cosmologists for many decades, specially with the advent of Quantum Theory in general and the more sophisticated machinery of Quantum Field Theory (QFT). The roots of the problem reside in the interpretation of the

cosmological constant (CC) term, Λ, in Einstein's equations as a quantity being connected with the VED, which is also a fundamental concept in QFT. The proposed connection is $\rho_{\rm vac} = \Lambda/(8\pi G_N)$, where G_N is Newton's constant. Accurate measurements of $\rho_{\rm vac}$ in the last decades from distant type Ia supernovae (SnIa) and the cosmic microwave background (CMB),[2–4] have put the foundations of the concordance ΛCDM model of cosmology.[1]

The concordance model is formulated in the context of the Friedman-Lemaitre-Robertson-Walker (FLRW) framework and is deeply ingrained in the General Relativity (GR) paradigm. However, one of the most important drawbacks of GR is that it is a non-renormalizable theory. This can be considered a serious theoretical obstruction for GR to be considered a fundamental theory of gravity. This fact adversely impacts on the ΛCDM too. GR cannot properly describe the short distance effects of gravity, i.e. the ultraviolet regime (UV), only the large distance effects (or infrared regime). As a consequence, GR cannot provide by itself a framework for quantizing gravity (the spacetime metric field) along with the rest of the fundamental interactions (assuming of course that gravity is amenable to be quantized on conventional grounds). In this sense, a first (rougher but effective) approach is to treat gravity as a classical (external or background) field and quantize only the matter fields of the fundamental interactions (electroweak and strong interactions). This is the main program of the semiclassical approach, namely the point of view of QFT in curved spacetime, see[5–8] for a review. This will be our pursue here as well. We shall nevertheless still be able to compute the quantum effects from matter and their contribution to the VED. Not only so, it will allow us to renormalize these (originally UV-divergent) quantum effects and obtain a finite quantity that can be better compared with observations. The renormalized VED found in the present framework is free from the traditional $\sim m^4$ effects (proportional to the quartic powers of the masses of the matter fields). This was first shown in the literature in the work[9] and further extended in.[10] It was demonstrated that $\rho_{\rm vac}$ appears (in the current universe) as a constant (dominant) term plus a dynamical component which varies as $\sim \nu H^2 m_{\rm Pl}^2$, with ν a small (dimensionless) and QFT-computable coefficient, $m_{\rm Pl}$ being the usual Planck mass ($m_{\rm Pl} = G_N^{-1/2}$). Quite obviously, such a result is highly compatible with the ΛCDM since it involves only a small departure from the rigid vacuum term enforced in it. Notwithstanding, it makes a significant qualitative (and quantitative) prediction: the quantum vacuum does not remain static throughout the cosmic evolution but is mildly dynamical, and such dynamics can be effectively evaluated from first principles, for ν (as mentioned) can be accounted for using QFT in curved spacetime. As long as the vacuum turns out to be free from the weird $\sim m^4$ effects obtained in simplified renormalization treatments, the finite result which is proposed here appears theoretically distinct and very tantalizing. It suggests to reassess if the Cosmological Constant Problem (CCP)[11–16] is still in force in the current theoretical framework. Remember that the CCP is one of the hardest and longstanding mysteries of theoretical physics,

and proves to be a serious impediment to reconcile cosmology with particle physics and quantum field theory in general.[17]

The smoother formulation of the quantum vacuum as put forward here is not only convenient from the theoretical point of view, but also from the observational side. It has long been known that, observationally, there appear to be some discrepancies or "tensions" between the results of data analyses from the Planck Collaboration, based on the ΛCDM,[4] and the local (distance ladder) measurements of the Hubble parameter today, the so called H_0 tension,[18,19] see e.g. the various reviews.[20–23] Not only so, there exist also tensions in the large scale structure (LSS) growth data, the so-called σ_8 tension.[21,22,24] Although such discordances in the arena of the 'concordance' model might admit a variety of more mundane astrophysical explanations,[25–27] or even disappear into thin air when more data will be available in the near future, it has been conceded already that they may well be passing the point of being attributable to a fluke.[19]

As it turns out, the smooth quantum vacuum phenomenological framework described here has the capacity to deal successfully with the H_0 and the σ_8 tensions. Such a framework represents the running vacuum model of cosmology (RVM) – see[17] for a detailed review and references therein. The latter was originally motivated by semi-qualitative renormalization group arguments,[28] which were later on formulated in some cases from an action functional viewpoint [29] – and was finally substantiated from full-fledged QFT calculations in.[9,10] For related studies of vacuum energy in QFT, see e.g.[30–35] In this summarized account I will mainly review the emergence of the RVM from the mentioned QFT calculations in curved spacetime, specifically in the context of the FLRW background as well as the most recent phenomenological applications. It is remarkable that it is also possible to derive a string-inspired version of the RVM cosmological model with gravitational anomalies in the early Universe, see[36] for a detailed exposition and[37–40] for more details and spin-off possibilities.

The structure of our presentation is as follows. In sections 2 and 3 we define our basic QFT framework in curved spacetime and the adiabatic expansion procedure. In section 4 we renormalize the energy-momentum tensor in the FLRW context and make contact with the RVM. In section 5 we apply the RVM to tackle the σ_8 and H_0 tensions. Finally, section 6 contains our conclusions and outlook.

2. Non-minimally coupled scalar field in FLRW background

We consider the semiclassical calculation of the energy density of the vacuum fluctuations of a quantized scalar field in FLRW spacetime. It serves as a representative case of study for the kind of results and difficulties we expect to encounter when dealing with generic quantized fields in a curved background. Such QFT calculation implies to perform renormalization since we meet UV-divergent integrals. Conventional approaches such as e.g. the minimal subtraction scheme lead to quartic dependence on the mass of the field ($\sim m^4$) enforcing a serious fine tuning among

the parameters, see e.g.[17] and references therein. Here we avoid using such an unsuccessful method and adopt the adiabatic renormalization procedure (ARP).[5–7] However, we follow the specific approach presented in,[9] which is related to that of.[34] For a full-fledged exposition and calculation details, see.[10]

2.1. *Action and classical energy-momentum tensor*

We start from the Einstein-Hilbert (EH) action for gravity plus matter[a]:

$$S_{\rm EH} = \frac{1}{16\pi G_N}\int d^4x\sqrt{-g}\,R - \int d^4x\sqrt{-g}\,\rho_\Lambda + S_m\,. \tag{1}$$

The matter action S_m is generic at this point, but will be specified shortly. The (constant) term ρ_Λ has dimension of energy density. Because it is unrelated to the matter part (fully contained in S_m), ρ_Λ is usually called the vacuum energy density (VED). However, we will not call it that way here since it is not yet the physical VED, $\rho_{\rm vac}$, as we shall see. For us the term ρ_Λ is just a bare parameter of the EH action, as the gravitational coupling G_N itself. The physical values can only be identified after renormalizing the bare theory. The corresponding gravitational field equations emerging from the variation of the action (1) can be put in the convenient form

$$\mathcal{M}_{\rm Pl}^2\,G_{\mu\nu} = -\rho_\Lambda g_{\mu\nu} + T^{\rm m}_{\mu\nu}\,, \tag{2}$$

where $\mathcal{M}_{\rm Pl} = m_{\rm Pl}/\sqrt{8\pi} = 1/\sqrt{8\pi G_N}$ is the reduced Planck mass, the expression $G_{\mu\nu} = R_{\mu\nu} - (1/2)g_{\mu\nu}R$ is the usual Einstein tensor and $T^{\rm m}_{\mu\nu}$ is the stress-energy-momentum tensor, or just energy-momentum tensor (EMT for short) of matter:

$$T^{\rm m}_{\mu\nu} = -\frac{2}{\sqrt{-g}}\frac{\delta S_{\rm m}}{\delta g^{\mu\nu}}\,. \tag{3}$$

For simplicity we will assume that there is only one (matter) field contribution to the EMT on the right hand side of (2) in the form of a real scalar field, ϕ. Such contribution will be denoted $T^{\phi}_{\mu\nu}$. We neglect for the moment the incoherent matter contributions from dust and radiation. They can be added a posteriori without altering the pure QFT aspects on which we wish to focus at this point. We assume that ϕ is non-minimally coupled to gravity. Thus, the part of the action involving ϕ reads

$$S[\phi] = -\int d^4x\sqrt{-g}\left(\frac{1}{2}g^{\mu\nu}\partial_\mu\phi\partial_\nu\phi + \frac{1}{2}(m^2+\xi R)\phi^2\right)\,. \tag{4}$$

The non-minimal coupling of ϕ to gravity is ξ. For $\xi = 1/6$, the massless ($m = 0$) action is conformally invariant. We will keep ξ general to explore its influence. We assume also that ϕ does not couple to itself and hence we shall not consider a

[a]Our conventions and other useful formulae are those of,[9,10] see the appendices of these references.

possible contribution from a classical potential for ϕ in our analysis. In this study, we wish to target mainly the zero-point energy (ZPE) of ϕ.

The classical EMT can be derived from the action (4) and reads as follows:

$$T^{\phi}_{\mu\nu} = -\frac{2}{\sqrt{-g}}\frac{\delta S[\phi]}{\delta g^{\mu\nu}} = (1-2\xi)\partial_\mu\phi\partial_\nu\phi + \left(2\xi - \frac{1}{2}\right) g_{\mu\nu}\partial^\sigma\phi\partial_\sigma\phi \\ - 2\xi\phi\nabla_\mu\nabla_\nu\phi + 2\xi g_{\mu\nu}\phi\Box\phi + \xi G_{\mu\nu}\phi^2 - \frac{1}{2}m^2 g_{\mu\nu}\phi^2. \tag{5}$$

Varying the action (4) with respect to ϕ we find the Klein-Gordon (KG) equation in curved spacetime:

$$(\Box - m^2 - \xi R)\phi = 0\,, \tag{6}$$

where $\Box\phi = g^{\mu\nu}\nabla_\mu\nabla_\nu\phi = (-g)^{-1/2}\partial_\mu\left(\sqrt{-g}\,g^{\mu\nu}\partial_\nu\phi\right)$. The FLRW line element for spatially flat three-dimensional geometry can be written in conformal coordinates as $ds^2 = a^2(\tau)\eta_{\mu\nu}dx^\mu dx^\nu$, where $\eta_{\mu\nu} = \mathrm{diag}(-1,+1,+1,+1)$ is the Minkowski metric in our conventions. The derivative with respect to the conformal time, τ, will be denoted $' \equiv d/d\tau$ and thus the Hubble rate in conformal time reads $\mathcal{H}(\tau) \equiv a'/a$. Since $dt = ad\tau$, the relation between the Hubble rate in cosmic and conformal times is simply $\mathcal{H}(\tau) = aH(t)$, with $H(t) = \dot{a}/a$ ($\dot{} \equiv d/dt$) the usual Hubble rate.

The KG equation (6) in conformally flat coordinates becomes

$$\phi'' + 2\mathcal{H}\phi' - \nabla^2\phi + a^2(m^2 + \xi R)\phi = 0\,, \tag{7}$$

where we used the curvature scalar of spacetime: $R = 6a''/a^3$. The separation of variables in these coordinates, namely $\phi(\tau, x) \sim \int d^3k\ A_{\mathbf{k}}\psi_k(\mathbf{x})\phi_k(\tau) + cc$, can be achieved with $\psi_k(x) = e^{i\mathbf{k}\cdot\mathbf{x}}$. However, in contrast to the Minkowski case we cannot take $\phi_k(\tau) = e^{\pm i\omega_k\tau}$ since the mode frequencies are not constant anymore. The form of the modes $\phi_k(\tau)$ in the curved spacetime case are determined by the KG equation. Starting from the Fourier expansion with separated space and time variables

$$\phi(\tau, \mathbf{x}) = \int \frac{d^3k}{(2\pi)^{3/2}}\left[A_{\mathbf{k}}e^{i\mathbf{k}\cdot\mathbf{x}}\phi_k(\tau) + A^*_{\mathbf{k}}e^{-i\mathbf{k}\cdot\mathbf{x}}\phi^*_k(\tau)\right] \tag{8}$$

(in which $A_{\mathbf{k}}$ and their complex conjugates $A^*_{\mathbf{k}}$ are the classical Fourier coefficients) and substituting it into (7) the mode functions $\phi_k(\tau)$ are determined by solving the nontrivial differential equation

$$\phi_k'' + 2\mathcal{H}\phi_k' + \left(\omega_k^2(m) + a^2\xi R\right)\phi_k = 0\,, \tag{9}$$

where $\omega_k^2(m) \equiv k^2 + a^2m^2$. The mode functions depend only on the modulus $k \equiv |\mathbf{k}|$ of the (co-moving) momenta. In the absence of gravitation ($R = 0$) the physical frequencies are $\tilde{\omega}_k = \sqrt{\tilde{k}^2 + m^2}$, with $\tilde{k} = k/a$ the physical momenta. However, for $R \neq 0$ and $\xi \neq 0$ the frequencies become a function of the gravitational field as well, which makes the particle interpretation hard. If we perform the change of field mode variable $\phi_k = \varphi_k/a$ the above equation simplifies to $\varphi_k'' + \left(\omega_k^2(m) + a^2\left(\xi - 1/6\right)R\right)\varphi_k = 0$. For conformally invariant matter ($m = 0$

and $\xi = 1/6$), such equation boils down to the form $\varphi_k'' + k^2\varphi_k = 0$, whose positive- and negative-energy solutions are just $e^{-ik\tau}$ and $e^{+ik\tau}$, respectively. On the other hand, in the massless case with minimal coupling ($\xi = 0$) the previous equation further simplifies to $\varphi_k'' + (k^2 - a^2R/6)\varphi_k = 0$. In the radiation epoch ($a \propto \tau$, thus $R = 6a''/a^3 = 0$) we find once more the trivial modes $\varphi_k(\tau) = e^{\pm ik\tau}$. Both in the de Sitter ($a = -1/(H\tau)$, H =const.) and matter-dominated ($a \propto \tau^2$) epochs we have $a^2R = 12/\tau^2$, which leads to $\varphi_k'' + (k^2 - 2/\tau^2)\varphi_k = 0$. This equation admits an exact (positive-energy) solution in terms of Hankel functions of half integer order, hence in close analytic form. In the de Sitter case ($\tau < 0$) one may impose the Bunch-Davies vacuum limit $\sim e^{-ik|\tau|}$ in the far remote past ($\tau \to -\infty$) and one finds $\varphi(\tau) \propto \ (1 - i/(k|\tau|))e^{-ik|\tau|}$. The same solution is valid for the matter-dominated era (for which $\tau > 0$). If, however, $m \neq 0$ and/or $\xi \neq 1/6$ no analytic solution of (9) is available, and this leads us to perform a WKB (Wentzel-Kramers-Brillouin) expansion of the solution. But before tackling that method, let us consider the quantization of the scalar field ϕ.

2.2. *Quantum fluctuations*

To account for the quantum fluctuations of the scalar field ϕ we must address the expansion of the field around its background value ϕ_b:

$$\phi(\tau, x) = \phi_b(\tau) + \delta\phi(\tau, x). \tag{10}$$

One starts defining an appropriate vacuum state, called adiabatic vacuum.[41] The vacuum expectation value (VEV) of ϕ is identified with the background value, $\langle 0|\phi(\tau, x)|0\rangle = \phi_b(\tau)$, whereas the VEV of the fluctuation is zero: $\langle\delta\phi\rangle \equiv \langle 0|\delta\phi|0\rangle = 0$. This is not the case for the VEV of the bilinear products of fluctuations, e.g. $\langle\delta\phi^2\rangle \neq 0$. It is convenient to decompose $\langle T_{\mu\nu}^{\phi}\rangle = \langle T_{\mu\nu}^{\phi_b}\rangle + \langle T_{\mu\nu}^{\delta\phi}\rangle$, where $\langle T_{\mu\nu}^{\phi_b}\rangle = T_{\mu\nu}^{\phi_b}$ is the contribution from the classical background part, whereas $\langle T_{\mu\nu}^{\delta\phi}\rangle \equiv \langle 0|T_{\mu\nu}^{\delta\phi}|0\rangle$ is the genuine vacuum contribution from the field fluctuations. Taking into account that ρ_Λ is also part of the vacuum action (1), the full vacuum contribution is the sum

$$\langle T_{\mu\nu}^{\rm vac}\rangle = -\rho_\Lambda g_{\mu\nu} + \langle T_{\mu\nu}^{\delta\phi}\rangle\,. \tag{11}$$

Thus, the total vacuum part receives contributions from both the cosmological term in the action as well as from the quantum fluctuations of the field (the ZPE). However, since these quantities are formally UV-divergent, the physical vacuum can only be identified a posteriori, namely upon suitable regularization and renormalization. For this we adopt the adiabatic method along the lines of.[9,10]

Obviously the classical and quantum parts of the field (10) obey the curved spacetime KG equation (9) separately. Similarly for $\varphi = \varphi_b + \delta\varphi$ (where $\phi = \varphi/a$). Denoting the frequency modes of the fluctuating part $\delta\varphi$ by $h_k(\tau)$, we can write

$$\delta\varphi(\tau, \mathbf{x}) = \int \frac{d^3k}{(2\pi)^{3/2}} \left[A_{\mathbf{k}} e^{i\mathbf{k}\cdot\mathbf{x}} h_k(\tau) + A_{\mathbf{k}}^\dagger e^{-i\mathbf{k}\cdot\mathbf{x}} h_k^*(\tau)\right]. \tag{12}$$

Here $A_{\mathbf{k}}$ and $A^{\dagger}_{\mathbf{k}}$ are now the (time-independent) annihilation and creation operators, which satisfy the commutation relations

$$[A_{\mathbf{k}}, A^{\prime\dagger}_{\mathbf{k}}] = \delta(\mathbf{k}-\mathbf{k}'), \qquad [A_{\mathbf{k}}, A^{\prime}_{\mathbf{k}}] = 0. \tag{13}$$

The frequency modes of the fluctuations, $h_k(\tau)$, satisfy the differential equation

$$h_k'' + \Omega_k^2(\tau) h_k = 0 \qquad \Omega_k^2(\tau) \equiv \omega_k^2(m) + a^2\,(\xi - 1/6)R\,. \tag{14}$$

Except in the simple cases mentioned above, the solution of that equation requires a recursive self-consistent iteration, the WKB expansion. One start from

$$h_k(\tau) = \frac{1}{\sqrt{2W_k(\tau)}} \exp\left(i\int^{\tau} W_k(\tilde{\tau})d\tilde{\tau}\right), \tag{15}$$

where the normalization factor $1/\sqrt{2W_k(\tau)}$ insures that the Wronskian condition $h_k' h_k^* - h_k h_k^{*\prime} = i$ is satisfied. It warrants the standard equal-time commutation relations. Functions W_k in the above ansatz obey the (non-linear) equation

$$W_k^2(\tau) = \Omega_k^2(\tau) - \frac{1}{2}\frac{W_k''}{W_k} + \frac{3}{4}\left(\frac{W_k'}{W_k}\right)^2, \tag{16}$$

which is amenable to be solved using the WKB expansion. The latter is applicable only for large k, therefore short wave lengths (as e.g. in geometrical Optics), and weak gravitational fields. The mode functions $h_k(\tau)$ are no longer of the form $\varphi_k(\tau) = e^{\pm i\omega_k \tau}$, hence particles with definite frequencies cannot be strictly defined in a curved background. Notwithstanding, an approximate Fock space interpretation is still feasible if the vacuum is defined as the quantum state which is annihilated by all the operators $A_{\mathbf{k}}$ of the above Fourier expansion. This defines in a precise way the notion of the adiabatic vacuum.[5–8,41]

2.3. *WKB expansion of the mode functions*

In the gravitational context, the WKB expansion leads to the adiabatic regularization procedure (ARP). For a review, see e.g. the classic books.[5,6] The regularization involved in the ARP amounts to subtracted integrals which become UV-finite and hence one obtains direct renormalization of the physical quantities. In the two successives works[9,10] the WKB expansion was performed first up to $4th$ and subsequently up to $6th$ adiabatic order. In the latter case the calculational details are rather cumbersome, but are necessary in order to study the on-shell renormalized theory. Here, however, we will limit ourselves to describe the results up to $4th$ order, which is enough to reormalize the theory off-shell. The counting of adiabatic orders in the WKB expansion follows the number of time derivatives. Thus: k^2 and a are of adiabatic order 0; a' and $\mathcal{H}$ of adiabatic order 1; $a'', a'^2, \mathcal{H}'$ and $\mathcal{H}^2$ as well as R are of adiabatic order 2. Each additional derivative increases the adiabatic order by one unit. The expansion collects the different adiabatic orders:

$$W_k = \omega_k^{(0)} + \omega_k^{(2)} + \omega_k^{(4)} + \omega_k^{(6)} \cdots, \tag{17}$$

General covariance precludes the odd adiabatic orders. The $\omega_k^{(j)}$ can be expressed in terms of $\Omega_k(\tau)$ and its time derivatives. Following[9,10] we consider an off-shell procedure in which the frequency ω_k of a given mode is defined not at the mass m of the particle but at an arbitrary mass scale M:

$$\omega_k \equiv \omega_k(\tau, M) \equiv \sqrt{k^2 + a^2(\tau)M^2}\,. \tag{18}$$

At the moment we will use just the notation ω_k to indicate such off-shell value, and when necessary we will distinguish it from the on-shell one using the forms $\omega_k(M)$ and $\omega_k(m)$, both being of course functions of τ (which we will omit to simplify notation). Working out the second and fourth order terms of (17) one finds[9]

$$\begin{aligned}
\omega_k^{(0)} &= \omega_k\,,\\
\omega_k^{(2)} &= \frac{a^2\Delta^2}{2\omega_k} + \frac{a^2 R}{2\omega_k}(\xi - 1/6) - \frac{\omega_k''}{4\omega_k^2} + \frac{3\omega_k'^2}{8\omega_k^3}\,,\\
\omega_k^{(4)} &= -\frac{1}{2\omega_k}\left(\omega_k^{(2)}\right)^2 + \frac{\omega_k^{(2)}\omega_k''}{4\omega_k^3} - \frac{\omega_k^{(2)\prime\prime}}{4\omega_k^2} - \frac{3\omega_k^{(2)}\omega_k'^2}{4\omega_k^4} + \frac{3\omega_k'\omega_k^{(2)\prime}}{4\omega_k^3}\,.
\end{aligned} \tag{19}$$

The quadratic mass differences $\Delta^2 \equiv m^2 - M^2$ must be counted as being of adiabatic order 2 since they appear in the WKB expansion along with other terms of the same adiabatic order[b]. The on-shell result is recovered for $M = m$, for which $\Delta = 0$ and corresponds to the usual ARP procedure.[5,6] One could extend the expansion up to the next nonvanishing adiabatic order, which is order $6th$, although we refrain from quoting the result here.[10] It is easy to see that the adiabatic expansion becomes an expansion in powers of $\mathcal{H}$ and its time derivatives. For example, the first two derivatives of ω_k read

$$\omega_k' = a^2\mathcal{H}\frac{M^2}{\omega_k}, \qquad \omega_k'' = 2a^2\mathcal{H}^2\frac{M^2}{\omega_k} + a^2\mathcal{H}'\frac{M^2}{\omega_k} - a^4\mathcal{H}^2\frac{M^4}{\omega_k^3}\,, \tag{20}$$

where we recall that $\mathcal{H}$ is the Hubble function in conformal time. From these elementary differentiations one can then compute the more laborious derivatives appearing in the above expressions, such as $\omega_k^{(2)\prime}, \omega_k^{(2)\prime\prime}$ etc. Therefore, the final result appears as an expansion in powers of $\mathcal{H}$ and multiple derivatives of it.

3. Adiabatic expansion of the ZPE

We have now all the necessary ingredients to compute the zero-point energy (ZPE) associated to the quantum vacuum fluctuations in curved spacetime with FLRW metric. We closely follow the presentation of.[9] Inserting the decomposition (10) of the quantum field ϕ in the EMT as given in Eq. (5) and selecting only the fluctuating

[b]In the context of the effective action, it can be justified more formally on replacing m by M in the heat kernel expansion of the propagator, but we shall not take this path here, see[10] for details.

parts $\delta\phi$, the ZPE (which is ssociated to the 00-component) reads

$$\langle T_{00}^{\delta\phi}\rangle = \left\langle \frac{1}{2}\left(\delta\phi'\right)^2 + \left(\frac{1}{2}-2\xi\right)\left(\nabla\delta\phi\right)^2 + 6\xi\mathcal{H}\delta\phi\delta\phi' \right. \\ \left. -2\xi\delta\phi\,\nabla^2\delta\phi + 3\xi\mathcal{H}^2\delta\phi^2 + \frac{a^2m^2}{2}(\delta\phi)^2 \right\rangle . \tag{21}$$

Notice that $\delta\phi'$, the fluctuation of the differentiated field (with respect to conformal time), is given by $\delta\phi' \equiv \delta\partial_0\phi = \partial_0\delta\phi = (\delta\phi)'$. Next we substitute the Fourier expansion of $\delta\phi = \delta\varphi/a$, as given in (12), into Eq. (21) and use the commutation relations (13). At the same time we symmetrize the operator field products $\delta\phi\delta\phi'$ with respect to the creation and annihilation operators. We present the final result in Fourier space, and hence we integrate $\int \frac{d^3k}{(2\pi)^3}(...)$ over solid angles:[9]

$$\begin{aligned}
\langle T_{00}^{\delta\phi(0-4)}\rangle = \frac{1}{8\pi^2a^2}\int dk k^2 \Bigg[& 2\omega_k + \frac{a^4M^4\mathcal{H}^2}{4\omega_k^5} - \frac{a^4M^4}{16\omega_k^7}(2\mathcal{H}''\mathcal{H} - \mathcal{H}'^2 + 8\mathcal{H}'\mathcal{H}^2 + 4\mathcal{H}^4) \\
& + \frac{7a^6M^6}{8\omega_k^9}(\mathcal{H}'\mathcal{H}^2 + 2\mathcal{H}^4) - \frac{105a^8M^8\mathcal{H}^4}{64\omega_k^{11}} \\
& + \left(\xi-\frac{1}{6}\right)\left(-\frac{6\mathcal{H}^2}{\omega_k} - \frac{6a^2M^2\mathcal{H}^2}{\omega_k^3} + \frac{a^2M^2}{2\omega_k^5}(6\mathcal{H}''\mathcal{H} - 3\mathcal{H}'^2 + 12\mathcal{H}'\mathcal{H}^2)\right. \\
& \left. - \frac{a^4M^4}{8\omega_k^7}(120\mathcal{H}'\mathcal{H}^2 + 210\mathcal{H}^4) + \frac{105a^6M^6\mathcal{H}^4}{4\omega_k^9}\right) \\
& + \left(\xi-\frac{1}{6}\right)^2\left(-\frac{1}{4\omega_k^3}(72\mathcal{H}''\mathcal{H} - 36\mathcal{H}'^2 - 108\mathcal{H}^4) + \frac{54a^2M^2}{\omega_k^5}(\mathcal{H}'\mathcal{H}^2 + \mathcal{H}^4)\right)\Bigg] \\
& + \frac{1}{8\pi^2a^2}\int dk k^2 \left[\frac{a^2\Delta^2}{\omega_k} - \frac{a^4\Delta^4}{4\omega_k^3} + \frac{a^4\mathcal{H}^2M^2\Delta^2}{2\omega_k^5} - \frac{5}{8}\frac{a^6\mathcal{H}^2M^4\Delta^2}{\omega_k^7}\right. \\
& \left. + \left(\xi-\frac{1}{6}\right)\left(-\frac{3a^2\Delta^2\mathcal{H}^2}{\omega_k^3} + \frac{9a^4M^2\Delta^2\mathcal{H}^2}{\omega_k^5}\right)\right] .
\end{aligned} \tag{22}$$

As expected, only even powers of $\mathcal{H}$ remain in the final result. The Minkowskian spacetime result for the on-shell ZPE ($M = m$) is obtained as a very particular case of the above expression for $a = 1$ ($\mathcal{H} = 0$):

$$\langle T_{00}^{\delta\phi}\rangle\Big|_{\text{Minkowski}} = \frac{1}{4\pi^2}\int dk k^2\omega_k = \int \frac{d^3k}{(2\pi)^3}\left(\frac{1}{2}\,\hbar\,\omega_k\right) , \tag{23}$$

where $\hbar$ has been restored only in the last expression for better cognizance. The result is quartically UV-divergent. Usual attempts (e.g. through the minimal subtraction scheme) to regularize and renormalize this quantity by e.g. cancelling the corresponding UV-divergence against the bare ρ_Λ term in the action (1) ends up with the well-known fine-tuning problem, which is considered to be the weirdest and toughest aspect of the CCP – see e.g.[17,42] and references therein. We will certainly not proceed in this way here. We seek (and will find) an alternative way.

4. Renormalization of the VED in curved spacetime: the RVM

The vacuum energy density in the expanding universe can be compared with a Casimir device in which the parallel plates slowly move apart ("expand").[17] Although the total VED cannot be measured, the distinctive effect associated to the presence of the plates, and then also to their increasing separation with time, it can. In a similar fashion, in the cosmological spacetime there is a distinctive non-vanishing spacetime curvature R as compared to Minkowskian spacetime that is changing with the expansion. We expect that the measurable VED must be that one which is associated to purely geometric contributions proportional to R, R^2, $R^{\mu\nu}R_{\mu\nu}$ etc., hence to H^2 and $\dot{H}$ (including higher powers of these quantities in the early Universe).

Following,[9,10] a subtraction of the VEV of the EMT is carried out at an arbitrary mass scale M, playing the role of renormalization point. Taking into account that the only adiabatic orders that are divergent in the case of the EMT are the first four ones, the subtraction at the scale M is performed only up to the fourth adiabatic order. The on-shell value of the EMT can be computed of course at any order. The terms beyond the 4th order are finite. The renormalized EMT in this context therefore reads

$$\langle T^{\delta\phi}_{\mu\nu}\rangle_{\rm Ren}(M) = \langle T^{\delta\phi}_{\mu\nu}\rangle(m) - \langle T^{\delta\phi}_{\mu\nu}\rangle^{(0-4)}(M)\,. \tag{24}$$

Let us apply this procedure to the ZPE part of the EMT, as given by Eq. (22). To ease the presentation of the explicit result, it proves convenient to recover at least in part the more explicit notation (18) so as to distinguish explicitly between the off-shell energy mode $\omega_k(M) = \sqrt{k^2 + a^2M^2}$ (formerly denoted just as ω_k) and the on-shell one $\omega_k(m) = \sqrt{k^2 + a^2m^2}$. With this notation, lengthy but straightforward calculations from equations (22) and (24) lead to the following compact result:[9]

$$\langle T^{\delta\phi}_{00}\rangle_{\rm Ren}(M) = \frac{a^2}{128\pi^2}\left(-M^4 + 4m^2M^2 - 3m^4 + 2m^4\ln\frac{m^2}{M^2}\right) - \left(\xi - \frac{1}{6}\right)$$
$$\times\,\frac{3\mathcal{H}^2}{16\pi^2}\left(m^2 - M^2 - m^2\ln\frac{m^2}{M^2}\right) + \left(\xi - \frac{1}{6}\right)^2\frac{9\left(2\mathcal{H}''\mathcal{H} - \mathcal{H}'^2 - 3\mathcal{H}^4\right)}{16\pi^2a^2}\ln\frac{m^2}{M^2} + \ldots \tag{25}$$

where dots stand just for higher adiabatic orders. The renormalized expression for the vacuum fluctuations, $\langle T^{\delta\phi}_{\mu\nu}\rangle_{\rm Ren}(M)$, is not yet the final one to extract the renormalized VED. As indicated in (11), the latter is obtained from including the contribution from the ρ_Λ-term in the Einstein-Hilbert action (1). Therefore, the renormalized vacuum EMT at the scale M is given by

$$\langle T^{\rm vac}_{\mu\nu}\rangle_{\rm Ren}(M) = -\rho_\Lambda(M)g_{\mu\nu} + \langle T^{\delta\phi}_{\mu\nu}\rangle_{\rm Ren}(M)\,. \tag{26}$$

We distinguish between VED and ZPE: the latter is caused by the vacuum fluctuations of the fields, whereas the former combines the ZPE and the parameter ρ_Λ in the action. The renormalized VED is precisely the 00th component of the above

expression:

$$\rho_{\rm vac}(M)=\frac{\langle T_{00}^{\rm vac}\rangle_{\rm Ren}(M)}{a^2}=\rho_\Lambda(M)+\frac{\langle T_{00}^{\delta\phi}\rangle_{\rm Ren}(M)}{a^2}\,, \tag{27}$$

where we have used the fact that $g_{00}=-a^2$ in the conformal metric. Explicitly, the VED comes out to be

$$\begin{aligned}\rho_{\rm vac}(M)=\rho_\Lambda(M)&+\frac{1}{128\pi^2}\left(-M^4+4m^2M^2-3m^4+2m^4\ln\frac{m^2}{M^2}\right)\\&-\left(\xi-\frac{1}{6}\right)\frac{3\mathcal{H}^2}{16\pi^2a^2}\left(m^2-M^2-m^2\ln\frac{m^2}{M^2}\right)\\&+\left(\xi-\frac{1}{6}\right)^2\frac{9\left(2\mathcal{H}''\mathcal{H}-\mathcal{H}'^2-3\mathcal{H}^4\right)}{16\pi^2a^4}\ln\frac{m^2}{M^2}+\cdots\end{aligned} \tag{28}$$

The (very) interesting aspect about this form of renormalized VED is that the first two terms of this expression (i.e. those not depending on $\mathcal{H}$) exactly cancel when we compute the difference of $\rho_{\rm vac}$ values at two scales, say M and M_0:

$$\begin{aligned}\rho_{\rm vac}(M)-\rho_{\rm vac}(M_0)=&\left(\xi-\frac{1}{6}\right)\frac{3\mathcal{H}^2}{16\pi^2a^2}\left(M^2-M_0^2-m^2\ln\frac{M^2}{M_0^2}\right)\\&+\left(\xi-\frac{1}{6}\right)^2\frac{9}{16\pi^2a^4}\left(\mathcal{H}'^2-2\mathcal{H}''\mathcal{H}+3\mathcal{H}^4\right)\ln\frac{M^2}{M_0^2}\,.\end{aligned} \tag{29}$$

To verify the cancellation of the mentioned terms, we rewrite Einstein's equations (2) using the renormalized parameters and including the higher derivative tensor $H_{\mu\nu}^{(1)}$, which is necessary for renormalization purposes.[5] We need to write only the vacuum part of the EMT since in doing the mentioned subtraction the background contribution of the field ϕ (and any other contribution, indicated below by $\ldots$) will cancel, except the (M-dependent) change of the vacuum EMT at the two scales:

$$\mathcal{M}_{\rm Pl}^2(M)G_{\mu\nu}+\alpha(M)H_{\mu\nu}^{(1)}=\langle T_{\mu\nu}^{\rm vac}\rangle_{\rm Ren}(M)+\ldots \tag{30}$$

On the *r.h.s.* we have used Eq. (26), which can be made more explicit using Eq. (25). We may now subtract side by side (30) at the scales M and M_0 and project the 00th component. Using the explicit form of G_{00} and $H_{00}^{(1)}$ in the FLRW metric we can perform the identifications on both sides of the subtracted equation. In particular, this renders specific expressions for the shifts $\mathcal{M}_{\rm Pl}^2(M)-\mathcal{M}_{\rm Pl}^2(M_0)$ and $\alpha(M)-\alpha(M_0)$, which we need not quote here[9,10] . After performing these identifications, what is left of $\langle T_{\mu\nu}^{\rm vac}\rangle_{\rm Ren}(M)-\langle T_{\mu\nu}^{\rm vac}\rangle_{\rm Ren}(M_0)$ must be zero. This is how we can prove that $\rho_\Lambda(M)-\rho_\Lambda(M_0)$ exactly cancels against the difference of the second term of (29) at the two scales (see Refs.[9,10] for more details):

$$\begin{aligned}&\rho_\Lambda(M)|_{M_0}^M+\frac{1}{128\pi^2}\left(-M^4+4m^2M^2-3m^4+2m^4\ln\frac{m^2}{M^2}\right)\Big|_{M_0}^M\\&=\rho_\Lambda(M)-\rho_\Lambda(M_0)+\frac{1}{128\pi^2}\left(-M^4+M_0^4+4m^2(M^2-M_0^2)-2m^4\ln\frac{M^2}{M_0^2}\right)=0\,.\end{aligned} \tag{31}$$

This important equality, enforced by the renormalized form of Einstein's equations, demonstrates that the renormalized EMT, and in particular the renormalized VED, is free from quartic contributions associated to mass scales. That is why the relation (29) between the VED at the two renormalization points M and M_0 is a smooth function $\sim M^2\mathcal{H}^2$. With no quartic mass term surviving in this renormalization procedure, there is no need of fine tuning. This is, of course, an extremely welcome feature, which obviously impinges on a possible solution of the CCP. Another appealing (and novel) feature of our renormalization framework is the following: Eq. (30) says that in Minkowski spacetime $\langle T_{00}^{\rm vac}\rangle_{\rm Ren}(M) = 0$, and as a result the renormalized VED in flat spacetime is also zero in this context, $\rho_{\rm vac}^{\rm Mink} = 0$.

Let us now assume that we define the renormalized VED in the context of some Grand Unified Theory (GUT) scale $M_0 = M_X$, where typically $M_X \sim 10^{16}$ GeV is associated with the inflationary scale. We denote by $\rho_{\rm vac}(M_X)$ the value of the VED at M_X. We can relate $\rho_{\rm vac}(M_X)$ with the current value of the VED, $\rho_{\rm vac}^0$, assuming that $\rho_{\rm vac}(M = H_0) = \rho_{\rm vac}^0$, where we choose the second scale at today's value of the Hubble parameter, H_0. This quantity can be used as an estimate for the energy scale of the background gravitational field associated to the FLRW universe at present. We neglect the $\sim H^4$ terms in the current universe. Then, according to Eq. (29), the connection between the two values of the VED is

$$\rho_{\rm vac}^0 = \rho_{\rm vac}(M_X) + \frac{3}{16\pi^2}\left(\frac{1}{6} - \xi\right) H_0^2 \left[M_X^2 + m^2 \ln \frac{H_0^2}{M_X^2}\right], \tag{32}$$

or swapping terms on both sides:

$$\rho_{\rm vac}(M_X) = \rho_{\rm vac}^0 - \frac{3\nu}{8\pi}\, H_0^2\, m_{\rm Pl}^2\,. \tag{33}$$

Here we have defined the 'running parameter' for the VED:

$$\nu \equiv \frac{1}{2\pi}\left(\frac{1}{6} - \xi\right) \frac{M_X^2}{m_{\rm Pl}^2}\left(1 + \frac{m^2}{M_X^2} \ln \frac{H_0^2}{M_X^2}\right). \tag{34}$$

We naturally expect $|\nu| \ll 1$, owing to the ratio $M_X^2/m_{\rm Pl}^2 \ll 1$. The vanishing of ν and hence of the dynamical $\sim H^2$ part of (32) is obtained only for conformal coupling: $\xi = 1/6$. There are, however, fermionic contributions to ν as well. They do not depend on ξ, of course, but shall not be addressed here.[43] The accurate determination of ν can only be obtained by fitting the RVM to the overall cosmological data, as it has been done e.g. in.[44–50] These analyses show that ν is positive and of order 10^{-3}. From (33) and (29) we can approximately estimate the VED near our time by taking M of order of the energy scale defined by the numerical value of H around the current epoch:[9]

$$\rho_{\rm vac}(H) \simeq \rho_{\rm vac}^0 + \frac{3\nu}{8\pi}\,(H^2 - H_0^2)\, m_{\rm Pl}^2 = \rho_{\rm vac}^0 + \frac{3\nu}{8\pi G_N}\,(H^2 - H_0^2)\,. \tag{35}$$

This expression reproduces the canonical form of the RVM.[17] A generalized form of the RVM is possible in which an additional term proportional to $\dot{H}$ (of order H^2)

can be included on the *r-h.s.* of (35) with another small coefficient $\tilde{\nu}$, see[9,10] for details. As noted, we have neglected the $\mathcal{O}(H^4)$ terms to derive the previous formulas. These terms can have an impact only for the early universe and produce inflation, but we refer once more the reader to[9,10] for an expanded discussion.

5. Phenomenological applications: H_0 and σ_8 tensions

We are now ready to produce some phenomenological output using the low-energy RVM form (35), or even the generalized one containing the $\sim \dot{H}$ term. In fact, we can use the following extended RVM structure for the VED:[9,10]

$$\rho_{\rm vac}(H) = \frac{3}{8\pi G_N}\left(c_0 + \nu H^2 + \tilde{\nu}\dot{H}\right) + \mathcal{O}(H^4)\,. \tag{36}$$

The additive constant c_0 is fixed by the boundary condition $\rho_{\rm vac}(H_0) = \rho^0_{\rm vac}$. For recent expositions of the RVM and its many phenomenological applications making use of the above form of VED, see[51,52] and references therein[c]. In what follows I will summarize the findings of the recent study,[50] which involves the most complete set of cosmological data. Since the parameters ν and $\tilde{\nu}$ are ultimately to be fitted to observations, we shall simplify our analysis here assuming one single parameter with the choice $\tilde{\nu} = \nu/2$. This does not change anything fundamental. As a result, if we neglect the higher order terms, Eq. (36) takes on the suggestive form

$$\rho_{\rm vac}(H) = \frac{3}{8\pi G_N}\left(c_0 + \frac{\nu}{12}R\right) \equiv \rho_{\rm vac}(R)\,, \tag{37}$$

where $R = 12H^2 + 6\dot{H}$ is the curvature scalar. For this reason we may call this form of the VED the 'RRVM'. Such a RRVM implementation has the double advantage of using one single parameter and provides a safe path to the early epochs of the cosmological evolution since when we approach the radiation dominated era we have $R \simeq 0$, or to be more precise: $R/H^2 \ll 1$. This fact insures that no conflict is generated with the BBN constraints. Early on the RVM has its own mechanism for inflation (as we have already mentioned), but we have no room to address these aspects here, see.[54–57] With one and the same VED given by Eq. (37) we may consider two types of RRVM scenarios, to wit: type I scenario, in which the vacuum interacts with matter; and type II, where matter is conserved at the expense of an exchange between the vacuum and a mildly evolving gravitational coupling $G(H)$. For type I models we assume that the vacuum exchanges energy with cold dark matter (CDM) only, as follows:

$$\dot{\rho}_{dm} + 3H\rho_{dm} = -\dot{\rho}_{\rm vac}\,. \tag{38}$$

[c]It is interesting to mention that at the pure cosmographic/cosmokinetic level (hence in a more model-independent way) the RVM appears also as a favoured model. For example, the form (36) has been used in[53] to study the different types of DE models in the framework of the cosmographic approach. Using the Hubble diagrams for SnIa, quasars, gamma-ray bursts as well as the data on baryonic acoustic oscillations in different combinations, it is found that the RVM fits better the cosmographic data than other DE models, including the concordance ΛCDM.

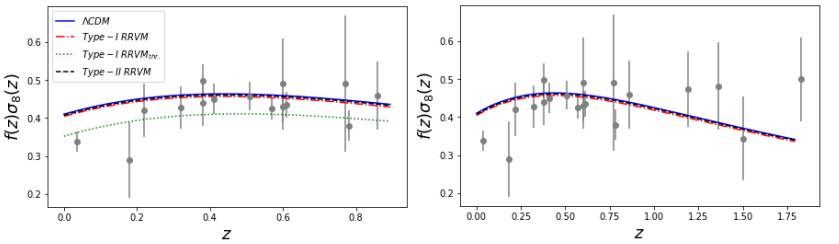

Fig. 1. Theoretically predicted curves of $f(z)\sigma_8(z)$ for the various models (type I and type II), testing the possible existence of a threshold redshift in the case of type I. The data points employed in our analysis are described in.[50] We present the results in two different redshift windows. It can be seen that the type I RRVM with threshold redshift $z_* \simeq 1$ has a most visible and favorable impact on solving the σ_8 tension.

Solving for the matter densities one finds[50]

$$\rho_m(a) = \rho_m^0 a^{-3\xi}\,, \quad \rho_{dm}(a) = \rho_m^0 a^{-3\xi} - \rho_b^0 a^{-3}\,, \tag{39}$$

where $\xi \equiv \frac{1-\nu}{1-\frac{3}{4}\nu}$. They recover the ΛCDM form for $\xi = 1$ ($\nu = 0$). The small departure of ν from zero (or ξ from one) is what permits a mild dynamical vacuum evolution:

$$\rho_{\rm vac}(a) = \rho_{\rm vac}^0 + \left(\frac{1}{\xi} - 1\right)\rho_m^0\left(a^{-3\xi} - 1\right)\,. \tag{40}$$

For type I models we admit also the possibility that the dynamics of vacuum is relatively recent (see e.g.[58]). For instance, one may assume that the vacuum became dynamical in the form (40) at a threshold redshift $z_* \simeq 1$ (so $\rho_{\rm vac}(z) = \rho_{\rm vac}^0$ for $z > z_*$). We shall compare this option with the situation when there is no such threshold. As for type II models, matter is conserved (hence no exchange with vacuum), but the vacuum can still evolve as long as the effective gravitational coupling also evolves (very mildly) with the expansion $G_{\rm eff} = G_{\rm eff}(H)$, starting from an initial value (which enters our fit). In this case, we do not consider the effect of the threshold because it proves to be much smaller. One can show that the approximate behavior of the VED in the present time is (recall that $|\nu| \ll 1$):[50]

$$\rho_{\rm vac}(a) = \frac{3c_0}{8\pi G_N}(1 + 4\nu) + \nu\rho_m^0 a^{-3} + \mathcal{O}(\nu^2)\,. \tag{41}$$

Once more, for $\nu = 0$ the VED remains constant at the value $\rho_{\rm vac} = 3c_0/(8\pi G_N) = \Lambda/(8\pi G_N)$, but otherwise it shows a moderate dynamics as in the type I case. One can also show that the effective gravitational coupling evolves approximately as $G_{\rm eff}(a) \simeq G_N(1 + \epsilon \ln a)$ in the current epoch (with $0 < \epsilon \ll 1$ of order ν), thus confirming the very mild (logarithmic) evolution of G. Since $\epsilon > 0$ the gravitational strength exhibits an asymptotically free behavior (i.e. being smaller in the past).

For an accurate comparison of the theoretical predictions and the observations, the LSS formation data are also of paramount importance, all the more if we take into account that one of the aforementioned ΛCDM tensions (the σ_8 one) stems

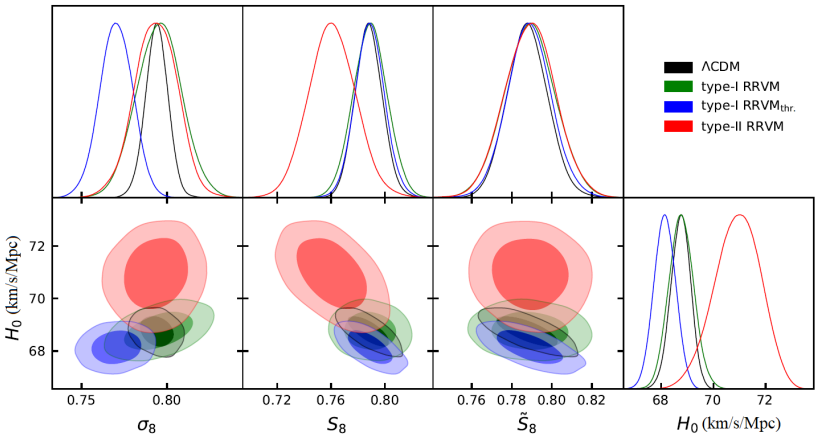

Fig. 2. The 1σ and 2σ c.l. contours in the H_0-$\sigma_8, S_8, \tilde{S}_8$ planes and the corresponding one-dimensional posteriors for the RRVM's obtained from the Baseline+H_0 data set (meaning that the local value of H_0 is included along with the remaining data, see[50]). It is apparent that the type II model alleviates the H_0 tension without spoiling the σ_8 one, whereas the type I model with threshold redshift $z_* \simeq 1$ can fully fix the latter (see also Fig. 1) but cannot reduce the former.

from it. As we shall see, allowing for some evolution of the vacuum can be the clue to alleviate the σ_8 tension since such dynamics affects significantly the cosmological perturbations.[59] We consider the perturbed, spatially flat, FLRW metric $ds^2 = -dt^2 + (\delta_{ij} + h_{ij})dx^i dx^j$, in which h_{ij} stands for the metric fluctuations. These fluctuations are nontrivially coupled to the matter density perturbations $\delta_m = \delta\rho_m/\rho_m$. We have implemented the full perturbations analysis in the context of the Einstein-Boltzmann code `CLASS`[60] (in the synchronous gauge).[50] Since baryons do not interact with the time-evolving VED the perturbed conservation equations are not directly affected. However, the corresponding equation for CDM is modified in the following way:

$$\dot{\delta}_{dm} + \frac{\dot{h}}{2} - \frac{\dot{\rho}_{\rm vac}}{\rho_{dm}}\delta_{dm} = 0\,, \tag{42}$$

with $h = h_{ii}$ denoting the trace of h_{ij}. We remark that the term $\dot{\rho}_{\rm vac}$ is nonvanishing for these models. Thus, it affects the fluctuations of CDM in a way which produces a departure from the ΛCDM. The above equation is, of course, coupled with the metric fluctuations and the combined system must be solved numerically. The analysis of the linear LSS regime is performed with the help of the weighted linear growth $f(z)\sigma_8(z)$, where $f(z)$ is the growth factor and $\sigma_8(z)$ is the rms mass fluctuation amplitude on scales of $R_8 = 8\,h^{-1}$ Mpc at redshift z. The quantity $\sigma_8(z)$ is directly provided by `CLASS`. Similarly, we can extract the (observationally measured) linear growth function $f(a)$ directly from the matter power spectrum $P_m(a, \vec{k})$, which is computed numerically by `CLASS` under adiabatic initial conditions. The results can be seen in Figures 1 and 2 for the various models.

To compare the RRVM's (types I and II) with the ΛCDM, we have defined a joint likelihood function $\mathcal{L}$. The overall fitting results are reported in Tables 1 and 2. The total χ^2 to be minimized in our case is given by

$$\chi^2_{\rm tot} = \chi^2_{\rm SnIa} + \chi^2_{\rm BAO} + \chi^2_H + \chi^2_{{\rm f}\sigma_8} + \chi^2_{\rm CMB}\,. \tag{43}$$

The above χ^2 terms are defined in the standard way from the data including the covariance matrices.[16] In particular, the χ^2_H part may contain or not the local H_0 value measured by Riess, see.[50] The local determination of H_0 (which is around 4σ away from the corresponding Planck 2018 value based on the CMB) is the origin of the so-called H_0 tension.[20–23] Taking into account that the RRVM's of type I and II have one and two more parameters, respectively, as compared to the ΛCDM, a fairer model comparison is achieved by computing the numerical differences between the Deviance Information Criterion (DIC) of the ΛCDM model against the RRVM's: $\Delta{\rm DIC} = {\rm DIC}_{\Lambda{\rm CDM}} - {\rm DIC}_{\rm RRVM}$. These differences will be (and in fact are) positive if the RRVM's fit better the overall data than the ΛCDM. The DIC is defined by[61] ${\rm DIC} = \chi^2(\overline{\theta}) + 2p_D$. Here $p_D = \overline{\chi^2} - \chi^2(\overline{\theta})$ is the effective number of parameters of the model, and $\overline{\chi^2}$ and $\overline{\theta}$ the mean of the overall χ^2 distribution and of the parameters, respectively. The posterior distributions and corresponding constraints for the various dataset combinations have been obtained with `Montepython`[62] in combination with `CLASS`.[60]

The DIC value can be obtained from the Markov chains generated with `MontePython`. If $+5 < \Delta{\rm DIC} < +10$ one should conclude strong evidence favoring the RRVM's over the ΛCDM. For $\Delta{\rm DIC} > +10$ it is said that the evidence is very strong. Such is the case when we use a threshold redshift $z_* \simeq 1$ in type I RRVM. In stark contrast, when the threshold is removed we find only moderate evidence against it (viz. $-3 < \Delta{\rm DIC} < -2$), although the fitting performance is still slightly better (smaller $\chi^2_{\rm min}$) than the ΛCDM. The effect of the threshold can be very important and suggests that a mild dynamics of the vacuum is welcome, especially if it gets activated at around the epoch when the vacuum dominance appears, namely at $z \simeq 1$. Unfortunately, type I models with fixed $G_{\rm eff} = G_N$ do not help an inch to solve the H_0 tension since the value of H_0 remains stuck around the CMB value.[50] In stark contrast, type II models can alleviate the two tensions at a time. The overall $\Delta{\rm DIC}$ value of the fit is quite significant (+5.5), still in the strong evidence region, providing values of H_0 markedly higher as compared to type I models (specifically $H_0 = 70.93^{+0.93}_{-0.87}$ Km/s/Mpc[50]) along with σ_8 and S_8 values in the needed moderate range ($\sigma_8 = 0.794^{+0.013}_{-0.012}$ and $S_8 = 0.761^{+0.018}_{-0.017}$).[50] The values of S_8 in all RRVM's are perfectly compatible with recent weak lensing and galaxy clustering measurements.[63] For type II models a related observable analogous to (but different from) S_8 is $\tilde{S}_8 = S_8\sqrt{G_{\rm eff}(0)/G_N}$. We show the corresponding contours in Fig. 2. The net outcome of this analysis is that the only model capable of alleviating the two tensions (H_0 and σ_8) is RRVM of type II, whereas the type I model can (fully) solve the σ_8 tension but has no bearing on the H_0 one.

6. Conclusions and outlook

In this short review presentation I have described the renormalization of the energy-momentum tensor (EMT) of a real quantum scalar field non-minimally coupled to classical gravity in the cosmological context. The main aim was to show that, out of the very quantum effects of matter, there emerges the running vacuum model (RVM) structure, which is the effective form of the renormalized vacuum energy density (VED). The method is based on an off-shell extension of the adiabatic regularization and renormalization procedure, which we have used in the recent works[9,10] and where for the first time we provided a calculation of the zero point energy (ZPE) of a quantum scalar field that is free from the need of extreme fine tuning. The latter is well-known to be one of the most striking and bizarre aspects of the cosmological constant problem.[11] The absence of need for fine-tuning is related to the non appearance in our framework of the terms which are proportional to the quartic mass of the fields, i.e. $\sim m^4$. In the standard model of particle physics, these terms are usually responsible for the exceedingly large contributions to the VED and requires preposterous fine-tuning with the renormalized vacuum parameter ρ_Λ in the action.[17] The calculational procedure in our approach is based on the WKB expansion of the field modes in the FLRW spacetime and the use of an appropriately renormalized EMT. The latter is obtained by performing a substraction of its on-shell value (i.e. the value defined on the mass shell m of the quantized field) at an arbitrary renormalization point M. The resulting EMT becomes finite because we subtract the first four adiabatic orders (the only ones that can be divergent). Since the off-shell renormalized EMT is a function of the arbitrary renormalization point M, we can compare the renormalized result at different epochs of the cosmic history. The introduction of such 'sliding' scale leads to the renormalization group (RG) flow, which in the case of FLRW cosmology we may associate in a natural way with Hubble's expansion rate H.

While the RG approach was actually the first qualitative idea behind the RVM,[17] with the present QFT calculations in curved spacetime we provide for the first time[9,10] a solid foundation of the RVM, in which the dynamical structure of the VED is seen to emerge from the quantum effects associated with the adiabatic renormalization of the EMT. Let us mention that even though our QFT calculation has been simplified by the use of a single (real) quantum scalar field, further investigations show that the generalization of these results for multiple fields, involving scalar as well as vector and fermionic components, lead as well to the generic RVM structure mentioned here up to (nontrivial) computation details.[43]

At the end of the day, we have been able to show that the genuine form of the VED for the current universe can be achieved from direct calculations of QFT in the FLRW spacetime. In such structure, the powers of H (and its time derivatives) are of even adiabatic order. This means that all of the allowed powers effectively carry an even number of time derivatives of the scale factor, which is essential to preserve the general covariance of the action. Linear terms (cubic, or in general of odd order)

in H are incompatible with such a covariance and in fact do not appear in the final result. To be more precise, all terms with an odd number of time derivatives of the scale factor are ruled out. The form of $\rho_{\rm vac}(H)$ predicted by the RVM at low energies is remarkably simple but it certainly goes beyond a rigid cosmological constant term. It consists of an additive constant (to be identified basically with the cosmological term) together with a small dynamical component $\sim \nu H^2$, in which the dimensionless parameter ν can be computed from the underlying QFT framework and is predicted to be small ($|\nu| \ll 1$). Ultimately, its value can only be known upon fitting the RVM to the overall cosmological data. The physical outcome is that today's cosmic vacuum is mildly dynamical. In fact, in previous works the model has been phenomenologically fitted to a large wealth of cosmological data and the running parameter ν has been found to be positive and in the ballpark of $\sim 10^{-3}$ cf.[44–47]

Recent phenomenological analyses involving a large set of updated cosmological data on SnIa+H(z)+BAO+LSS+CMB [50,64] and analyzed with the Boltzmann code `CLASS`[60] confirm to a large extent the results reported in the aforementioned works, which were carried out within an approximate treatment of the CMB. The basic result is still the same, they point to substantial evidence that a mild dynamics of the cosmic vacuum is helpful to describe the overall cosmological observations as compared to the standard cosmological model with a rigid Λ-term. From our analysis of two variants of the RVM, we have found that for type I models the σ_8 tension can be fully overcome ($\lesssim 0.4\sigma$ c.l.) provided there exists a threshold redshift $z_* \simeq 1$ where the vacuum dynamics is triggered. Solving the H_0 tension, however, proves more demanding as it requires the combination of vacuum dynamics with running G, which is the characteristic of the type II models. Interestingly enough, the two tensions can actually be dealt with at a time, the H_0 remaining at $\sim 1.6\sigma$ and the σ_8 one at $\sim 1.3\sigma$ (or at only $\sim 0.4\sigma$ if stated in terms of S_8).[63] The successful cutback of the two tensions is highly remarkable and is strongly supported by standard information criteria, such as the deviance information criterion (DIC). More work will be needed, of course, to confirm if the RVM can fully solve the σ_8 and H_0 tensions.[64] It will depend also on the upcoming data in the next few years.

Acknowledgements

It is my pleasure to thank N.E. Mavromatos for inviting me to speak in the DM1 parallel session: "Interacting Dark Matter" of the MG16 Marcel Grossmann virtual Conference, July 5-10 2021. Work partially funded by projects PID2019-105614GB-C21 and FPA2016-76005-C2-1-P (MINECO, Spain), 2017-SGR-929 (Generalitat de Catalunya) and CEX2019-000918-M (ICCUB). The author acknowledges participation in the COST Association Action CA18108 "*Quantum Gravity Phenomenology in the Multimessenger Approach (QG-MM)*". This presentation is based in part on works with A. Gómez-Valent, J. de Cruz Pérez and C. Moreno-Pulido. I thank them warmly for the enjoyable collaboration.

I summarize our recent results to use the orbits of globular clusters (GCs) in the Fornax dwarf spheroidal (dSph) galaxy to learn more about dark matter (DM) properties. Our focus is on clarifying how dynamical friction (DF) from the DM halo is modified from the different microscopic properties of DM, which may alter *both* the scattering processes responsible of DF and the DM profiles (in particular generating a core), which also modifies DF. We consider: (*i*) fermionic degenerate dark matter (DDM), where Pauli blocking should be taken into account in the dynamical friction computation; (*ii*) self-interacting dark matter (SIDM) and (*iii*) ultralight dark matter (ULDM), for which this problem has been addressed by a variety of methods in recent literature. We derive DF with a Fokker-Planck formalism, reproducing previous results for ULDM and cold DM, while providing new results for DDM. Furthermore, ULDM, DDM and SIDM may generate cores in dSphs, which suppress dynamical friction and prolong GC orbits. We conclude that in all these cases the modifications in the DM modelling does not easily solve the so-called timing 'problem' of Fornax GCs. We finally study this 'problem' in terms of the initial conditions, demonstrating that the observed orbits of Fornax GCs are consistent with this expectation of a cuspy DM profile with a mild 'fine-tuning' at the level of $\sim 25\%$.

Keywords: Dark matter; globular clusters; dynamical friction.

1. Introduction and motivation

The presence of dark matter (DM) in the universe is probed by several different methods. In particular, the rotation curves of *tracers* of the gravitational potential in galaxies has long been considered as one of the most pressing motivations for the existence of a halo of DM extending beyond the volume occupied by visible matter. When tracers move in this *medium*, their dynamics may also be altered by direct momemtum exchange with the DM, which may lead to further dynamical consequences beyond rotation curves, as for instance tidal disruptions, dynamical heating or dynamical friction. The latter is the focus of this contribution, and in particular using it to learn about properties of DM.

Dynamical friction is generated by the relative motion between the tracer (probe) and the DM medium. Indeed, as the probe moves in the DM halo, its gravitational interaction with the latter leaves behind an overdensity of DM particles (wake) that pulls back gravitationally from it. The net result is a friction force, first calculated

by Chandrasekhar,[1] and that can be parameterized as (for a probe of mass $m_\star$)[2]

$$\frac{d\mathbf{V}}{dt} = -\frac{4\pi G^2 m_\star \rho}{V^3}\, C\, \mathbf{V}, \tag{1}$$

where $\mathbf{V}$ is the relative velocity, G is Newton's constant, ρ is the energy density of the DM medium and C is a parameter depending on the way momentum is exchanged between the probe and the DM medium. For a classical gas of particles with mass m, and with a cold distribution in velocities v_m given by $f(v_m)$, the later reads

$$C_{\rm class} = 4\pi \ln\Lambda \int_0^V dv_m v_m^2 f_v(v_m). \tag{2}$$

In this formula, $\ln\Lambda$ represents the so-called Coulomb logarithm, and is a factor of $O(1)$. We can already understand that different models of DM may alter the previous formula through modifications of the microscopic scattering (for instance if DM is not a simple collection of free classical particles, but has some coherent or quantum properties), different DM energy densities ρ or distribution functions f_v.

The question we want to address is if these features can lead to observable consequences. For this, let us consider a system where DF is supposed to have played a relevant role in current observations: the globular clusters (GCs) of the Milky Way dwarf spheroidal (dSph) satellite galaxies. The latter are believed to be DM dominated 'compact' galaxies.[3,4] One intriguing puzzle about the dSph galaxies related to DF concerns the GCs of the Fornax dSph.[5] Fornax is a very luminous nearby (kpc away) dwarf satellite, with a stellar mass or around $\sim 4\times 10^7\, M_\odot$ and of $\sim$ kpc scale. It contains six known GCs,[4,6] with masses around $m_\star \sim 10^5\, M_\odot$, which we consider as our 'probes' moving in the DM halo. The puzzle arises because 2 of the most innermost GCs should have lost enough momentum due to DF to make them fall to the center of Fornax, while they live relatively far away from this point. In other words, from the expression (1), one can naïvely estimate the typical time scale to fall to center for GCs,

$$\tau \equiv \frac{|\mathbf{V}|}{|d\mathbf{V}/dt|} \sim 1.8 \left(\frac{V}{12\ {\rm km/s}}\right)^3 \left(\frac{10^5\, M_\odot}{m_\star}\right) \frac{2\times 10^7 \frac{M_\odot}{\rm kpc^3}}{\rho}\ {\rm Gpc}. \tag{3}$$

When applied to the six GCs of Fornax assuming the usual CDM cusp density profile (see, e.g.[7]), this time scale for the six GCs is presented in Table 2[8] (see also[9]). On the other hand, the stellar content of the GCs (and most of the stellar content of Fornax) is old, with life estimates > 10 Gyr[10,11].[12,13] Hence these GCs had enough time to fall to the center since their 'birth'.

This puzzle (in particular the time scales for GC3 and GC4) has been highlighted as a possible tension of the standard DM paradigm that may be solved by changing the properties of DM, see e.g.[9] A first important observation is that the Jeans analysis based on kinematic information of Fornax (the velocity dispersion along the line of sight of ~ 2500 stars as a function of radius) is compatible with the energy density profiles M19 NFW and M19 ISO expected from standard CDM,[7] but also

Table 1. Some details of Fornax GCs: mass, projected radius and CDM instantaneous DF time (Eq. (3)). See Ref.[8] for more details about how these number are obtained and the origin of the discrepancies with previous literature.

	$m_\star\ [10^5 M_\odot]$	$r_\perp$[kpc]	$\tau_{\rm CDM}$[Gyr]
GC1	0.42 ± 0.10	1.73 ± 0.05	119
GC2	1.54 ± 0.28	0.98 ± 0.03	14.7
GC3	4.98 ± 0.84	0.64 ± 0.02	2.63
GC4	0.76 ± 0.15	0.154 ± 0.014	0.91
GC5	1.86 ± 0.24	1.68 ± 0.05	32.2
GC6	~ 0.29	0.254 ± 0.015	5.45

with the presence of a cored distribution arising in different interesting DM models. The latter include fermionic DM of masses where quantum degeneracy may be relevant (DDM) in the dynamics of Fornax,[14–19] ultra-light DM with de Broglie wavelength large enough to affect the dynamics of Fornax[9] or self-interacting DM (SIDM) within the parameter space allowed by other observables, e.g.[20,21] A key motivation for our work is exploring whether DF may distinguish among these options, and hint towards new properties of DM.

2. Derivation of DF for different DM models with a Fokker-Planck approach

In order to include non-trivial properties of the DM microphysics into the expression (1), we followed a Fokker-Planck (FP) approach in,[8] where the probe particle (a GC in our case) correspond to species 1 traveling through a gas of spectator particles (species 2) with a certain distribution f_2 (DM particles in our case). We consider the following elastic scattering process of two particle species,

$$1(p) + 2(k) \to 1(p') + 2(k').$$

The phase space distribution function for the particle species 1 (the GC) evolves according to the Boltzmann equation,

$$\frac{df_1}{dt} = C[f_1]. \tag{4}$$

The collision integral $C[f_1]$ contains information about the elastic scattering processes, and is written as

$$C[f_1] = \frac{(2\pi)^4}{2E_p} \int d\Pi_k d\Pi_{p'} d\Pi_{k'}\, \delta^{(4)}(p + k - p' - k') |\overline{\mathcal{M}}|^2 \times \Big[f_1(p') f_2(k') (1 \pm f_1(p))(1 \pm f_2(k)) - f_1(p) f_2(k) (1 \pm f_1(p'))(1 \pm f_2(k')) \Big], \tag{5}$$

where $|\overline{\mathcal{M}}|^2$ is a squared matrix element averaged over initial and final spins, and $d\Pi_k = \frac{g}{2E_k} \frac{d^3k}{(2\pi)^3}$ is the Lorentz invariant phase element with the number of internal

degrees of freedom g. The sign in $1 \pm f_i$ refers to bosons (+) or fermions (−), respectively. The Boltzmann equation can be greatly simplified if the momentum exchange

$$q = p' - p, \tag{6}$$

is smaller than the typical momentum in the distribution function f_1. This is the adequate limit to compute DF.[2] In such cases, the Boltzmann equation reduces to the nonlinear Fokker-Planck equation,

$$\frac{df_1}{dt} = -\frac{\partial}{\partial p^i}\left[f_1(1 \pm f_1)D_i\right] + \frac{1}{2}\frac{\partial}{\partial p^i}\left[\frac{\partial}{\partial p^j}(D_{ij}f_1) \pm f_1^2\frac{\partial}{\partial p^j}D_{ij}\right], \tag{7}$$

where the diffusion coefficients are defined in.[2,8] Furthermore, the gravitational scattering of a probe particle of mass $m_\star$ and a particle in the medium with mass m is described by the spin-averaged matrix element

$$|\overline{\mathcal{M}}|^2 = \frac{1}{2s+1}\frac{(16\pi G)^2 m^4 m_\star^4}{\left[(q^0)^2 - \mathbf{q}^2\right]^2}, \tag{8}$$

where s is the spin of the particle in the medium, and $(q^0, \mathbf{q})$ is the transferred 4−momentum. In the nonrelativistic limit, we can neglect q^0 and maintain only $\mathbf{q}$ in Eq. (8).

Of particular importance for our analysis is the diffusion coefficient $D_{||}$, corresponding to the diffusion in momentum parallel to the probe object's instantaneous velocity. Indeed, the DF deceleration on a probe of mass $m_\star$ moving with velocity $\mathbf{V}$ w.r.t. the medium is[2]

$$\frac{d\mathbf{V}}{dt} = \frac{D_{||}}{m_\star}\hat{\mathbf{V}}. \tag{9}$$

From (1), we see that the dimensionless coefficient C of the DF reads,

$$C = -\frac{V^2 D_{||}}{4\pi G^2 m_\star^2 \rho}. \tag{10}$$

When computed for a gas of classical particles (where f_2 corresponds to a classical distribution), one reproduces the known results of the Chandrasekhar[1] formula, with C given by (2). This limit is also the relevant one for the SIDM case of interest here, since the corresponding cross-sections always correspond to large mean-free paths, where the approximation of the Chandrasekhar calculation holds.

Regarding DDM, when one assumes that f_2 is given by a Fermi-Dirac distribution close to the degeneracy limit[a] one finds

$$C_{\rm DDM} \to \ln\Lambda \begin{cases} 1 & V \gg v_F \\ \frac{V^3}{v_F^3} & V \ll v_F \end{cases}, \tag{11}$$

[a]Note that it is not known what is the momentum distribution for degenerate fermions interacting only gravitationally. Still, one normally assumes an equilibrium configuration as a first approximation. This assumption may also be used to constrain the mass of fermionic DM from virialized DM objects.[19,22]

where v_F is the Fermi velocity, related to the DM energy density by

$$\rho = \frac{g m_{\rm DM}^4 v_F^3}{6\pi^2}, \tag{12}$$

where g represents the number of degrees of freedom of the species (see also[23]). We used $m_{\rm DM}$ for the DM mass. This modification of the DF formula changes the falling time τ, though not parametrically. Furthermore, the DDM case also generates a *core* due to the quantum degeneracy pressure. Both effects are useful to reduce DF and hence prolong τ.

A similar calculation can be done for the bosonic case with large occupation numbers. In this case, the collision term is also modified and allows our formalism to capture the most relevant phenomena for DF in the ULDM case described in.[9,24–26] Indeed, these Bose-enhancement terms in (7) generate large-scale density fluctuations, causing additional velocity drift that can be characterised by an extra term to $C \to C + \Delta C$ as

$$\Delta C = \ln\Lambda \left(\frac{m_{\rm eff}}{m_\star}\right)\left({\rm erf}(X_{\rm eff}) - \frac{2X_{\rm eff}}{\sqrt{\pi}} e^{-X_{\rm eff}^2}\right), \tag{13}$$

where $m_{\rm eff} = \pi^{3/2}\rho/(m_{\rm DM}\sigma)^3$ is the ULDM mass enclosed in an effective de Broglie volume and $X_{\rm eff} \equiv v/\sqrt{2}\sigma_{\rm eff}$ with $\sigma_{\rm eff} = \sigma/\sqrt{2}$. Numerically, $m_{\rm eff} \approx 1.2\times10^6 \left(10^{-21}\ {\rm eV}/m_{\rm DM}\right)^3 [\rho/(3\times10^7\ M_\odot/{\rm kpc}^3)][(10\ {\rm km/s})/\sigma]^3\ {\rm M}_\odot$. With these numbers and keeping in mind a typical GC mass $m_\star \sim 10^5\ {\rm M}_\odot$, the ΔC effect becomes quantitatively important in Fornax for $m \lesssim 3\times10^{-20}$ eV. This value starts to be in tension with other constraints of ULDM, see e.g.[27,28] Notice that the previous calculation is correct in the limit $r > \lambda_{\rm db}$, where $\lambda_{\rm db}$ is the de Broglie wavelength of DM. In the opposite regime, one can have effects coming from the coherent nature of the DM waves which affect the scattering cross-section,[9] or even resonant processes that our formalism does not capture, see e.g.[26,29]

3. Timing of Fornax GCs for different DM models

From the previous calculation, one can estimate the falling time of the GCs in Fornax once the profile of DM energy density is known. For the latter, one can use a Jeans method consistent with the line-of-sight velocity (LOSV) observed for Fornax.[2] However, as already stressed, the latter is equally well fitted by a M19 NFW, M19 ISO CDM profiles, as long as DDM of mass $m_{\rm DM} \approx 135$ eV (which should generate a degenerate core of kpc) or a SIDM model with velocity averaged cross section $\langle\sigma v\rangle/m_{\rm DM} \sim 25\ {\rm cm}^2\ {\rm g}^{-1}\ {\rm km\ s}^{-1}$ (also generating a isothermal cored profile of kpc size, this time due the SIDM scatterings[20]). These cases are shown, together with the relevant data of the dispersion in the LOSV, σ_{LOS}, as a function of radius in the left panel of Fig. 1. It should be clear from this panel that this data agrees well with the models just described. The right panel shows the different energy density profiles for these cases also as a function of radius. For completeness we have also shown the energy density of the star content of Fornax, to show explicitly that

DM is needed in this system. Another CDM model (coreNFW) is also shown. This models aims at describing a DM dominated halo where the baryonic feedback is somehow taken into account.

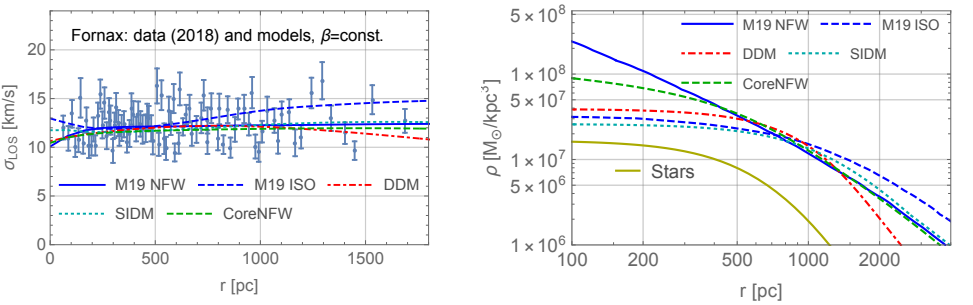

Fig. 1. **Left panel**: LOSVD data and fits for the M19 NFW and M19 ISO of,[7] DDM with mass $m \approx 135\,\mathrm{eV}$ and SIDM models with cores of order kpc. **Right panel**: Density profiles corresponding to these cases. The the energy density of the star content of Fornax is also shown.

Now that we have all the ingredients to compute the DF, we proceed to find the orbital motion of the different GCs of Fornax by solving the equation

$$\frac{d\mathbf{V}}{dt} = -\frac{GM(r)}{r^2}\hat{r} - \frac{4\pi G^2 m_\star \rho}{V^3}\, C\, \mathbf{V}, \tag{14}$$

for the relevant cases. This is a 'semi-analytical' approach that yields good agreement with simulations.[8] The results are only mildly dependent on the Coulomb logarithm $\ln\Lambda$, which we calibrate to numerical work in.[8] As an example, we show in Fig. 2 the evolution of the radius as a function of time, as compared to two profiles studied numerically in.[7]

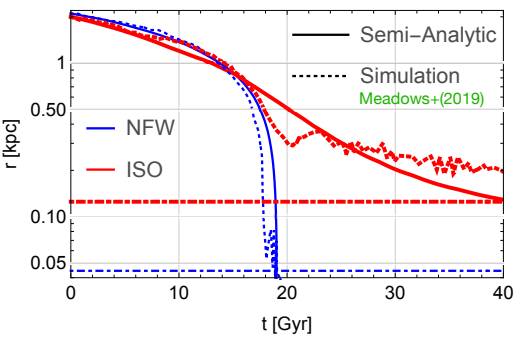

Fig. 2. Radius of an infalling orbit of a GC with mass $m_\star = 3 \times 10^5\, M_\odot$. n dotted blue (thick dotted red) we plot the simulation result in[7] for the NFW (ISO) halo. In solid lines, we plot our semi- analytic integration. Horizontal dot-dashed lines show the radii where the semi-analytic treatment breaks down.

From the previous analysis, we are now in the position to find the time τ that it takes to a GC to fall to the center of Fornax for different DM models. We will address the initial conditions momentarily. For now, let us compare the 'instantaneous' time in the DF formulae for the different GCs in CDM, DDM of mass $m_{\rm DM} \approx 135\,{\rm eV}$ and SIDM generating a kpc core. This is shown in Table 2 and Fig. 3. The conclusion is clear: both models beyond CDM prolong the plunging time of the problematic GCs, and hence alleviate the timing problem.

Table 2. Instantaneous DF times for the GCs of Fornax in the DDM and SIDM models described in the main text.

	$\tau_{\rm CDM}$[Gyr]	$\tau^{(135)}_{\rm DDM}$ [Gyr]	$\tau_{\rm SIDM}$ [Gyr]
GC1	119	122	79.3
GC2	14.7	7.12	8.82
GC3	2.63	1.48	2.21
GC4	0.91	10.7	14.8
GC5	32.2	30.1	20
GC6	5.45	16.1	22

This conclusion is confirmed by a numerical study of the orbits, where the different DM profiles and dispersion properties are taking into account for the different models. The latter analysis is vital to find the real dynamics of the GCs, since the timescales can vary by $O(1)$ factors. We will skip the details of this study in this short contribution, and the interested reader is invited to check our work[8] for details. Let us simply mention that beyond the numerical integration of Eq. (14), in[8] we also considered different projection effects that alter the radius of the different GCs and their velocities. The main lesson we learned is that the conclusions extracted from the estimates in Table 2 and Fig. 3 are robust against these uncertainties.

The main lesson from Fig. 3 is that cores (including those in coreNFW) increase the time τ, but to make GC4's settling time substantially different, one requires a

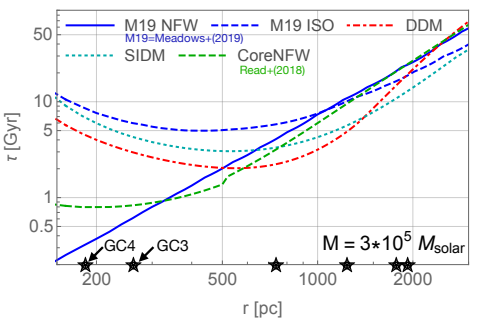

Fig. 3. Instantaneous DF time, evaluated for different DM models for $m_\star = 3 \times 10^5 M_\odot$ as a function of distance to the center of Fornax. The stars represent the positions of the different GCs.

large (kpc-size) core. Note that the microscopic properties in the DF formula are not particularly relevant in our calculations.

Before closing this section, let us notice that in Table 2 and Fig. 3 we have focused on DM models which help prolonging the orbits of GCs in Fornax. However, for the DDM case this requires models with masses already in strong tension with Ly-α observations[30] (and light tension with Jeans analysis of other systems[19]). In fact, regarding the Ly-α constraints, the interesting reader may also find in our work[8] a rather model independent bound from these observations

$$g m_{\rm DM}^4 > 2 \times (1.4 \text{ keV})^4 \,, \tag{15}$$

confirmed in the recent detailed work.[31] On the contrary, the SIDM model we used for the existence of a core at kpc distances can be read from the relation

$$r_c \sim \frac{m_{\rm DM}}{\rho \sigma} = 48 \frac{10^8 M_\odot/\text{kpc}^3}{\rho} \frac{1 \text{ cm}^2/\text{gr}}{\sigma/m_{\rm DM}} \text{kpc} \,, \tag{16}$$

related to the isothermal profile generated by scattering of DM particles with cross-section σ. The ballpark used in the previous formulae corresponds to viable models of DM,[20,21] which puts our analysis on a solid phenomenological basis. Indeed, one is tempted to conclude that the Fornax GCs favour the SIDM model.

4. Brief discussion on the late-time distribution of GCs

Our discussion has so far focused on the falling time of the innermost GCs of Fornax. The 'puzzle' we are trying to address relies on this time being smaller than what one would naively expect for arbitrary GCs that have lived in the dSph DM halo for long enough. However, given a collection of GCs, one expects some of them to be form currently at distances that could seem fine tuned for the average GC. Hence, the best-posed question to learn about the DM effects in the dynamics of GCs in Fornax (given that we observe 6 of them) is which is the long-term distribution function of these objects as a function of radius and for different initial conditions. Note first, that the problem of initial conditions has already been identified as a candidate to explain the phenomenology we are discussing.[7,32] Here we will summaryze the *analytical* treatment developed in.[8] For this, the key analytical tool is the time it takes an object to move from radius r_0 to r_f. In the case of nearly-circular orbits, this time can be estimated as

$$\Delta t \left(r_i; r_f\right) = \int_{r_f}^{r_0} \frac{dr}{2r} \left(1 + \frac{d \ln M}{d \ln r}\right) \tau \left(r, v_{\rm circ} \left(r\right)\right) . \tag{17}$$

Quite remarkably, one can show that for objects that today at at small radii $r \ll r_{\rm crit}$, with $r_{\rm crit}$ parametrizing the radius such that any object that *started* its life at $r < r_{\rm crit}$ as already fallen into the center, the conditional distribution function (CDF) of GCs as a function of radius in a NFW profile satisfies

$$F_{\Delta t}(r) \approx A \frac{\tau(r)}{\Delta t}, \tag{18}$$

independently on initial conditions. This prediction is modified in the case of cored profiles. To have a better picture of this effect, we show in Fig. 4 the number of GCs expected to be enclosed at projected radius $r_\perp$, when numerically integrating the orbital motion with our semianalytical model (no need of N-body simulations). The initial conditions we used for these plots are discussed in.[8] They are not very particularly relevant for this discussion since we found that the main features of Fig. 4 are reproduced by all reasonable initial conditions we considered.

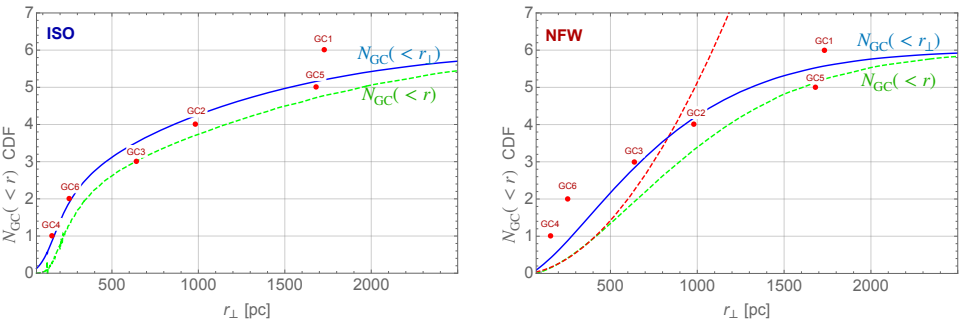

Fig. 4. CDF (number of clusters at $r_\perp$ below the value of the x axes) of projected radii using $\tau(r)$ from Fig. 3. **Left:** Cored ISO halo. **Right:** NFW halo. The solid blue line shows the CDF after projection effects are taken into account. The dashed green line shows the result before projection. For the NFW case, the small-r prediction of Eq. (18) is shown by the red dashed line. Observed Fornax GCs are also shown. The initial radial GC PDFs used to make the plot are explained in.[8]

A visual comparison of the left panel in Fig. 4 (performed with an isothermal cored for the model of SIDM described above) and the right panel (performed with NFW) shows that GC4, GC6 and GC3 tend to align better over the CDF of the second one, in particular after projection effects are taken into account (blue-solid line). As we just mentioned, these figures were produced for one of many possible initial conditions that reproduce reasonably well the distribution of final GCs, and we could not find any other reasonable initial data which could account for the position of GC4 today without destroying the agreement of the rest of GCs. Still, these figures also show that the level of 'fine-tuning' to explain GC4, GC6 and GC3 within the standard NFW profile is not very problematic, which implies that a solid conclusion about the role of DF in the final distribution of GCs requires the observation of (several) other similar systems. Another interesting observation is that any reasonable distribution agreeing with current data should have included several inner GCs which should have fallen to the center of Fornax and generated a nuclear cluster of $\mathcal{O}(10^6\, M_\odot)$. The absence of this nuclear cluster in Fornax may also have something to say about DM properties, though this is a different story.

We are fully aware that the dynamics of GCs is more complex than what we presented in.[8] Still, we believe that our simple analytical model captures some

interesting (even intriguing) part of the dynamics, that we hope to study in the future with more realistic methods.

5. Conclusions and outlook

In this presentation, we revisited the timing 'problem' of the GCs in the Fornax dSph, and use it to learn about new properties of DM. The latter are manifested in either a modification of the microscopic origin of dynamical friction (DF) or the halo morphologies, also influencing DF. Some of the 6 GCs of Fornax are placed too close to the center of this galaxy, which may pose a tuning problem in terms of typical time-scales to plunge to the center of this object. Indeed, the last part of the work described in[8] (and briefly reviewed in Sec. 4) was devoted to quantifying this degree of tuning for the standard CDM paradigm yielding NFW profiles. The observations presented in Table 2 can be accounted for as a moderate fluctuation with a Poisson probability of about around 25%.

Still, it is quite interesting that the calculation of DF in different DM models allows us to reduce this tension and find better accuracy with data. This is why a large part of this short presentation has consisted in a succinct explanation of how to derived DF from a Fokker-Planck formalism (which allows the introduction of fermionic and baryonic effects in the collision term). As summarized in Fig. 3, the presence of a small core due to baryonic feedback may slightly alleviate this tension, but not at an interesting level. Once one considers other DM models (as DDM, ULDM and SIDM) a large core (of kpc size) may be formed, which predicts enough reduction of dynamical friction to better reproduce the observed positions of the GCs in Fornax. Still, in these cases, the GC distribution depends strongly on initial conditions. From these models, it seems that SIDM with $\sigma/m_{\rm DM} \approx 1$ cm^2/gr seems favoured, since it does not contradict any other observation, but more data is required to confirm this claim.

The way forward is clear: applying our methods to more extensive data, aiming at enough statistical significance to generate robust conclusions about DM properties. The hint about SIDM we just discussed makes this project particularly exciting, since future data from GCs may finally start closing up on the fundamental nature of DM.

Acknowledgments

The Lambda-Cold Dark Matter (ΛCDM) model agrees with most of the cosmological observations, but has some hindrances from observed data at smaller scales such as galaxies. Recently, Berezhiani and Khoury proposed a new theory involving interacting superfluid dark matter with three model parameters in,[1] which explains galactic dynamics with great accuracy. In the present work, we study the cosmological behaviour of this model in the linear regime of cosmological perturbations. In particular, we compute both analytically and numerically the matter linear growth factor and obtain new bounds for the model parameters which are significantly stronger than previously found. These new constraints come from the fact that structures within the superfluid dark matter framework grow quicker than in ΛCDM, and quite rapidly when the DM-baryon interactions are strong.

Keywords: Dark matter, cosmological perturbations

1. Introduction

With the advent of precision cosmology and satellites like Planck and WMAP, we have gained new insights about the evolution of the universe. Till date, Lambda-Cold Dark Matter (ΛCDM) provides the best fit to these available data and has been widely accepted as the standard model of cosmology.[2] The hypothesis of CDM, which are assumed to be collisionless non-relativistic particles, along with baryonic matter explains the CMB temperature anisotropy, matter power spectra, large scale galaxy distributions and lensing data remarkably well. In fact, the abundance of galaxy clusters and observed large scale structure formation history strongly supports the collisionless CDM scenario as opposed to any alternative theories to ΛCDM.[3–5] However, at smaller scales, CDM faces a number of challenges that need to be addressed.[6] For example, the Baryonic Tully-Fisher relation and the

corresponding tight correlation between the mass and dispersion velocity at the high-mass end can not satisfactorily be explained by CDM halo which predicts a larger scatter due to feedback processes in the galaxy.[7] Apart from this, there is another issue with the standard CDM picture in the galactic scale, known as the *cusp-core problem*.[8] The simulations of galactic halos with CDM produce a kink (cusp) at the center of the galaxy, whereas observations of various galactic density profile suggest a flat core. With improved observations of the faint dwarf galaxies and substructures within the galaxies like Milky Way and Andromeda, new set of discrepancies arise. While the missing satellite problem in dwarf galaxies[9] has been addressed to some extent, the *Too Big To Fail Problem*, arising from the prediction of satellites that are too massive and too dense by ΛCDM, compared to those observed, still remains unresolved.[10,11]

Due to the above unresolved issues, scientists have looked into other alternative explanations through modifications of General Relativity (GR). Several models have been proposed so far with the aim to explain existing data to the same degree of accuracy as ΛCDM as well as overcome its drawbacks. Many of them have already been ruled out or are highly constrained by the ongoing observations of gravitational waves, but some theories like $f(R)$, $f(T)$, $f(\mathcal{G})$, Scalar-tensor-vector theories of gravity etc. are still consistent with the data, and new observations are required to falsify these theories.[12–18] These theories are relativistic corrections of GR which modify the dynamics of spacetime through the modified field equations. The theory of Modified Newtonian Dynamics (MOND), on the other hand, is a modification to the Newtonian force law that changes the dynamics of interaction between two massive bodies in the non-relativistic limit.[19,20] MOND was first proposed in 1983 by Milgrom to account for the flattened galaxy rotation curves near the edge of the spiral galaxies like Milky Way. There is a universal acceleration scale a_0 in MOND, whose value is obtained as $10^{-8} cm/s^2$. For accelerations much lower than this scale, the Newtonian law is modified, and this explains the flat galaxy rotation curve data for a large number of galaxies.[21] Interestingly, the Baryonic Tully-Fisher relation in galaxies can exactly be derived from MOND where $M \propto v_c^4$. MOND can also explain several other galactic observations like the planar structure of galaxies, low merger rate etc.[22] Thus, we see that MOND, with just one free parameter, is a very well-behaved theory at the galactic scale. However, despite these successes, MOND faces several challenges in extragalactic and cosmological scales. Proper relativistic extension of MOND is not available.[23] Hence it cannot be applied at cosmological scales.

The effectiveness of MOND at small scales and success of ΛCDM at cosmological scales are the main motivations for scientists to look for models which are CDM-MOND hybrids i.e., theories that include usual cold dark matter as collisionless particles at cosmological scales, but give rise to a MOND-like modified force law at galactic scales such that they satisfy both sets of observations. This class of models take into consideration the interacting dark matter-baryon picture where

a MOND-like force is mediated through this new interaction term. Based on this idea, many models have been proposed which can reproduce both CDM features as well as MOND in their respective regime of validity.[1,24–27]

In this paper we shall focus on one such model proposed recently by Berezhiani and Khoury,[1] where CDM can form condensates at galactic scales depending upon the surrounding temperature and can behave as superfluid. It has already been shown by the authors that such model can explain a number of galactic scale observations due to their MONDian behaviour, which normal CDM fails to explain.[1,28–30] Although there are recent studies which suggest that the superfluid DM model is disfavoured compared to a spherically symmetric CDM halo at galactic scales as the superfluid DM overestimates the vertical acceleration which has to be counterbalanced to match the observations.[31,32] There are two free parameters in the theory which are assumed to be temperature dependent. It has been argued that at cosmological scales, the theory behaves as usual CDM and thus the background evolution and other cosmic histories remain unchanged as compared to ΛCDM. Here, we study the cosmological evolution of the background as well as the matter perturbations. We check whether the present model remains well-behaved at cosmological scales as has been claimed by the authors and compare our results with ΛCDM.

2. Dark Matter Superfluid-Overview

The central idea of this model is that CDM is made up of particles which undergo phase transition below a particular critical temperature and becomes a superfluid. This requires that the particle CDM needs to be strongly interacting below a particular temperature. The superfluid behaviour depends on the strength of interaction and the mass of the particle. It has been shown in[1] that in order to form a Bose-Einstein Condensate (BEC) the following condition must be satisfied

$$m \lesssim \left(\frac{\rho}{v^3}\right)^{1/4} \tag{1}$$

where m and v corresponds to the mass and velocity of the particle respectively and ρ is the density of the condensate. Assuming virialization of dark matter halo at galactic scales, this gives an upper bound on the mass of the particle forming the halo

$$m \lesssim 2.3(1+z_{vir})^{3/8}\left(\frac{M}{10^{12}h^{-1}M_{\odot}}\right)^{-1/4}\text{eV} \tag{2}$$

Further assuming thermalization of CDM particles, one obtains the bound on interaction cross section as

$$\frac{\sigma}{m} \gtrsim 52(1+z_{vir})^{-7/2}\left(\frac{m}{eV}\right)^{4}\left(\frac{M}{10^{12}h^{-1}M_{\odot}}\right)^{2/3}\text{cm}^2\text{g}^{-1} \tag{3}$$

Using equipartition law, the critical temperature T_c of the CDM condensate can be obtained as

$$T_c = 6.5 \left(\frac{\text{eV}}{\text{m}}\right)^{5/3} (1 + z_{vir})^2 \text{mK} \tag{4}$$

It has been argued in[1] that the temperature of CDM at cosmological scales is much below the critical temperature ($\mathcal{O}(10^{-28})$ for $m \sim$ eV) which implies that the condensate behaves as a $T \approx 0$ superfluid at cosmological scales.

The description of superfluid dark matter is given in terms of a low energy effective theory with the Lagrangian of the form:

$$\mathcal{L} = \frac{2\Lambda(2m)^{3/2}}{3} \left(\dot{\theta} - m\Phi - \frac{(\nabla\theta)^2}{2m}\right)^{3/2} \tag{5}$$

Let us now understand the motivation of choosing such a Lagrangian. Here, θ is the phase of the wavefunction describing the superfluid phonon modes and Φ is the gravitational potential in which the DM particle sits and is given by the standard Newtonian potential in the usual non-relativistic case. This Lagrangian has a free parameter Λ which defines the strength of the superfluid (i.e. defined by the number of particles in the condensate state). The power of the Lagrangian is defined by the choice of the equation of state (EoS), and a fractional power of $5/2$ is indeed obtained in superfluids formed by ultra cold atoms. In the case of CDM superfluid, the choice of the power $3/2$ in the Lagrangian is somewhat arbitrary, but motivated by the fact that the superfluid DM should give rise to MOND-like dynamics at galactic scales when baryons are also included. This also corresponds to an equation of state $P \sim \rho^3$ which is suggestive of a dominant three-body interaction process. What kind of particles can lead to such a superfluid with this particular EoS and the physics of its formation has not been discussed earlier and is beyond the scope of this paper. For our purpose, we shall assume the form of this Lagrangian to study the characteristic features of the resultant superfluid DM model.

In the effective field theory formalism, the superfluid is described in terms of interacting phonon modes. The phonon modes can be described by the scalar field θ, which, at a constant chemical potential μ, can be expanded as,

$$\theta = \mu t + \phi$$

where ϕ denotes the excitation of the phonon modes.

The DM superfluid couples to the baryons through the phonon modes via an interaction given by the Lagrangian:

$$\mathcal{L}_{int} = -\alpha \frac{\Lambda}{M_{Pl}} \theta \rho_b \tag{6}$$

This kind of interaction ensures a MOND force. Here α is a dimensionless free parameter, which sets the interaction strength of the interaction, and ρ_b is the baryonic mass density.

Thus, the complete Lagrangian for an interacting superfluid DM is given by,

$$\mathcal{L} = \frac{2\Lambda(2m)^{3/2}}{3}\left(\dot{\theta} - m\Phi - \frac{(\nabla\theta)^2}{2m}\right)^{3/2} - \alpha\frac{\Lambda}{M_{Pl}}\theta\rho_b \tag{7}$$

It has been shown in[1] that the MONDian acceleration arises as a special case of the dynamics of the above Lagrangian. The validity of this model in solar system and Bullet cluster has also been discussed there.

In the cosmological context, although the authors in[1] discuss some general points regarding the background behaviour and the equation of state of this new superfluid dark matter, they do not shed much light on other important points such as growth of perturbations and structure formation. In the next sections, we solely focus on the cosmological aspects of this new theory.

3. Cosmological Solutions

In this section, we will study this theory in cosmological context. This is of particular interest since the theory also needs to be consistent with the present cosmological data.

3.1. *Background Solutions*

For the background cosmology, we have $\theta = \theta(t)$. In the FLRW background with a scale factor a, the equation of motion for θ can be derived from the action as,

$$\frac{d}{dt}\left[(2m)^{3/2}a^3\dot{\theta}^{1/2}\right] = -\frac{\alpha}{M_{Pl}}a^3\rho_b \tag{8}$$

Assuming the evolution of baryons i.e. $\rho_b \propto 1/a^3$ as in standard ΛCDM, we get,

$$\rho_m = -\frac{\alpha\Lambda}{M_{Pl}}m\rho_b t + \frac{m\Lambda C}{a^3} \tag{9}$$

Here C is an integration constant which has to be determined from the present DM density. The second term (ρ_{dust}) corresponds to the dust like evolution. The form of the density is similar to those obtained in dynamical space-time theories as discussed in.[33–35] For the second term to dominate (such that ρ_m behaves as dust), it can be shown that one needs to satisfy the following constraint:

$$\frac{\alpha\Lambda\rho_b}{M_{Pl}\rho_{dust}}mt_0 \leq 1 \tag{10}$$

where t_0 is the present age of the universe.

Bounds on the model parameters:

- **From the EoS**- Equation of state for the DM superfluid (assuming negligible interaction) is given by,

$$w = \frac{\rho_{dust}^2}{12\Lambda^2 m^6} \tag{11}$$

For DM to behave as dust at the background level, Λ should be bounded from below,

$$\Lambda \gg 0.1 \left(\frac{m}{\text{eV}}\right)^{-3} \text{eV} \tag{12}$$

- **From coupling to baryons**- From (10) and (12), and assuming a constant baryon-to-DM ratio ($\rho_{dust}/\rho_b = 6$), we get,

$$\alpha \ll 2.4 \times 10^{-4} \left(\frac{m}{\text{eV}}\right)^2 \tag{13}$$

These bounds are different from the bounds obtained for galaxies, as discussed in.[1,28]

3.2. *Perturbations*

Study of linear perturbation theory in the context of ΛCDM has been an important step towards understanding the evolution of the universe. CMB spectra carries information about the inhomogeneities present in the early universe. Hence, any cosmological model needs to satisfy the CMB data to a high degree of accuracy. This requires analysing the matter power spectrum resulting from the initial density perturbations. In this section, we examine the growth of cosmological perturbations in DM superfluid model at linear order.

The Lagrangian of the theory in an FLRW matter dominated universe is given as,

$$\mathcal{L} = c_1 \left(\dot{\theta} - \frac{(\nabla\theta)^2}{2m} - m\Phi\right)^{3/2} - c_2\rho_b\theta \tag{14}$$

where c_1, c_2 are constants expressed as,

$$\begin{aligned} c_1 &= \frac{2\Lambda(2m)^{3/2}}{3} \\ c_2 &= \alpha\frac{\Lambda}{M_{Pl}} \end{aligned} \tag{15}$$

Here, $\theta(x,t) = \bar{\theta}(t) + \delta\theta(x,t)$ is a scalar field which is a fucntion of both space and time.

We can find the Euler-Lagrange equation from the above equation as:

$$\frac{d}{dt}\left(\frac{\partial\mathcal{L}}{\partial\dot{\theta}}\right) - \frac{\partial\mathcal{L}}{\partial\theta} = 0 \tag{16}$$

This gives us the background equation of motion as shown in the previous subsection as well as the first order perturbation equation of the dark matter density. But this single governing equation is inadequate to obtain the complete numerical solution which requires a complete set of differential equations.

In order to get the full set of perturbation equations, we start with the fluid equations that govern the dynamics of the dark matter superfluid. The fluid equations, namely the continuity equation and the Navier-Stokes equation can be derived using the Hamiltonian formalism, as described in.[36] In,[36] the authors work out the fluid equations for an interacting two-component BEC dark matter. Here in this work, we follow the same prescription for a superfluid dark matter which interacts with the baryonic matter. The corresponding Lagrangian is given by (14).

From the Lagrangian, we get the conjugate momentum as,

$$\begin{aligned}\Pi_\theta &= \frac{\partial \mathcal{L}}{\partial \dot{\theta}} \\ &= \Lambda(2m)^{3/2}\left[\dot{\theta} - m\Phi - \frac{(\nabla\theta)^2}{2m}\right]^{1/2}\end{aligned} \tag{17}$$

The Hamiltonian H describing the superfluid can be obtained as,

$$H = \Pi_\theta \dot{\theta} - \mathcal{L} \tag{18}$$

Since, $\dot{\theta} = m\Phi + \frac{(\nabla\theta)^2}{2m} + \frac{\Pi_\theta^2}{\Lambda^2(2m)^3}$ from (17), we get the Hamiltonian H as follows,

$$H = \frac{\Pi_\theta^3}{3\Lambda^2(2m)^3} + \left(m\Phi + \frac{(\nabla\theta)^2}{2m}\right)\Pi_\theta + \frac{\alpha\Lambda}{M_{pl}}\rho_b\theta \tag{19}$$

3.2.1. *Hamilton's equation of motion*

The Hamilton's equations of motion are :

$$\dot{\theta} = \frac{\partial H}{\partial \Pi_\theta} \tag{20}$$

and

$$\dot{\Pi}_\theta = -\frac{\partial H}{\partial \theta} \tag{21}$$

For this model, the two equations become, respectively,

$$\dot{\theta} = \frac{\Pi_\theta^2}{\Lambda^2(2m)^3} + m\Phi + \frac{(\nabla\theta)^2}{2m} \tag{22}$$

and

$$\dot{\Pi}_\theta = \frac{1}{m}\nabla\cdot(\Pi_\theta\nabla\theta) - \frac{\alpha\Lambda}{M_{pl}}\rho_b \tag{23}$$

3.2.2. *Fluid equations*

In order to get the fluid equations from the above Hamilton's equations of motion, we identify the terms as corresponding hydrodynamical variables. We define the mass density term (as the co-efficient of Φ in the Hamiltonian) and the four-velocity of the fluid, $\vec{u}$ as

$$\rho_m = m\Pi_\theta, \quad \vec{u} = -\frac{\nabla\theta}{m}. \tag{24}$$

Using the above definitions, we get the fluid equations from equation (23) and (22) as follow,

$$\dot{\rho}_m + \nabla\cdot(\rho_m\vec{u}) = -\frac{\alpha\Lambda m}{M_{pl}}\rho_b \tag{25}$$

$$\dot{\vec{u}} + (\vec{u}\cdot\nabla)\vec{u} = -\frac{\rho_m\nabla\rho_m}{4\Lambda^2 m^6} - \nabla\Phi \tag{26}$$

These are the two fluid equations: Continuity equation and Navier-Stokes equation.

Now, the Poisson's equation can be written as

$$\nabla^2\Phi = 4\pi G(\bar{\rho} + \delta\rho) \tag{27}$$

Integrating twice and substituting the background density using Friedmann equations, we get the potential as:

$$\Phi = -\frac{1}{2}(\dot{H} + H^2)l^2 + \phi \tag{28}$$

where l is the proper distance defined as $\vec{l} = a(t)\vec{x}$ and ϕ is the potential due to inhomogeneities.

Similarly, the four-velocity $\vec{u}$ can be split into two parts, Hubble flow and a peculiar velocity $\vec{v}$ as follows:

$$\vec{u} = H\vec{l} + \vec{v} \tag{29}$$

Expressing everything in comoving co-ordinates $\vec{x}$ and using $\nabla_l = \frac{1}{a(t)}\nabla_x$, we get,

$$\dot{\rho}_m + 3H\rho_m + \frac{1}{a}\nabla\cdot(\rho_m\vec{v}) = -\frac{\alpha\Lambda m}{M_{pl}}\rho_b \tag{30}$$

and

$$\dot{\vec{v}} + H\vec{v} + \frac{1}{a}(\vec{v}\cdot\nabla)\vec{v} = -\frac{\rho_m\nabla\rho_m}{4a\Lambda^2 m^6} - \frac{\nabla\phi}{a} \tag{31}$$

These are the two fluid equations of motion that we shall use for the rest of our calculations.

3.2.3. *Evolution of perturbations*

The total DM density ρ_m and the baryonic density ρ_b can be split into two parts: background and perturbation:

$$\rho_m = \bar{\rho}_m + \delta\rho_m, \quad \rho_b = \bar{\rho}_b + \delta\rho_b$$

respectively.

We define, the relative density perturbations for these two components as,

$$\delta_m = \frac{\delta\rho_m}{\bar{\rho}_m + \bar{\rho}_b} \quad \text{and} \quad \delta_b = \frac{\delta\rho_b}{\bar{\rho}_m + \bar{\rho}_b}.$$

In the linear perturbation regime, we treat $\delta\rho_m$, $\delta\rho_b$ and $\vec{v}$ to be small, and hence, neglect the higher orders of these terms. Perturbing the two fluid equations in the linear regime gives:

$$\dot{\delta}_m + \frac{\bar{\rho}_m}{a\bar{\rho}}\nabla\cdot\vec{v} = -\frac{\alpha\Lambda m}{M_{pl}}\delta_b \tag{32}$$

and

$$\dot{\vec{v}} + H\vec{v} = -\frac{\bar{\rho}_m\nabla\delta\rho_m}{4a\Lambda^2 m^6} - \frac{1}{a}\nabla\phi \tag{33}$$

By using the above equations along with the Poisson's equation and assuming $\bar{\rho}_m \sim \bar{\rho}$, we get the evolution equation for δ_m as follows:

$$\ddot{\delta}_m + 2H\dot{\delta}_m - \frac{\bar{\rho}_m\delta_m}{2M_{pl}^2} - \frac{\bar{\rho}_m^2\nabla^2\delta_m}{4a^2\Lambda^2 m^6} = -\frac{\alpha\Lambda m\dot{\delta}_b}{M_{pl}} - 2H\frac{\alpha\Lambda m\delta_b}{M_{pl}} + \frac{\bar{\rho}_b\delta_b}{2M_{pl}^2} \tag{34}$$

This is a second order differential equation. The coefficient of the spatial derivative ∇^2 gives the square of the sound speed c_s. Thus, we get,

$$c_s^2 = \frac{\bar{\rho}_m^2}{4\Lambda^2 m^6} \tag{35}$$

Below in Fig. 1, we show the plot for c_s^2 vs the redshift z for $m = 1$ eV and $\Lambda = 500$ eV. We take the time evolution of the background density $\bar{\rho}_m$ as

$$\bar{\rho}_m = \frac{0.4(1+z)^3}{(1+1000)^3} \tag{36}$$

where the value of $\bar{\rho}_m$ at equality ($z = 1000$) is set as 0.4 eV^4 ([36]). As evident from the plot, the sound speed is very small (compared to the speed of light $c = 1$).

3.3. *Analytical Solution*

We now have the perturbation equations (32) and (33) supplemented by the Poisson equation. In the absence of baryons, we recover the usual evolution of CDM as a non-relativistic fluid. This can be seen as follows.

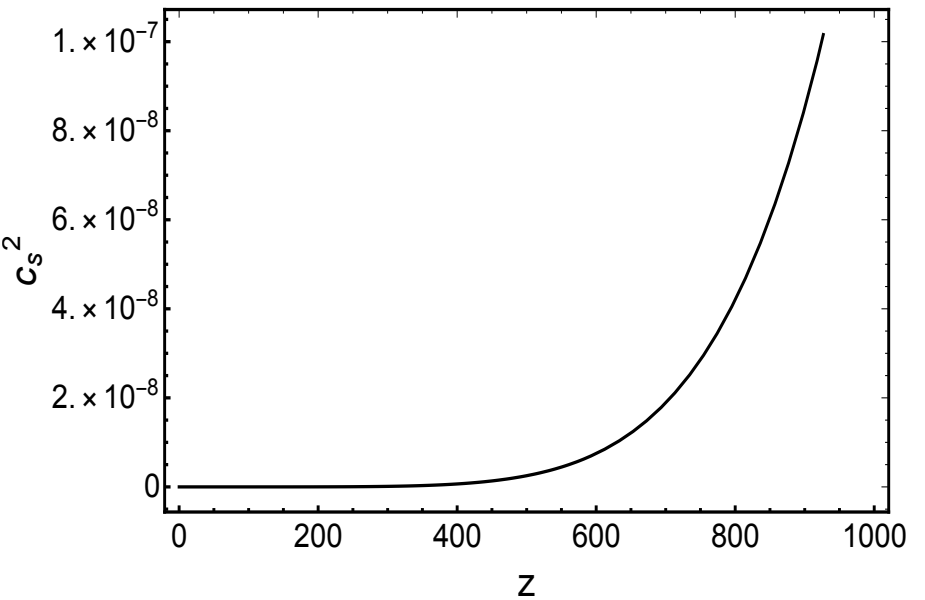

Fig. 1. Plot for c_s^2 vs z. As can be seen, the sound speed is very small compared to the speed of light ($c = 1$ in this case) at all times.

Without baryons:
In the absence of baryons, i.e. by setting $\bar{\rho}_b = 0$ and $\delta\rho_b = 0$ in equations (32) and (33), we obtain a set of equations as follows:

$$\dot{\delta}_m + \frac{1}{a}\nabla \cdot \vec{v} = 0 \tag{37}$$

and

$$\dot{\vec{v}} + H\vec{v} = -\frac{\bar{\rho}_m \nabla \delta\rho_m}{4a\Lambda^2 m^6} - \frac{1}{a}\nabla\phi \tag{38}$$

For $\Lambda \gg 1$, i.e, when the sound speed c_s is taken to be very small, the above set of equations reduce to the usual perturbation evolution equations in a ΛCDM model in the matter-dominated regime.[37] Thus, in the absence of baryons, usual CDM like evolution is recovered at the background level as well as for the perturbations. This can also be seen from the second order differential equation governing the evolution. From equation (34), in the absence of baryons, we obtain,

$$\ddot{\delta}_m + 2H\dot{\delta}_m - \frac{\bar{\rho}_m \delta_m}{2M_{pl}^2} - \frac{\bar{\rho}_m^2 \nabla^2 \delta_m}{4a^2\Lambda^2 m^6} = 0 \tag{39}$$

As expected, the above equation is the usual evolution equation for CDM in a flat ΛCDM universe, with a small sound speed given by (35). Since the sound speed

is very small, for all practical purposes, this term can be neglected and we end up with the following second order differential equation:

$$\ddot{\delta}_m + 2H\dot{\delta}_m - \frac{\bar{\rho}_m \delta_m}{2M_{pl}^2} = 0 \tag{40}$$

This is the evolution equation of non-relativistic CDM in the ΛCDM model.[38] The growing solution of this equation is the usual CDM like evolution, which is $\delta \propto a$ for a matter dominated universe.[37,38] In the absence of baryons, the superfluid dark matter thus behaves exactly like CDM and the growth of perturbations follow the ΛCDM-like evolution.

With baryons:
We now investigate how the perturbations evolve when both baryons and baryonic interactions with superfluid dark matter is present. A complete solution is to be found numerically for different values of the model parameters. This will be pursued in the next section. For now, we try to find the generic nature of the DM perturbations growth with some basic assumptions regarding the baryonic density evolution and the interaction strength between baryons and the superfluid. We assume that the baryon perturbation δ_b follows the same rate of growth as in ΛCDM i.e. at late times $\delta_b \propto a$ as obtained from the observed power spectrum. We now consider equation (34) which is the single second order evolution equation. We are only interested in the temporal behaviour of δ_m. With the assumption that $c_s^2 \ll 1$, equation (34) can be analytically solved for two limiting cases. For the first case when the interaction strength is negligible, one can set $\alpha = 0$. With this condition, the only remaining term in the RHS of (34) is the last term. The resulting equation has a power law solution of the form $\delta \propto t^{2/3} \propto a$ in the matter dominated era. This is the usual CDM-like behaviour as expected when the interaction strength is negligible. The other limiting case solution can be obtained by setting a very strong interaction strength i.e. by taking a large enough α such that the first two terms in the RHS of (34) become dominant. In this case, the solution for the matter dominated universe comes out to be of the form

$$\delta_m \propto t^{5/3} \propto a^{5/2} \tag{41}$$

The time evolution of The DM perturbation growth in the two cases is thus captured by the following form:

$$\delta_m \propto a \qquad \text{for no interaction} \tag{42}$$

$$\delta_m \propto a^{5/2} \qquad \text{for strong interaction} \tag{43}$$

Important distinct features arise when we look at the time evolution of δ_m for each mode. During the matter dominated era, δ_m grows as a in ΛCDM whereas in this model, it grows as $a^{5/2}$ i.e. at a much faster rate compared to ΛCDM.

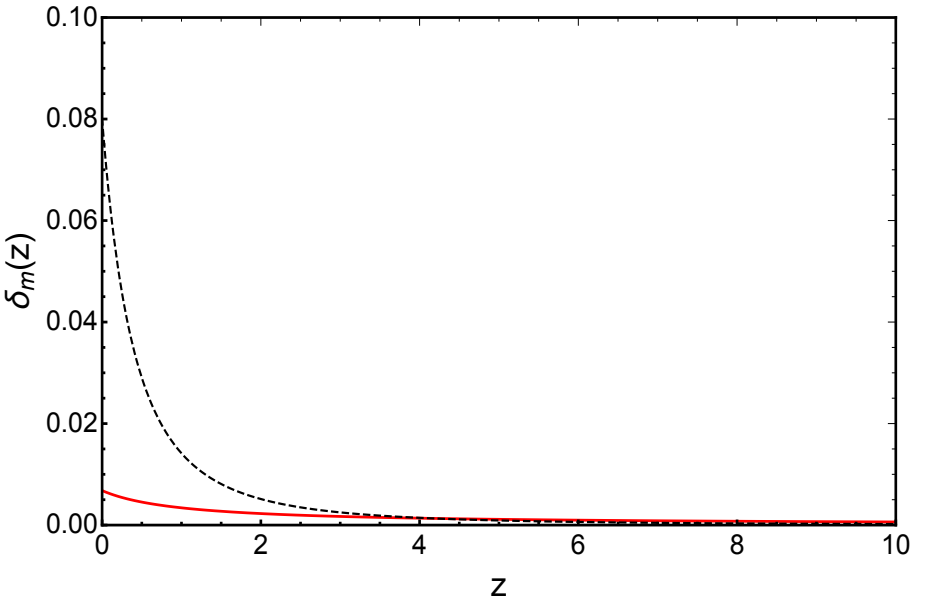

Fig. 2. Growth of δ_m with respect to z. The red solid line represents the growth for ΛCDM and the black dashed line corresponds to the growth for superfluid for $\alpha = 10^{-6}$. The growth in case of superfluid DM is dominated by the term proportional to $a^{5/2}$ and is higher compared to ΛCDM. The higher the value of α, i.e. the stronger the superfluid DM-baryonic interaction, the steeper is the growth rate (as will be discussed in the next section).

For convenience, we write the evolution of δ_m in terms of the redshift:

$$\delta_m \propto \frac{1}{(1+z)^{5/2}} \tag{44}$$

Fig. 2 shows the nature of growth in both the models (red solid curve representing ΛCDM, black dashed curve representing superfluid DM).

A proper way to find the full solution for the perturbed quantities is to solve coupled differential equations using a numerical approach. In the next section we solve the perturbation equations numerically in the linear regime and look for any possible deviations from ΛCDM.

4. Numerical Solution

In order to obtain the solutions for δ_m, we rewrite equations (32) and (33) in the Fourier domain in physical co-ordinate as,

$$\dot{\delta}_m + \frac{\bar{\rho}_m}{\bar{\rho}}(ikv) = -\frac{\alpha \Lambda m}{M_{pl}}\delta_b \tag{45}$$

and

$$ik\dot{v} + ikHv = \frac{k^2\bar{\rho}_m\bar{\rho}\delta_m}{4\Lambda^2 m^6} + \frac{a^2}{2M_{pl}^2}\left(\delta\rho_m + \delta\rho_b + \frac{3iaH\bar{\rho}v}{k}\right) \tag{46}$$

To solve the above equations, we write them in terms of redshift,

$$-H(1+z)\frac{d\delta_m}{dz} + \frac{\bar{\rho}_m}{\bar{\rho}}(ikv) = -\frac{\alpha\Lambda m}{M_{pl}}\delta_b \tag{47}$$

and

$$-ikH(1+z)\frac{dv}{dz} + ikHv = \frac{k^2\bar{\rho}_m\bar{\rho}\delta_m}{4\Lambda^2 m^6} + \frac{\bar{\rho}}{2M_{pl}^2(1+z)^2}\left(\delta_m + \delta_b + \frac{3iHv}{k(1+z)}\right) \tag{48}$$

Parameters and initial conditions:

The model parameters involved are m, Λ and α. We take $m = 1$ eV and $\Lambda = 500$ eV while keeping the parameter α as free parameter which is varied to check where the model deviates from flat ΛCDM.

We integrate the perturbation equations using the following initial conditions at the epoch of equality $z = 1000$: We set $\delta_b(z = 1000) = \delta_m(z = 1000) = 10^{-5}$ and $H(z = 1000) = m = 1$ eV.

Since $\bar{\rho_m} \gg \bar{\rho}_b$, we assume $\bar{\rho} = \bar{\rho}_m + \bar{\rho}_b \approx \bar{\rho}_m$ as given in (36).

The initial value of v at $z = 1000$ is chosen to be around 1. For the time evolution of the background density and Hubble parameter, we take the usual ΛCDM evolution of these quantities in matter-dominated era, i.e. $\bar{\rho}_m \propto 1/a^3$ and $H \propto 1/a^{3/2}$. Furthermore, we take $\delta_b \propto a$. We keep the wavenumber k fixed at 0.0001 eV, although the nature remains same for larger values of k.

Figure 3 shows the evolution of the DM density perturbation δ_m with respect to the redshift z for different values of $\alpha = 10^{-8},\ 10^{-7},\ 10^{-6},\ 10^{-4}$ and also for ΛCDM corresponding to $\alpha = 0, \Lambda \to \infty$. As expected, the smaller the value of α, the closer the resemblance with ΛCDM-like evolution. As we see in Fig. 3, the plot for $\alpha = 10^{-8}$ coincides with ΛCDM. When α is large enough, the growth is very steep. This is because a large enough α implies large interaction strength between the superfluid phonons and baryons, ensuring that structure formation takes place at an earlier epoch as compared to ΛCDM.

In Figure 4, we plot the relative differences between the perturbation growth in ΛCDM model and superfluid DM model for different values of α in terms of $\delta_{\text{superfluid}}/\delta_{\Lambda\text{CDM}}$. As expected, the ratio is very high at a lower redshift. As we go to higher redshifts, the ratio tends to 1 i.e., they eventually agree with ΛCDM at very high redshifts and matches exactly at $z = 1000$ where we set our initial conditions. The ΛCDM model corresponds to $\alpha = 0$. For $\alpha = 10^{-8}$, the deviation from ΛCDM at low redshift goes up to 0.13% at $z = 0.01$. The larger the value of α, the higher is the ratio, implying a stronger deviation from ΛCDM at low enough redshifts. As α is increased to 10^{-7}, the deviation from ΛCDM becomes much larger ($\sim 62\%$).

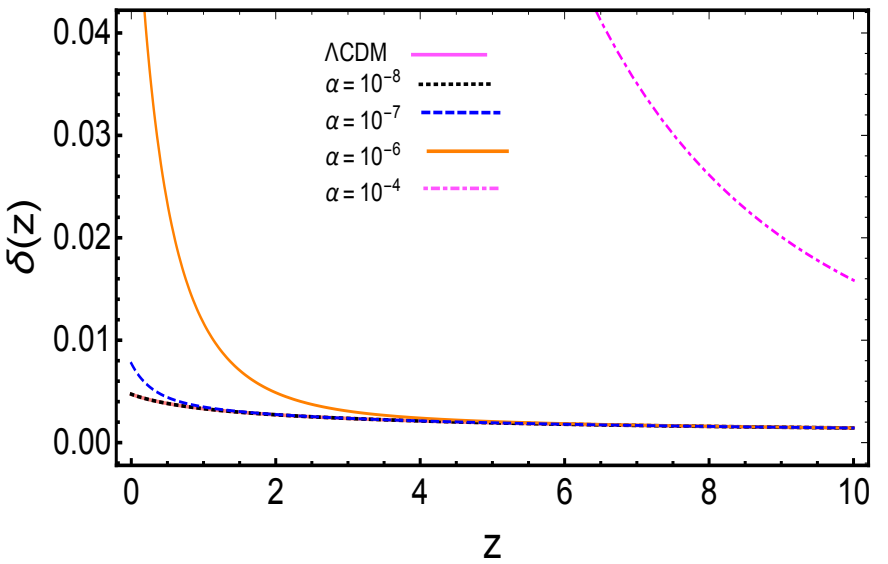

Fig. 3. Plot for δ_m vs z for different values of α as obtained numerically. The different curves correspond to different α as shown in the figure. The curve corresponding to $\alpha = 10^{-8}$ coincides with ΛCDM. For higher values of α, the deviation from ΛCDM increases gradually. The growth rate at a given redshift is maximum for $\alpha = 10^{-4}$ for the cases considered here.

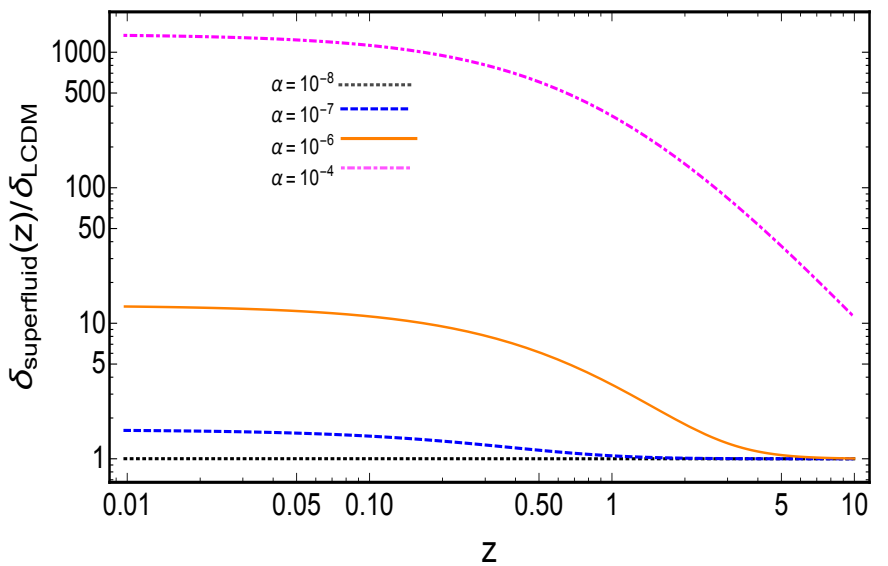

Fig. 4. Plot for $\delta_{\rm superfluid}/\delta_{\Lambda\rm CDM}$ vs z for different values of α. For an exact coincidence with ΛCDM, this ratio should be 1. Values > 1 signify larger deviation from ΛCDM. For $\alpha = 10^{-8}$, the ratio is almost nearly 1 showing a deviation only up to 0.13% at $z = 0$. For $\alpha = 10^{-7}$, the deviation increases up to 62% at the same redshift.

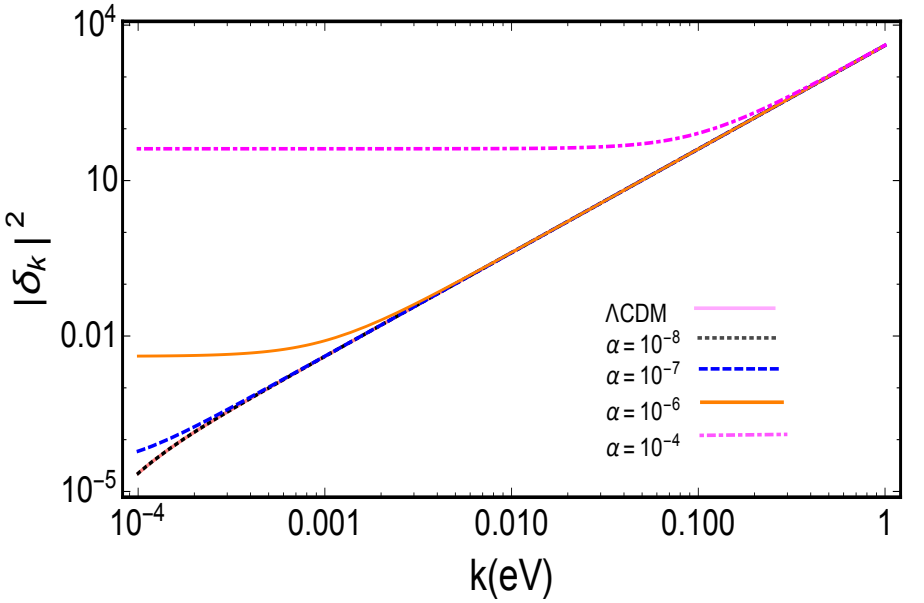

Fig. 5. Plot for $|\delta_k|^2$ vs k at $z = 0$. This is the matter power spectrum up to a constant factor. The plot reaffirms our previous results. In general the power increase approximately linearly with k. However, for large enough α, it becomes relatively flatter.

We can also plot the matter power spectrum $P(k)$ as a function of k at $z = 0$. The matter power spectrum $P(k) \propto |\delta_m(k)|^2$. In Fig. 5, we plot $|\delta_m(k)|^2$ vs. k which shows how the power varies for different values of α. As shown in the figure, the power spectrum for $\alpha = 10^{-8}$ matches with the ΛCDM prediction. As can be seen, the power increases for larger values of α at a given value of k. This is because the perturbation growth is stronger for large α as discussed earlier.

5. Results and Discussions

The superfluid dark matter model is a very promising and newly emerging model of cosmology combining together the rich physics of condensed matter, particle physics and cosmology. In view of its success in explaining a number of observations within the galaxies where ΛCDM fails to provide a satisfactory explanation, this model can be said to offer a greater understanding of the universe. In their earlier works, Khoury and his collaborators have investigated the implications of this model at galactic scales. However, a complete study of cosmological implications have not been performed earlier. In this paper, we have tried to investigate, both analytically and numerically, whether the predicted cosmology of the model tallies well with the observations and how different the predictions are from that of ΛCDM. In the realm of non-relativistic low energy effective theory of superfluid, the background cosmology agrees with the predictions of ΛCDM, and this gives a constraint on the

two model parameters α and Λ which turn out to be different than their galactic scale constraints. This result has also been discussed in.[1] At the level of first order perturbation, we find that the above constraints lead to a cosmology which differ significantly from ΛCDM. In particular, our analytical results suggests that the growth of density perturbations of dark matter superfluid roughly goes as $a^{5/2}$, which is much higher compared to the ΛCDM picture ($\delta_m \propto a$). This might be due to the strong interaction between superfluid phonons and baryonic matter. This behaviour has also been verified from the numerical solutions. For the numerical calculations, in particular, we have kept two of the model parameters m and Λ fixed at 1 eV and 500 eV respectively. This gives an upper bound on the third parameter: $\alpha \leq 10^{-8}$ corresponding to just 0.13% deviation from ΛCDM. This is different from the value quoted in.[1] The bound obtained in,[1] for $m = 1$ eV, is $\alpha \leq 10^{-4}$, which, even though predicts the correct background evolution, strongly deviates from ΛCDM in the context of perturbation growth in the present epoch. This can be seen in Figs. 3, 4 and 5. In our analysis, we have assumed the baryonic component to follow standard dust evolution ($\propto \frac{1}{a^3}$). In the absence of baryons, however, this model successfully reproduces the usual non-relativistic CDM evolution as obtained in case of a flat matter dominated ΛCDM universe, both at the background as well as first order perturbation level.

A more complete analysis of the perturbation growth should rely on the proper relativistic extension of the theory, which has not been attempted in this paper. Some relativistic models have been discussed in the original paper,[1] however a rigorous analysis is still lacking. We hope to address the same in a future work. Our work looks into the solution in the linear regime where perturbations are taken to be small. In future, we plan to extend our analysis to the non-linear regime and study the structure formation through spherical collapse. It would also be interesting to see how well this model predicts the CMB or the halo mass function.

In this work, we discuss a cosmological model with dark energy – dark matter interaction. Demanding that the interaction strength Q_ν in the dark sector must have a field theory description, a unique form of interaction strength can be obtained. We show the equivalence between the fields and fluids for the $f(R, \chi)$ model where f is an arbitrary, smooth function of R and classical scalar field χ, which represents dark matter. Up to first order in perturbations, there is a one-to-one mapping between the classical field theory description and the phenomenological fluid description of interacting dark energy and dark matter, which exists only for this unique form of interaction. Different formulations of interacting dark energy models in the literature can be classified into two categories based on the field-theoretic description. Then we discuss the quantifying tools to distinguish between the interacting and non-interacting dark sector scenarios. We focus on the variation of the scalar metric perturbed quantities as a function of redshift related to structure formation, weak gravitational lensing, and the integrated Sachs-Wolfe effect and show that the difference in the evolution becomes significant for lower redshifts ($z < 20$), for all length scales.

Keywords: Dark matter - dark energy interaction, based on the work Ref. 1

1. Introduction

Dark matter dominates the galaxy mass, and dark energy forms the majority of our Universe's energy density.[2,3] However, we have little information about the properties of these two components that dominate the energy content of the Universe today.[4] The only information we have about the two components is that (i) Dark energy contributes negative pressure to the energy budget, and (ii) Dark matter has negligible, possibly zero, pressure. The above properties are based on gravitational interactions. More importantly, we do not know how they interact with each other and Baryons/Photons.

It has been shown that the dark matter-dark energy interaction can reconcile the tensions in the Hubble constant H_0.[5,6] In most interacting dark sector models, phenomenologically, the interaction is proposed between the fluid terms in the dark sector (Cf. Ref.[1]). More specifically, individually, dark matter (DM) and dark energy (DE) do not satisfy the conservation equations; however, the combined sector satisfies the energy conservation equation,[7] i. e.,

$$\nabla^\mu T^{(\mathrm{DE,DM})}_{\mu\nu} = Q^{(\mathrm{DE,DM})}_\nu, \quad Q^{(\mathrm{DE})}_\nu + Q^{(\mathrm{DM})}_\nu = 0 \tag{1}$$

where Q determines the interaction strength between dark matter and dark energy. Since the gravitational effects on dark matter and dark energy are opposite, even a small interaction can impact the cosmological evolution.[8] Since we have little information about the dark sector, in many of these models, the interaction strength Q_ν is put in by hand. However, it is unclear whether these broad classes of phenomenological models can be obtained from a field theory action.

In this work, we show that under conformal transformations, $f(R,\chi)$ is equivalent to a model with two coupled scalar fields. The dark energy - dark matter interaction, represented by the coupling between the classical scalar fields, can also be represented by the evolution equations of the dark energy (represented by a scalar field) and dark matter (represented by a fluid). We show that a one-to-one mapping exists between the field theory and fluid description for a unique interaction term.

To detect the signatures of the interacting dark sector from the observations, one needs to construct theoretical tools to distinguish interacting dark sector models from non-interacting ones. We focus on the three cosmological phenomena: (i) structure formation, (ii) weak gravitational lensing (iii) integrated Sachs Wolfe effect. We study the evolution of the relevant perturbed quantities in the redshift range $0 \leq z \leq 1500$ at different length scales. We see that there is a clear difference in the perturbed evolution in the interacting dark sector model as compared to non-interacting ones. This difference becomes significant for $z < 20$, especially at smaller length scales.

2. Dark sector interaction: Field and fluid description

Consider the following action in Jordan frame:

$$S_J = \int d^4x\sqrt{-\tilde{g}}\left[\frac{1}{2\kappa^2}f(\tilde{R},\tilde{\chi}) - \frac{1}{2}\tilde{g}^{\mu\nu}\tilde{\nabla}_\mu\tilde{\chi}\tilde{\nabla}_\nu\tilde{\chi} - V(\tilde{\chi})\right] \tag{2}$$

where $f(\tilde{R},\tilde{\chi})$ is an arbitrary, smooth function of Ricci scalar, and scalar field $\tilde{\chi}$, and $V(\chi)$ is the self-interaction potential of the scalar field $\tilde{\chi}$. Under the conformal transformation:

$$g_{\mu\nu} = \Omega^2\tilde{g}_{\mu\nu}, \quad \text{where} \quad \Omega^2 = F(\tilde{R},\tilde{\chi}) \equiv \frac{\partial f(\tilde{R},\tilde{\chi})}{\partial\tilde{R}} \tag{3}$$

and a field redefinition, the action in the Einstein frame takes the following form

$$S = \int d^4x\sqrt{-g}\left(\frac{1}{2\kappa^2}R - \frac{1}{2}g^{\mu\nu}\nabla_\mu\phi\nabla_\nu\phi - U(\phi) - \frac{1}{2}e^{2\alpha(\phi)}g^{\mu\nu}\nabla_\mu\chi\nabla_\nu\chi - e^{4\alpha(\phi)}V(\chi)\right). \tag{4}$$

where

$$U = \frac{F\tilde{R} - f}{2\kappa^2F^2}\,.$$

and $\alpha(\phi)$ denotes the interaction between dark energy and dark matter.

Defining the dark matter fluid by specifying the four velocity energy density and pressure

$$u_\mu = -\left[-g^{\alpha\beta}\nabla_\alpha\chi\nabla_\beta\chi\right]^{-\frac{1}{2}}\nabla_\mu\chi \tag{5}$$

$$p_m = -\frac{1}{2}e^{2\alpha}\left[g^{\mu\nu}\nabla_\mu\chi\nabla_\nu\chi + e^{2\alpha}V(\chi)\right], \quad \rho_m = -\frac{1}{2}e^{2\alpha}\left[g^{\mu\nu}\nabla_\mu\chi\nabla_\nu\chi - e^{2\alpha}V(\chi)\right]. \tag{6}$$

Then the interaction function in the field theory and fluid descriptions are given by

$$Q_\nu^{(\mathrm{F})} = -e^{2\alpha(\phi)}\alpha_{,\phi}(\phi)\nabla_\nu\phi\left[\nabla^\sigma\chi\nabla_\sigma\chi + 4e^{2\alpha(\phi)}V(\chi)\right] = -\alpha_{,\phi}(\phi)\nabla_\nu\phi(\rho_m - 3p_m) \tag{7}$$

A one-to-one mapping between the field theory description and fluid description of the interacting dark sector described above exist *only* for this form of interaction function. A classification of interacting dark sector models based on the existence of this mapping is given below.[1]

Interacting DE-DM model	**DE-DM Interaction** $\nabla^\mu T^{(\mathrm{DE,DM})}_{\mu\nu} = Q^{(\mathrm{DE,DM})}_\nu$	**Is** $\boldsymbol{Q_\nu \propto Q_\nu^{(\mathrm{F})}}$?

[a] Violates causality condition ($D(\phi) > 0$) for the disformal transformations[32]

3. Cosmological evolution with dark energy – dark matter interaction

Consider the perturbed FRW metric in the Newtonian gauge

$$g_{00} = -(1+2\Phi)\,, \quad g_{0i} = 0, \quad g_{ij} = a^2(1-2\Psi)\delta_{ij}\,, \tag{8}$$

For the FRW Universe, the background evolution of the scalar fields in the field theory description is given by

$$\ddot{\overline{\chi}} + 3H\dot{\overline{\chi}} + e^{2\alpha}V_{,\chi}(\overline{\chi}) + 2\alpha_{,\phi}(\overline{\phi})\dot{\overline{\phi}}\dot{\overline{\chi}} = 0$$
$$\ddot{\overline{\phi}} + 3H\dot{\overline{\phi}} + U_{,\phi}(\overline{\phi}) + 4e^{4\alpha}\alpha_{,\phi}(\overline{\phi})V(\overline{\chi}) - e^{2\alpha}\alpha_{,\phi}(\overline{\phi})\dot{\overline{\chi}}^2 = 0\,.$$

In the fluid description, the dark energy scalar field $\bar{\phi}$ and the dark matter fluid energy density $\bar{\rho}_m$ evolve as

$$\ddot{\overline{\phi}}\dot{\overline{\phi}} + 3H\dot{\overline{\phi}}^2 + U_{,\phi}(\overline{\phi})\dot{\overline{\phi}} = \overline{Q}^{(\mathrm{F})}, \quad \dot{\overline{\rho}}_m + 3H(\overline{\rho}_m + \overline{p}_m) = -\overline{Q}^{(\mathrm{F})}$$

where the interaction term $\overline{Q}^{(\mathrm{F})}$ is given by

$$\overline{Q}^{(\mathrm{F})} = -\alpha_{,\phi}(\overline{\phi})\dot{\overline{\phi}}(\overline{\rho}_m - 3\overline{p}_m) = \alpha_{,\phi}(\overline{\phi})\dot{\overline{\phi}}e^{2\alpha(\overline{\phi})}\left[\dot{\overline{\chi}}^2 - 4e^{2\alpha}V(\overline{\chi})\right]. \tag{9}$$

Then the dark matter fluid energy density evolves as

$$\overline{\rho}_m = \overline{\rho}_{m_0}a^{-3(1+\omega_m)}e^{[\alpha(\overline{\phi})-\alpha_0](1-3\omega_m)}, \tag{10}$$

The perturbed evolution in the Newtonian gauge is given by

$$\delta\dot{\rho}_m + 3H(\delta p_m + \delta\rho_m) + (\overline{p}_m + \overline{\rho}_m)\left[\frac{\nabla^2\delta u^s}{a^2} - 3\dot{\Psi}\right] = -\delta Q \tag{11}$$

$$\dot{\overline{\phi}}\left(\dot{\delta\phi} - \frac{\nabla^2\delta\phi}{a^2} - 2\Phi\dot{\overline{\phi}} + U_{,\phi\phi}(\overline{\phi})\delta\phi\right) + \dot{\delta\phi}\left(\dot{\overline{\phi}} + 6H\dot{\overline{\phi}} + U_{,\phi}(\overline{\phi})\right)$$
$$-\frac{\dot{\overline{\phi}}^2}{2}\left(3\dot{\Psi} + \dot{\Phi} + 6H\Phi\right) = \delta Q, \tag{12}$$

where

$$\delta Q^{(\mathrm{F})} = -(\delta\rho_m - 3\delta p_m)\alpha_{,\phi}(\overline{\phi})\dot{\overline{\phi}} - (\overline{\rho}_m - 3\overline{p}_m)\left[\alpha_{,\phi\phi}(\overline{\phi})\dot{\overline{\phi}}\delta\phi + \alpha_{,\phi}(\overline{\phi})\dot{\delta\phi}\right] \tag{13}$$

The metric perturbations Φ and Ψ satisfy the equations

$$\Psi - \Phi = 0 \tag{14}$$

$$\dot{\Psi} + H\Phi = \frac{\kappa^2}{2}\left[\dot{\overline{\phi}}\delta\phi - (\overline{\rho}_m + \overline{p}_m)\,\delta u^s\right] \tag{15}$$

$$3H\dot{\Psi} - \frac{\nabla^2\Psi}{a^2} + 3H^2\Phi = -\frac{\kappa^2}{2}\left(\delta\rho_m + \dot{\delta\phi}\dot{\bar{\phi}} - \Phi\dot{\bar{\phi}}^2 + U_{,\phi}(\bar{\phi})\delta\phi\right) \tag{16}$$

$$\begin{aligned} &3\ddot{\Psi} + \frac{\nabla^2\Phi}{a^2} + 6\Phi\left(H^2 + \dot{H}\right) + 3H\left(2\dot{\Psi} + \dot{\Phi}\right) \\ &\quad = \frac{\kappa^2}{2}\left(\delta\rho_m + 3\delta p_m + 4\dot{\delta\phi}\dot{\bar{\phi}} - 4\Phi\dot{\bar{\phi}}^2 - 2U_{,\phi}(\bar{\phi})\delta\phi\right) \end{aligned} \tag{17}$$

4. Observable signatures of interacting dark sector

To detect the signatures of dark energy – dark matter interaction in cosmological observation, one needs to study the evolution of perturbed quantities related to cosmological observations. For this purpose, we consider the following cosmological phenomena and the relevant perturbed quantities

(1) Structure formation: $\delta_m(t,x,y,z) \equiv \frac{\delta\rho_m(t,x,y,z)}{\overline{\rho_m}(t)}$
(2) Weak lensing : $\Phi + \Psi$
(3) Integrated Sachs-Wolfe (ISW) effect: $\Phi' + \Psi'$

where *prime* denoted derivative with respect to $N \equiv \ln a$.

To illustrate the difference between the evolution of perturbations in the interacting and non-interacting scenarios, we consider the following dark energy scalar field potential and interaction function

$$U(\phi) \sim \frac{1}{\phi}, \quad \alpha(\phi) \sim \phi \tag{18}$$

We then study the evolution of the flowing quantities in the redshift range $0 \leq z \leq 1500$ at different length scales

$$\Delta\delta_m = \delta_{m_i} - \delta_{m_{ni}}, \quad \Delta\Phi = \Phi_i - \Phi_{ni}, \quad \Delta\Phi' = \Phi'_i - \Phi'_{ni} \tag{19}$$

Evolution these quantities are given in Figs. 1 and 2.

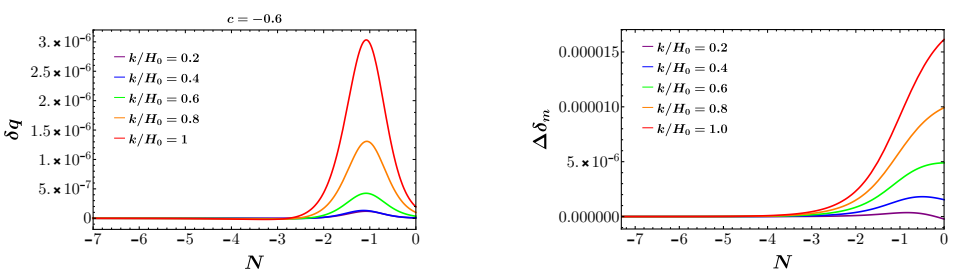

Fig. 1. Evolution of δq(left panel) and $\Delta\delta_m$(right panel) as a function of N for different values of k.

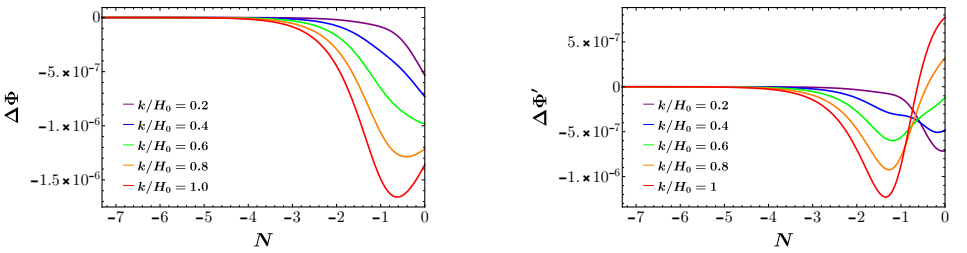

Fig. 2. Evolution of $\Delta\Phi$(left panel) and $\Delta\Phi'$(right panel) as a function of N for different values of k.

where δq is the scaled interaction function given by

$$\delta q = \frac{\delta Q}{H^3 M_{Pl}^2}. \tag{20}$$

Here we see that the evolution of perturbed quantities in the interacting dark sector models shows significant differences for $z < 20$, especially at lower length scale (larger values of k). This trend is consistent with the evolution of scaled interaction function δq.

5. Conclusion

In this work, we consider an interacting dark sector model. We demand that the energy-momentum of individual components of dark sector is conserved, but that of the individual components is not. This model is implemented through a field theory action where dark energy and dark matter are represented by classical scalar fields. This field theory description can be derived from a $f(\tilde{R}, c\tilde{h}i)$ by means of a conformal transformation and field redefinition. We show that there is a one-to-one mapping between the classical field theory description of the dark energy – dark matter interaction and the fluid description of the interacting dark sector. This mapping exist *only* for a unique interaction term $Q_\nu^{(\mathrm{F})}$. We then classified the popular interacting dark sector models found in literature based on whether or not this mapping is applicable to those models.

We then look at the evolution of first-order scalar perturbations in the interacting dark sector in the redshift range of $0 \leq z \leq 1500$. We consider an inverse power-law dark energy scalar field potential and a linear interaction function. To detect the potential signatures of dark energy - dark matter interaction from cosmological observations, we focus on three cosmological phenomena and related perturbed quantities: (i) structure formation (δ_m) (ii) weak gravitational lensing ($\Phi + \Psi$)(iii) integrated Sachs Wolfe effect ($\Phi' + \Psi'$). We see that the density perturbation δ_m grows at a faster rate in the interacting scenario, especially at the smaller length scales. The effect of the interaction becomes significant for redshift $z < 20$. This is consistent with the evolution of perturbed interaction function δq. We see a similar

trend in the case of Φ and Φ', which indicates that the future observations of weak gravitational lensing and integrated Sachs Wolfe effect can be used to distinguish between the interacting and non-interacting models of dark sector.

In this work we present a summary of recent studies on the effects of elastic self interactions in the evolution of Warm Dark Matter models (WDM), focusing on structure formation and the evolution of cosmological perturbations. We pay special attention to a particular class of sterile neutrino WDM known as νMSM and provide examples for the case of vector field self interactions. We calculate the effects of assuming self interacting dark matter in X-Ray astrophysical observations, in the formation of fermionic DM halos in (quasi) equilibrium states and in the evolution of DM perturbations in the early universe, assuming particle masses between $\mathcal{O}(1-100)$ keV. In the latter topic, we perform simulations using a modification to the public Boltzmann solver CLASS and compare our results with observations. We find self interactions to be an interesting addition to WDM models, which can alleviate tensions both present in standard CDM cosmology and regarding WDM itself, as well as provide an interesting avenue for DM halo formation.

Keywords: Dark Matter, Self Interactions, Cosmology

1. Introduction

Several observations at large and small scales, such as the distribution of large-scale structure, CMB anisotropies and the internal structure of DM halos has lead to a standard model of cosmology: ΛCDM.[1,2] DM in this model is assumed to be "Cold": a distribution of colissionless, non relativistic particles with negligible velocity dispersion, which forms structure in a "bottom-up" fashion. However, recent observations have challenged this paradigm[3]; namely, the so called missing satellites problem[4–6]; the too big to fail problem[7]; and the core-cusp problem,[3,8,9] among others. While these by no means rule out the standard model, it has sparked interest in the community in other families of DM models.

In one of these families of models, known as Warm Dark Matter (WDM),[10–12] the DM particles are produced while relativistic, but become non relativistic before the energy budget of the universe is dominated by matter. These particles would have a significant amount of velocity dispersion today, which causes a significant reduction of small scale structure population and an alleviation to some of the tensions we mentioned above. While traditionally these models were also expected to aid the *core-cusp* problem, it was shown[13] that the particle mass requirement for this to happen was inconsistent with existing bounds, in what was known as the "catch-22" problem in WDM. However, in recent years it has been shown that WDM halos with a core-halo distribution can exist[14] (and are indeed stable[15]) as end results of the process of violent relaxation, which fit observations from both Milky Way and dwarf galaxies. While these collisionless relaxation processes are thought to result in the formation and thermalization of these halos,[16,17] it has been argued in[18] that the process of Self Interactions can contribute to this end.

A particularly interesting particle candidate that can belong in the family of WDM models can be found in νMSM (Neutrino Minimal Standard model)[12,19] which assumes a light sterile neutrino to be the sole DM component, produced out of equilibrium via neutrino oscillations in the plasma, and requiring only a minimal extension to the Standard Model Lagrangian. Several observations heavily constrain the parameter space of this model, such as X-Ray constraints from astrophysical objects,[20–22] structure formation constraints,[23,24] production bounds[25]), among others. In recent years, Lyman-α observations have been particularly important, almost entirely ruling out the non-thermal production of WDM sterile neutrinos.[24,26] These tight constraints may be alleviated by performing simple extensions to this model: in particular, we focus here on the inclusion of DM Self Interactions, in what we name Self Interacting Warm Dark Matter (SIWDM).[27] As we will summarize in this work, these may not only contribute in the aforementioned challenges, but also allow us to potentially address tensions in ΛCDM previously unaccounted by WDM models alone.

2. Self Interactions and WDM

The addition of DM Self Interactions is a well studied problem, with many realizations mostly based on CDM models.[28,29] Its main assumption is the existence of non gravitational interaction terms between DM particles through a Standard Model or a Dark mediator. Typically, in the realm of structure formation the interactions considered are elastic, and therefore do not change the number or identity of particles. We focus here on interaction channels of these kinds in WDM and characterize their possible effects across cosmological history.

Self Interactions have been invoked in N-body simulations of structure formation, where it has been realized that the inclusion of these interactions can "flatten"

the inner cores of dwarf galaxies (as indicated by observations) via a process of thermalization in the inner regions of these halos.[30,31] Thus, a combined model of WDM with the addition of Self Interactions may overcome both structure formation ("missing satellites" and "too big to fail") as well as inner halo dynamics ("core-cusp") challenges at the same time, preserving the benefits of both WDM and Self Interacting models. While there can be many particle physics models that reflect these interactions, we focus here instead on maintaining a certain model independence: some examples of particular model realizations can be found in the literature.[32–35]

Since the first introduction of Self Interactions in WDM,[36] it was realized that a combined model could provide interesting modifications in their dynamics. Indeed, Self Interactions do not only have an effect during structure formation, but also in perturbation evolution[37,38] and DM production.[12,39] This last point was studied in the past in the context of νMSM and, in particular, as mentioned in reference,[40] the phenomenon of mediator decay can significantly relax the parameter space of the model. There it was considered the case of a WDM model with vector field interactions, previously suggested in the literature to provide interesting consequences for DM halos.[41] These studies focus on WDM core-halo distributions,[14] known in the literature as RAR profiles, extended it via a Self Interacting model and calculated its potential effects on νMSM bounds coming from X-Ray observations. Interestingly, although bounds of the same order of magnitude as previous studies (that use N-body simulation-borne DM distributions) were obtained when considering observations of the MW galactic center, it was shown that these core-halo distributions are only compatible with νMSM bounds with the inclusion of additional production channels, such as Self Interactions. We present these results here in figure 1, where we plot the parameter space for νMSM, together with the bounds obtained from X-Ray observations of the MW Galactic Center.

While it was shown in reference[40] that the DM distribution of these halos is not affected by Self Interactions, it is an interesting open question if the formation of these systems may be affected by the inclusion of DM scattering. Indeed, these profiles are constructed assuming (General Relativistic) thermal equilibrium between DM particles. While coarse-grained equilibrium can be achieved by a collisionaless fluid, as was shown in previous works,[14,17,42] Self Interactions can thermalize the inner regions of these systems[30] and, potentially, lead to the formation of a fermionic core.

3. SIWDM and Linear Cosmology

Self Interactions have already been found to have significant effects in the evolution of linear cosmological perturbations.[36–38] In particular, the effects of these interactions can be realized in the power spectrum and, in the realm of WDM, it

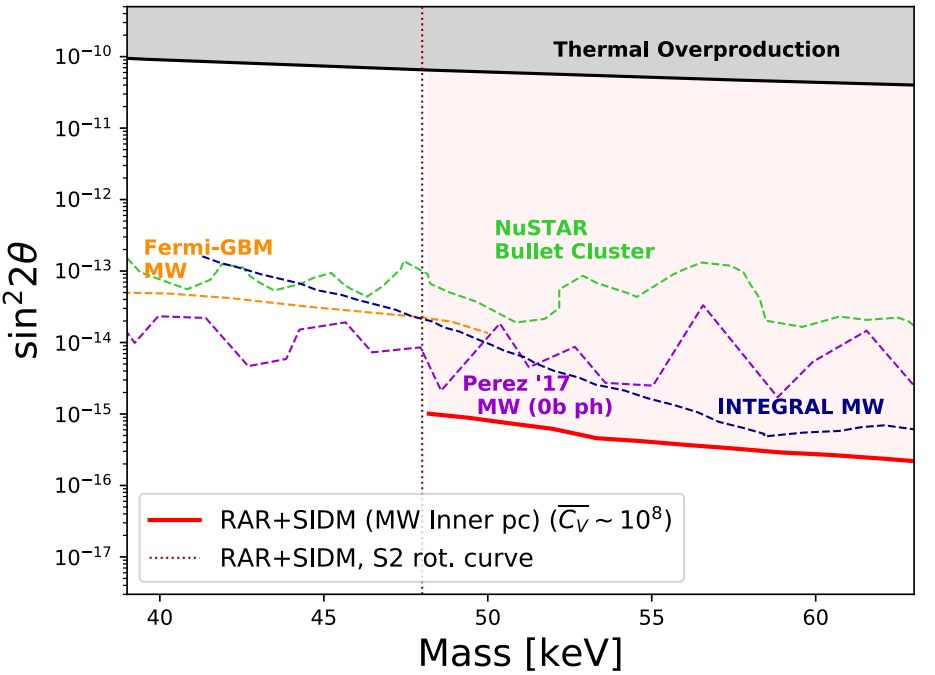

Fig. 1. Sterile neutrino parameter space limits obtained for MW GC observations using RAR+SIDM profiles (continuous red line), when assuming DM production due to self interactions and interaction strength according to Bullet Cluster constraints. The light Red shaded region above the continuous red line corresponds to RAR+SIDM limits given by X-ray bounds (i.e. indirect detection analysis), while the vertical shaded region below 48 keV labels the smallest DM mass compatible with S-cluster stars' rotation curve data that can provide a BH alternative. The upper shaded region corresponds to production mechanism bounds, while other dotted lines refer to several X-ray bounds corresponding to different observations/DM profiles.[20] Reproduced from reference.[40]

can lead to interesting scenarios such as non relativistic self decoupling (a.k.a. late kinetic decoupling). Particularly, the first challenge consists in implementing correctly a collision term in the first order Boltzmann equation for massive species.[43] While many implementations involve performing fluid approximations for the DM component,[44,45] it was realized that this approach is inaccurate in the case of light relics, such as SM interacting neutrinos.[43,46] Based on this realization, some of us obtained a reduced, kernel-based form for the Boltzmann collision term,[27] based on an ansatz for the interaction amplitude that encompasses most tree-level massive mediator models in an exact way. We refer the reader to reference[27] for a full expression of these terms.

The system of equations derived in[27] allows us to study the evolution of DM perturbations under the Relaxation Time Approximation (RTA),[47] shown to be very precise for the case of massive mediator interactions.[46] We can express the Legendre

expansion of the first order Boltzmann equation in the synchronous gauge as

$$\begin{aligned}
\dot{F}_0(k, E_q, \tau) &\simeq -\frac{qk}{E_q} F_1(k, E_q, \tau) + \frac{\dot{h}}{6} \frac{\partial f_0}{\partial \ln q} \\
\dot{F}_1(k, E_q, \tau) &\simeq \frac{qk}{3E_q} F_0(k, E_q, \tau) - \frac{2qk}{3E_q} F_2(k, E_q, \tau) \\
\dot{F}_2(k, E_q, \tau) &\simeq \frac{qk}{5E_q} \Big[2F_1(k, E_q, \tau) - 3F_3(k, E_q, \tau) \Big] - \frac{\partial f_0}{\partial \ln q} \left[\frac{1}{15} \dot{h} + \frac{2}{5} \dot{\eta} \right] - a \frac{F_2(k, E_q, \tau)}{\tau_{rel}} \\
\dot{F}_l(k, E_q, \tau) &\simeq \frac{qk}{(2l+1)E_q} \Big[l F_{(l-1)}(k, E_q, \tau) - (l+1) F_{(l+1)}(k, E_q, \tau) \Big] \\
&\quad - a \frac{F_l(k, E_q, \tau)}{\tau_{rel}} \quad l \geq 3,
\end{aligned} \tag{1}$$

where $f(\vec{k}, \vec{q}, \tau) = F(\vec{k}, \vec{q}, \tau) + f_0(q, \tau)$ is the DM distribution, $F(\vec{k}, \vec{q}, \tau)$ is the first order perturbation and we have defined the Legendre moments and the gravitational potentials h, η as in reference.[48] The collision rate $\Gamma(\tau)$ is defined as

$$\tau_{rel}^{-1} = \frac{g_i^3}{32(2\pi)^3} \frac{\int dE_q \, dE_l \, ds \, f_{eq}(E_q, \tau) \, f_{eq}(E_l, \tau) \, \chi(s)}{\int dE_q \, q \, E_q \, f_{eq}(E_q, \tau)} \ , \tag{2}$$

where this expression is defined according to the notation in references.[18,27] In the same references particular expressions for the collision kernel χ for various interaction models can be found.

These equations involve the background DM distribution f_0. While in the standard approach, this function remains in a relativistic form reminiscent of WDM, a few circumstances can alter this assumption. In particular, if the Self Interactions maintain the DM fluid in kinetic equilibrium all the way until the fluid becomes non relativistic, the background at that moment will switch into a non relativistic form, constituting the scenario known as Non Relativistic Self Decoupling. The consequences of this scenario were explored by some of us in reference.[18] There, it was found that, if one imposes continuity of the limiting expressions for the energy density, the non relativistic distribution function becomes

$$f_0(T < m) \sim 4.534 \mathcal{C}_{\rm NR} \exp\left[-1.075 q^2 / T_{0,\rm R}^2 \right] \ , \tag{3}$$

where $\mathcal{C}_{\rm NR}, T_{0,\rm R}$ are the normalization and temperature of the species in the relativistic limit.

4. SIWDM Cosmology: Simulations and Observation

In reference[18] some of us developed a numerical implementation of these Self Interacting WDM models using a modified CLASS code, a publicly available Boltzmann solver.[49] This modification is available at the following link github.com/yunis121/siwdm-class. We show there a few examples of the resulting power spectra for the Self Interacting models in figure 2.

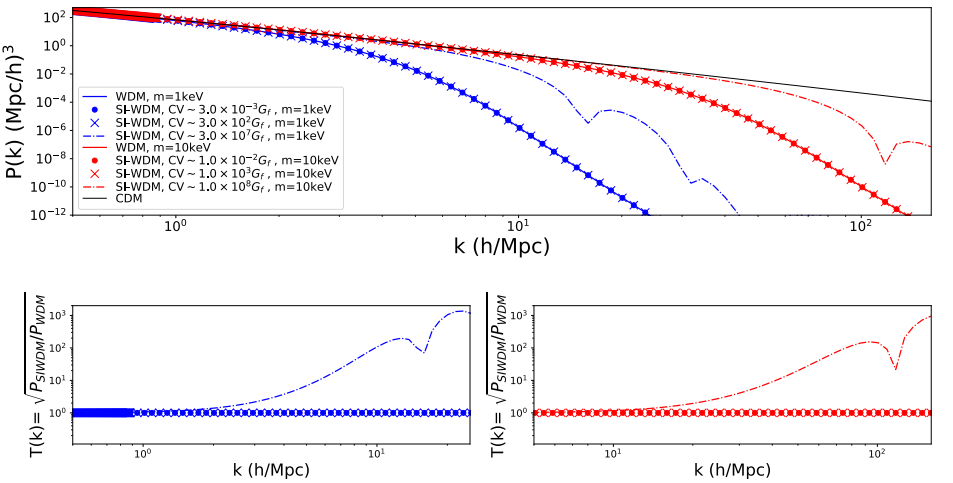

Fig. 2. Power Spectrum (*top panel*) and Transfer Functions with respect to standard WDM (*bottom panels*) for a vector field SI-WDM model, simulated using a modification to CLASS. We assume the relaxation time approximation (1), and consider two values of the DM particle mass: 1 and 10 keV. Also plotted are the power spectra of a CDM model and of WDM models with DM mass of 1 and 10 keV. All WDM and SI-WDM models consider a nonresonant production scenario (Dodelson-Widrow mechanism,[50]) with $T \sim (4/11)^{1/3} T_\gamma$. Reproduced from reference[18]

There, we see some of the particular features of the models. We see that the inclusion of Self Interactions, while modifying slightly the high k behavior of the power spectra, remain small elsewhere in the power spectrum for all models that do not undergo Non Relativistic Self Decoupling. However, for models with Non Relativistic Self Decoupling, the resulting power spectra may differ significantly from its relativistic counterpart. Indeed, we find that in this regime the models are "colder" (i. e. as if they correspond to a higher particle mass), and show even at smaller k values a distinctive oscillatory pattern. This indeed has the effect of increasing the amount of small structure formed for these models.

Most of the tensions inherent to νMSM WDM models come from structure formation, namely MW satellite counts and Lyman-α observations. These are related to the fact that the preferred parameter ranges may underproduce small structure and almost rule out the available parameter space. So, the inclusion of Self Interactions can significantly relax the existing bounds on this family of models.

Reference[18] provides an evaluation of the predictions of these models for the number of MW satellites[23] as well for the observations of the Lyman-α forest. We have found that a maximally interacting model (as allowed by the observations of the Bullet Cluster[41]) can readmit a significant portion of the νMSM parameter space, and we illustrate this in figure 3.

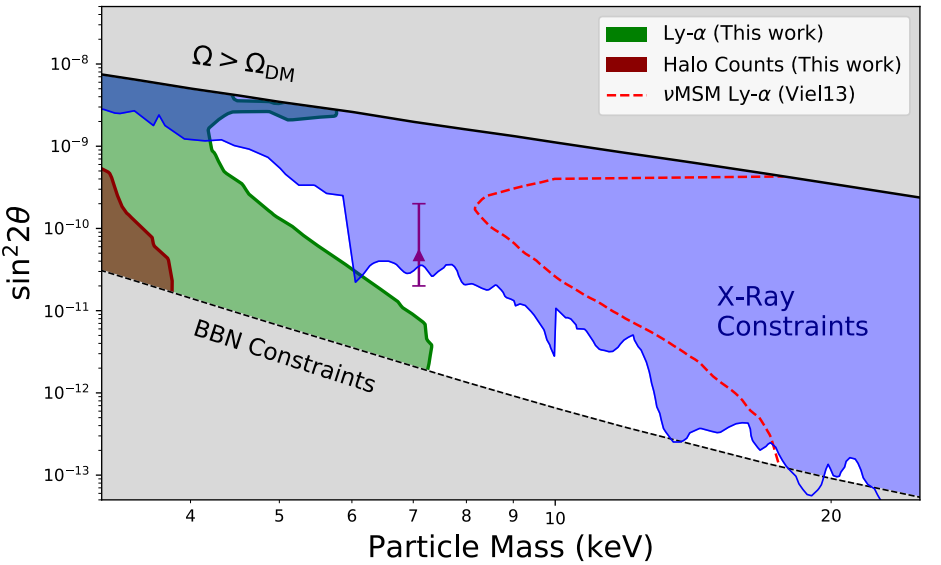

Fig. 3. Parameter space constraints for νMSM, where MW satellite halo counts and Lyman-α forest bounds are analyzed under a self interacting model as outlined above. We consider a self interacting model under a vector field mediator, with its interaction constant given by $\sigma/m \sim 0.144 C_v^2/m^3 = 0.1\text{cm}^2/g$, the upper limit given by Bullet Cluster constraints.[41] For comparison, we plot the Lyman-alpha bounds for the non interacting case for a comparable analysis, according to the results in.[26] We also plot other bounds to the νMSM parameter space for informative purposes.[12,21–23,25] Also for informative purposes, we plot a model compatible with a tentative 3.5 keV DM signal as a purple triangle[51–53] for informative purposes. Reproduced from reference[18]

5. Conclusions

We have studied in detail the evolution of Warm Dark Matter in the presence of Self Interactions. With the aim of contributing to a detailed study of this subject from both a cosmological and astrophysical perspective we provide here an overview of the results obtained so far.

Reference[40] presents and exploration of the consequences of considering WDM core halo RAR distributions[14] in the parameter space of sterile neutrino WDM. There it is suggested that the inclusion of Self Interactions can at the same time relax the WDM sterile neutrino parameter space via additional production channels, readmit RAR core-halo distributions into these models and assist with relaxation and thermalization of these systems.

Reference[27] provides a theoretical framework for the treatment of cosmological perturbations in WDM that allows to quantify the effects of these extended models in the cosmological perturbations. There, we developed a kernel-based expression for the collision terms based on an ansatz for the interaction amplitude, as well as

considered a few approximations to the resulting Boltzmann hierarchies such as the Relaxation Time Approximation. Reference[18] presents a numerical application to these models in CLASS and a comparison of the resulting spectra with MW subhalo and Lyman-α observables, both in the standard decoupling scenario as well as in the non relativistic case.

We have reached conclusions that indicate the Self Interacting models may provide an interesting extension of the sterile neutrino WDM models. In the future, we hope to contribute further in the development of a more accurate treatment of these Self Interactions at a Cosmological level, as well as complementary models for early universe histories and, possibly, a deeper insight into the formation of these core-halo models. While further research is needed if this model is to be considered a viable alternative to standard DM approaches, we believe the work summarized here may be an important stepping stone in the study of these extensions.

Interaction energy between a charged medium and its electromagnetic field as a dark matter candidate

Mayeul Arminjon

In the scalar theory of gravitation with a preferred reference frame, a consistent formulation of electrodynamics in the presence of gravitation needs to introduce an additional energy tensor: the interaction energy tensor. This energy is gravitationally active and might contribute to the dark matter, because it has an exotic character and it is not localized inside matter. In order to check if that energy might form representative dark halos, one has to model the interstellar radiation field in a galaxy as a complete electromagnetic field obeying the Maxwell equations. A model has been built for this purpose, based on assuming axial symmetry and on recent results about axisymmetric Maxwell fields. Its predictions for the variation of the spectral energy density inside our Galaxy are relatively close to those of a recent radiation transfer model, except on the symmetry axis of the Galaxy, where the present model predicts extremely high values of the energy density.

Keywords: Dark matter; interstellar radiation field; Maxwell equations; Milky Way.

1. Introduction

Our initial motivation for the present work was independent of the problem of dark matter. It was to develop a consistent electrodynamics in an alternative theory of gravity: "the scalar ether theory", or SET. This is a preferred-frame theory based on a scalar field only,[1,2] that reduces to special relativity (SR) when the gravitational field vanishes. In general relativity (GR), the modification of the equations of electrodynamics in the presence of a gravitational field consists simply in rewriting the equations that are valid in SR, by using the "comma goes to semicolon" rule: $_{,\nu} \rightarrow {}_{;\nu}$, i.e.: partial derivatives are replaced by covariant derivatives based on the metric connection. (See Ref. 3 for an interesting discussion.) In particular, the dynamical equation for the energy(-momentum-stress) tensor $\boldsymbol{T}$ that is valid in SR is: $T^{\lambda\nu}_{\ \ ,\nu} = 0$. Using the rule mentioned above, that equation is modified to: $T^{\lambda\nu}_{\ \ ;\nu} = 0$, which is indeed the dynamical equation in GR and in many of its extensions or modifications. However, in the general situation, the latter equation is not equivalent to the dynamical equation of SET,[1] hence the foregoing rule cannot be used in SET.

Therefore, in that alternative theory, a different and less obvious path has to be taken for the purpose of adaptating classical electrodynamics in the presence of a gravitational field. It turns out that this leads to introduce an exotic form of energy,

and that this new form is a possible candidate for dark matter. In this conference paper, we quickly follow that path. We then summarize the Maxwell model of the interstellar radiation field, that we built to prepare the test of this candidate.

2. Necessity of an interaction tensor in SET

In SET, we assume classically that the electromagnetic field tensor $\boldsymbol{F}$ derives from a 4-potential A_μ:

$$F_{\mu\nu} := A_{\nu,\mu} - A_{\mu,\nu} = A_{\nu;\mu} - A_{\mu;\nu}. \tag{1}$$

This is (locally) equivalent to assuming that (i) $\boldsymbol{F}$ is antisymmetric ($F_{\mu\nu} = -F_{\nu\mu}$) and (ii) the first group of the Maxwell equations is satisfied:

$$F_{\lambda\mu\,,\nu} + F_{\mu\nu,\lambda} + F_{\nu\lambda,\mu} \equiv F_{\lambda\mu\,;\nu} + F_{\mu\nu;\lambda} + F_{\nu\lambda;\mu} = 0. \tag{2}$$

(The first equality in (2) is indeed an identity due to the antisymmetry of the field tensor and to the symmetry of the metric connection.) Therefore, in SET, the first group of the Maxwell equations is left unchanged. In a first version of electrodynamics in the presence of a gravitational field in SET, the second group of the Maxwell equations was got by applying the dynamical equation of SET to a charged medium in the presence of the Lorentz force, assuming that the following holds for the energy tensors, as is the case in SR and still in GR:

$$\text{(A) Total energy tensor } \boldsymbol{T} = \boldsymbol{T}_{\text{charged medium}} + \boldsymbol{T}_{\text{field}}. \tag{3}$$

(The total energy tensor $\boldsymbol{T}$ is the source of the gravitational field — more precisely, in SET, that source is the component T^{00} in the preferred reference frame of the theory; see Ref. 1 for details.) The additivity (3) leads to a form of Maxwell's second group of equations in SET.[4] But that form of Maxwell's second group in SET predicts charge production/destruction at untenable rates, therefore it has to be *discarded*.[5] The additivity assumption (3) is contingent and may be abandoned. This means introducing an "interaction" energy tensor $\boldsymbol{T}_{\text{inter}}$, such that

$$\boldsymbol{T} = \boldsymbol{T}_{\text{charged medium}} + \boldsymbol{T}_{\text{field}} \underline{+\boldsymbol{T}_{\text{inter}}}\,. \tag{4}$$

One then has to constrain the form of $\boldsymbol{T}_{\text{inter}}$ and to derive equations for it.

3. Form of the interaction tensor

In SR, the additivity (3) of the energy tensors does apply, thus $\boldsymbol{T}_{\text{inter}} = \boldsymbol{0}$. In SET we may impose that $\boldsymbol{T}_{\text{inter}}$ should be Lorentz-invariant in the situation of SR, i.e. when the metric $\boldsymbol{\gamma}$ is Minkowski's metric $\boldsymbol{\gamma}^0$ ($\gamma^0_{\mu\nu} = \eta_{\mu\nu}$ in Cartesian coordinates). This is true if and, one can prove,[6] *only if* we have:

$$T_{\text{inter}\ \mu\nu} = p\,\gamma^0_{\mu\nu} \qquad \text{(situation of SR)}, \tag{5}$$

with some scalar field p. This is equivalent to:

$$T^{\mu}_{\text{inter}\ \ \nu} = p\,\delta^\mu_\nu \qquad \text{(situation of SR)}. \tag{6}$$

The definition

$$T^{\mu}_{\text{inter}\ \ \nu} := p\,\delta^{\mu}_{\nu}, \qquad \text{or} \quad (T_{\text{inter}})_{\mu\nu} := p\,\gamma_{\mu\nu}, \tag{7}$$

thus got in a Minkowski spacetime, is in fact generally-covariant. Hence, we adopt (7) for the general case. With a general metric $\boldsymbol{\gamma}$, the tensor (7) is still pointwise Lorentz-invariant — in the sense that we have $(T_{\text{inter}})_{\mu\nu}(X) = p(X)\,\eta_{\mu\nu}$ in any coordinates that are Cartesian at a given event X, and this form remains invariant after any coordinate transformation that is Lorentz at X, i.e., such that the matrix $\left(\frac{\partial x'^{\mu}}{\partial x^{\nu}}(X)\right)$ belongs to the Lorentz group.

4. SET electrodynamics with the interaction tensor

With the additivity assumption (3) of the energy tensors, i.e., $\boldsymbol{T}_{\text{inter}} = \mathbf{0}$, the system of equations of electrodynamics of SET is closed, but violates charge conservation. With the interaction energy tensor (7) we have just one unknown more: the scalar field p. So we need just one scalar equation more. It turns out to be consistent to add *charge conservation* as the new scalar equation.[7] Then the system of equations of electrodynamics of SET is again closed, and now it satisfies charge conservation.

Based on that closed system, equations were derived that *determine the field p in a given general electromagnetic (EM) field $(\mathbf{E}, \mathbf{B})$ and in a given weak gravitational field with Newtonian potential U*:[7] the scalar field p (or more exactly, its first approximation p_1) obeys an advection equation:

$$\partial_T\, p_1 + u^j \partial_j\, p_1 = S. \tag{8}$$

That equation has given source S and given characteristic curves, the latter being the integral curves $\mathcal{C}(T_0, \mathbf{x}_0)$ of the spatial vector field $\mathbf{u}$ in Eq. (8). Here, "given" means that the source field S, as also the vector field $\mathbf{u}$ and hence the characteristic curves $\mathcal{C}(T_0, \mathbf{x}_0)$, do not depend on the unknown field p_1. It follows that p_1 can be obtained by integrating the source field S along those curves.[7]

The "medium" defined by the corresponding interaction energy tensor field $\boldsymbol{T}_{\text{inter}} = p\boldsymbol{\gamma}$ can be counted as "dark matter", for

- it is not localized inside (usual) matter: indeed, the equations for the field p_1 show that its source S is, in general, non-zero as soon as there is a general EM field: $\mathbf{E} \neq 0,\ \mathbf{B} \neq 0,\ \mathbf{E}.\mathbf{B} \neq 0$, and a variable gravitational field with $\partial_T U \neq 0$, where the time derivative $\partial_T U$ of the Newtonian potential is taken in the preferred frame;[7]
- it is gravitationally active, since, from its definition (4), it contributes to the source of the gravitational field in SET, that is the component T^{00} in the preferred frame;
- it is "exotic", i.e., it is not usual matter — as shown by the form (7) of its energy tensor, which is very different from the possible energy tensors of any fluid, solid, or EM field. The fact that it is Lorentz-invariant means

that no velocity can be defined for that medium. The energy tensor (7) depends only on one scalar field (p), hence no equation of state is needed.

The foregoing considerations are at the classical level, hence do not tell if the "matter" with the energy tensor (7) is made of quantum particles.

5. Maxwell model of the ISRF

In order to check if the interaction energy E_{inter} might be distributed in the form of dark halos and contribute significantly to the dark matter distribution, we have to compute the field p for a model of a galaxy. This needs that we have a model of the Interstellar Radiation Field in a galaxy (ISRF) that provides that field as a solution of the Maxwell equations. However, the existing models of the ISRF (e.g. Refs. 8–13) focus on the radiation transfer (mainly via absorption, reemission or scattering by dust particles). They follow the paths of light rays or photons. To the best of our knowledge, no previous model of the ISRF did consider the full EM field with its six interacting components subjected to the Maxwell equations. Therefore, we had to build a model entirely from scratch, which involved both theoretical and numerical difficulties.[17]

5.1. *Maxwell model of the ISRF: Main assumptions*

i) *Axial symmetry* is a relevant approximation for many galaxies, and is in fact often used in the existing models of the ISRF (see e.g. Refs. 13–16). We adopt cylindrical coordinates (ρ, ϕ, z) whose the z axis is the symmetry axis.

The primary source of the ISRF is made of the stars or other bright astrophysical objects. We want to describe the ISRF as a smoothed-out field at the galactic scale, not the field in the stars or in their neighborhood. Therefore:

ii) we consider the *source-free* Maxwell equations.

We proved the following result:[18]

Theorem. Any time-harmonic axisymmetric source-free Maxwell field is the sum of two simple fields of that same kind:

- **1**) one deriving from a vector potential $\mathbf{A}$ having just $A_z \neq 0$, with A_z a time-harmonic axisymmetric solution of the scalar wave equation;
- **2**) one deduced from a field of the form (**1**) by EM duality, i.e.

$$\mathbf{E}' = c\mathbf{B}, \quad \mathbf{B}' = -\mathbf{E}/c. \tag{9}$$

5.2. *Maxwell model of the ISRF: Form of the model*

We consider an EM field having a finite set of frequencies (ω_j) $(j = 1, ..., N_\omega)$. That EM field is thus the sum of N_ω time-harmonic EM fields. Using the Theorem above,

each of them is generated by potentials A_{jz}, A'_{jz}. The scalar potential A_{jz}, for the field of the form (1) above with frequency ω_j, can be a priori any time-harmonic axisymmetric solution of the scalar wave equation having frequency ω_j.[18] However, in the relevant "totally propagating" case, such a solution can be written explicitly in terms of a spectrum function $S_j = S_j(k) \quad (-K_j \leq k \leq K_j, \quad K_j := \frac{\omega_j}{c})$: $A_{jz} = \psi_{\omega_j\, S_j}$, with[19]

$$\psi_{\omega_j\ S_j}\,(t,\rho,z) := e^{-\,\mathrm{i}\,\omega_j t}\int_{-K_j}^{K_j} J_0\left(\rho\sqrt{K_j^2-k^2}\right)\ e^{\mathrm{i}\,k\,z}\,S_j(k)\ \mathrm{d}\,k, \tag{10}$$

where J_0 is the Bessel function of the first kind and of order 0. The "dual" potential A'_{jz}, for the field of the form (2) above with frequency ω_j, has just the same form (10), with, in the general case, another spectrum function, say S'_j.

5.3. *Maxwell model of the ISRF: Model of a galaxy*

We model an axisymmetric galaxy as a finite set $\{\mathbf{x}_i\}$ of point-like "stars", the azimuthal distribution of which is uniform. That set of points is obtained by pseudo-random generation of their cylindrical coordinates ρ, ϕ, z with specific probability laws, ensuring that[17]

- the distribution of ρ and z is approximately that valid for the star distribution in the galaxy considered (in the numerical application, we took our Galaxy);
- the set $\{\mathbf{x}_i\}$ is approximately invariant under azimuthal rotations of any angle ϕ.

5.4. *Maxwell model of the ISRF: Determining the potentials*

To determine the potentials $A_{j\,z}$ and $A'_{j\,z}$ $(j = 1, ..., N_\omega)$ that generate the model ISRF (Subsect. 5.2), we are fitting to the form (10) a sum of spherical potentials emanating from the "stars" at points $\mathbf{x}_i$, thus determining the unknown spectrum functions S_j and S'_j.[17] For the purpose of this fitting, every point-like "star" is indeed assumed to contribute spherical scalar waves $\psi_{\mathbf{x}_i\,\omega_j}$ having the same frequencies ω_j as has the model ISRF, and whose emission center is the spatial position $\mathbf{x}_i$ of the star:

$$\psi_{\mathbf{x}_i\,\omega_j}\ (t,\mathbf{x}) := \psi_{\omega_j}\ (t,\mathbf{x}-\mathbf{x}_i) = \frac{e^{\mathrm{i}(K_j\,r_i-\omega_j t)}}{K_j\,r_i}. \tag{11}$$

Here $r_i := |\mathbf{x}-\mathbf{x}_i|$, $K_j := \frac{\omega_j}{c}$, and the function

$$\psi_{\omega_j}\ (t,\mathbf{x}) = \frac{e^{\mathrm{i}(K_j\,r-\omega_j t)}}{K_j\,r}, \qquad r := |\mathbf{x}| \tag{12}$$

is (up to an amplitude factor) the unique time-harmonic solution of the scalar wave equation, with frequency ω_j, that has spherical symmetry around $\mathbf{x} = \mathbf{0}$ and that

is an outgoing wave. Spherical symmetry is assumed in order to ensure that all of the directions starting from the star are equivalent, of course. Of course also, the uniqueness of the solution (12) means the uniqueness of the solution translated from $\mathbf{x} = \mathbf{0}$ to $\mathbf{x} = \mathbf{x}_i$: the function $\psi_{\mathbf{x}_i\,\omega_j}$ given by Eq. (11). This implies that we cannot define different contributions of the "star" at $\mathbf{x}_i$ to the $A_{j\,z}$ potential and to the "dual" potential $A'_{j\,z}$, other than through multiplying $\psi_{\mathbf{x}_i\,\omega_j}$ by two different amplitude factors — for which there is no apparent reason. Therefore, we actually must assume that $A_{j\,z} = A'_{j\,z}$, thus $S_j = S'_j$, and our fitting problem writes

$$\sum_{i=1}^{i_{\max}} \psi_{\mathbf{x}_i\,\omega_j} \cong \psi_{\omega_j\ S_j} \quad \text{on } G \qquad (j = 1, ..., N_\omega). \tag{13}$$

Here the symbol $\cong$ indicates that the equality is in the sense of the least-squares, the two sides being evaluated on some spatio-temporal grid G. The unknown spectrum function S_j is defined (approximately) by its values $S_{nj} := S_j(k_{nj})$ at a regular discretization $k_{nj} = -K_j + n\frac{2K_j}{N}$ $(n = 0, ..., N)$ of the integration interval $[-K_j, +K_j]$ for k in the integral (10).[17] With this discretization, (13) becomes the explicit least-squares system

$$\sum_{i=1}^{i_{\max}} \psi_{\mathbf{x}_i\,\omega_j} \cong \sum_{n=0}^{N} f_{nj}\, S_{nj} \quad \text{on } G \qquad (j = 1, ..., N_\omega), \tag{14}$$

with $f_{nj}(t, \rho, z) = \exp(-\,\mathrm{i}\,\omega_j t)\, g_{nj}(\rho, z)$ a specific time-harmonic function.[20] The complex numbers S_{nj} $(n = 0, ..., N;\ j = 1, ..., N_\omega)$ are the solved-for parameters. Note that (14) defines N_ω fitting problems. Previously, a unique "grouped fitting" was done: solving the least-squares system obtained by summing on the frequency index j on both sides of (14).[17] The "separate fitting" (14) is more precise — and also less time-consuming, since actually the common harmonic time dependence can be removed from both sides of (14), thus eliminating the time variable, and hence considering only a spatial grid G' instead of a spatio-temporal grid G.[20] The computer time is indeed an important point to be considered, because a precision better than quadruple must be implemented.[17]

5.5. *Application to the spatial variation of the spectral energy density in the Galaxy*

Because we consider an EM field with a finite frequency spectrum (ω_j) $(j = 1, ..., N_\omega)$, each among its six components has the following form:

$$F^{(q)}(t, \mathbf{x}) = \mathcal{R}e\left(\sum_{j=1}^{N_\omega} C_j^{(q)}(\mathbf{x}) e^{-\,\mathrm{i}\,\omega_j t}\right) \qquad (q = 1, ..., 6). \tag{15}$$

It follows that the time-averaged volumic energy density of the field is given by:[21]

$$\overline{U}(\mathbf{x}) := \overline{\frac{\delta W}{\delta V}}(\mathbf{x}) = \sum_{j=1}^{N_\omega} u_j(\mathbf{x}), \qquad u_j(\mathbf{x}) := \frac{1}{4}\sum_{q=1}^{6} \alpha_q \left| C_j^{(q)}(\mathbf{x}) \right|^2, \tag{16}$$

where $\alpha_q = \epsilon_0$ for an electric field component, whereas $\alpha_q = \epsilon_0 c^2$ for a magnetic field component (here ϵ_0 is the vacuum permittivity, with $\epsilon_0 = 1/(4\pi \times 9 \times 10^9)$ in SI units). Thus, the spectral energy density (SED) has a discrete form.

Specializing to the present axisymmetric model, we thus have $C_j^{(q)} = C_j^{(q)}(\rho, z)$ and $u_j = u_j(\rho, z)$. The potentials $A_{jz} = A'_{jz} = \psi_{\omega_j S_j}$ are determined by the spectrum functions S_j in Eq. (10), which are given in the numerical model by the values $S_{nj} := S_j(k_{nj})$, that are the output of the fitting. These potentials generate the EM field, hence the $C_j^{(q)}(\rho, z)$ coefficients in Eq. (15) are expressed uniquely in terms of the S_{nj} 's.[21] However, in the least-squares problem (14), the scalar radiations emitted by every point-like "star" are taken to be exactly $\psi_{\mathbf{x}_i\, \omega_j}$. Clearly, we may multiply the l.h.s. of (14) by some number $\xi_j > 0$, thus obtaining now new values $S'_{nj} = \xi_j S_{nj}$ $(n = 0, ..., N)$ as the solution of (14). We determine the numbers $\xi_j > 0$ so that the SED measured at our local position $\mathbf{x}_{\rm loc}$ in the Galaxy coincides with the calculated values $u_j(\mathbf{x}_{\rm loc})$. This allows us then to make predictions: in particular, ones of the spatial variation of the SED in the Galaxy, which we may compare with the predictions of the existing models of the ISRF. Figures 1–2 show this comparison for the four positions in the Galaxy for which the predicted SED is shown in Ref. 13. The predictions of the two models are quite reasonably close, although the SED predicted by the present model has rather marked oscillations as function of the wavelength. Note that the different wavelengths are fully uncoupled due to the "separate fitting" defined by the N_ω least-square problems (14).

A surprising prediction of this model is that for the values of the maximum of the energy density,

$$u_{j\max} = \mathrm{Max}\{u_j(\rho_m, z_p);\ m = 1, ..., N_\rho,\ p = 1, ..., N_z\}, \tag{17}$$

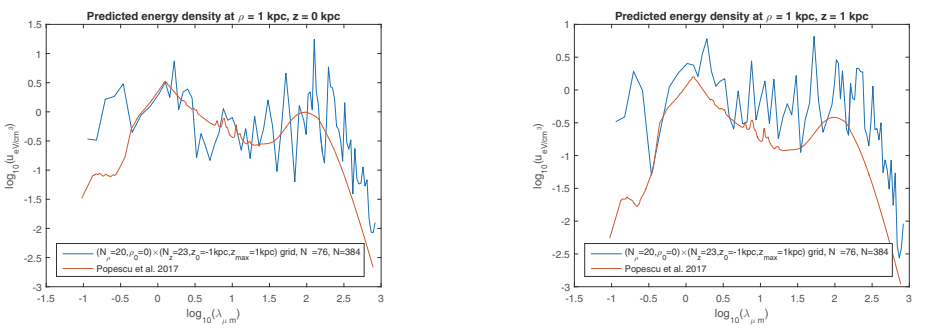

Fig. 1. SEDs at ($\rho = 1\,$kpc, $z = 0$) and at ($\rho = 1\,$kpc, $z = 1\,$kpc).

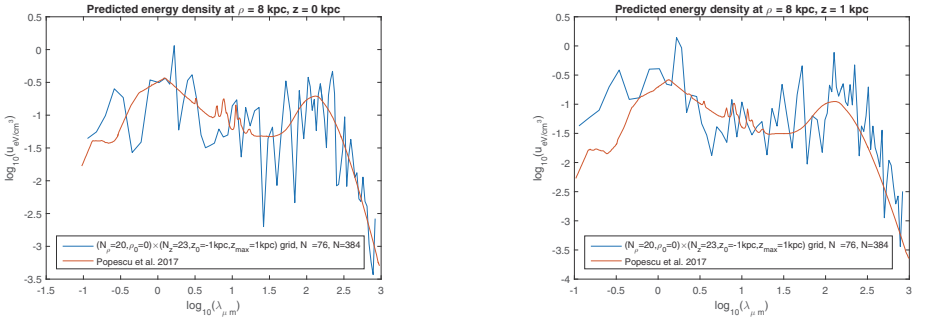

Fig. 2. SEDs at ($\rho = 8\,\mathrm{kpc}$, $z = 0$) and at ($\rho = 8\,\mathrm{kpc}$, $z = 1\,\mathrm{kpc}$).

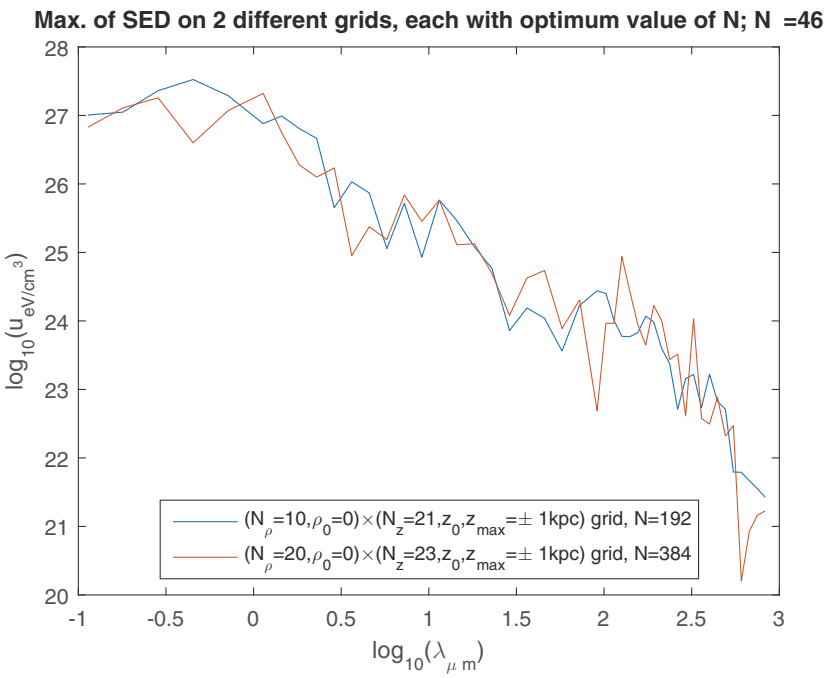

Fig. 3. Maximum of energy density; comparison between two spatial grids.

found for the different spatial grids ($N_\rho \times N_z$) investigated, all having ρ varying regularly from $\rho_0 = 0$ to $\rho_{\max} \simeq 10\,\mathrm{kpc}$ and z varying regularly from $z_0 = 0$ or $z_0 = -z_{\max}$ to $z_{\max} \leq 1\,\mathrm{kpc}$. Figure 3 compares the curves $u_{j\max} = f(\lambda_j)$ found with two spatial grids. It is seen that the two curves are quite close to one another, and both show extremely high levels of $u_{j\max}$, from $10^{27}\mathrm{eV/cm}^3$ to $10^{21}\mathrm{eV/cm}^3$. This is confirmed by a rather detailed investigation of the effects of the settings of the calculation (the spatial grid, and also the fineness of the frequency mesh: N_ω,

and that of the discretization: N).[20] The values of the maximum of u_j are always found on the axis of the Galaxy ($\rho = 0$), moreover the level of u_j decreases very rapidly when one departs from the axis.[20] This prediction of the model may be described as a kind of self-focusing effect of the ISRF in an axisymmetric galaxy.

6. Conclusion

In the "scalar ether theory" of gravity (SET), a consistent electrodynamics in a gravitational field needs the introduction of an additional energy tensor: $\boldsymbol{T}_{\text{inter}}$, with $T^{\mu}_{\text{inter}\ \ \nu} := p\,\delta^{\mu}_{\nu}$. Thus, this energy tensor was not designed to build missing mass. However, it turns out that the corresponding "medium" could contribute to dark matter, for it is not localized inside matter, it is gravitationally active, and it is "exotic". Moreover, the scalar field p, that determines $\boldsymbol{T}_{\text{inter}}$, can be in principle calculated from the data of the EM field and the gravitational field, through explicit equations. This however demands to be able to model the EM field in a galaxy, which is essentially in the form of the interstellar radiation field (ISRF).

Therefore, we built a Maxwell model of the ISRF. This was motivated by the foregoing, but it is also interesting independently of that, as the ISRF is a very important physical characteristic of a galaxy and interacts strongly with the cosmic rays. In any case, this model in itself is totally independent of the theory of gravitation and the assumption about the interaction tensor. It is based on an explicit representation of any time-harmonic axisymmetric source-free Maxwell field through a pair of scalar potentials, and on determining these potentials by fitting contributions emanating from a set of point-like "stars" schematizing a galaxy. The predictions of the model for the variation of the spectral energy distribution in the Galaxy are currently being checked. They are relatively close to the predictions of a recent radiation transfer model — except for the fact that the Maxwell model of the ISRF predicts extremely high values of the energy density on the axis of the Galaxy, that however decrease very rapidly when departing from that axis. We hope to be able in a future work to apply the model to calculate the interaction energy and to check if its distribution resembles a dark halo.

The maximum mass of dilute axion stars

Pierre-Henri Chavanis

Laboratoire de Physique Théorique, Université de Toulouse, CNRS, UPS, France
E-mail: chavanis@irsamc.ups-tlse.fr

We consider the possibility that dark matter is made of bosons in the form of Bose-Einstein condensates. We establish the mass-radius relation $M(R)$ of nonrelativistic self-gravitating Bose-Einstein condensates with repulsive or attractive self-interaction. If the self-interaction is repulsive there exists an equilibrium state for any value of the mass but if the self-interaction is attractive, as in the case of axions, equilibrium states exist only below a maximum mass $M_{\rm max}^{\rm NR}=5.073\, M_P/\sqrt{|\lambda|}$ [P.H. Chavanis, Phys. Rev. D **84**, 043531 (2011)]. This is the maximum mass of dilute axion stars. Above that mass, the star collapses leading to a bosenova, a black hole, a dense axion star or axion drops. We consider how the maximum mass changes with the dimension of space, the presence of a central black hole, a cosmological constant, and relativistic effects. We apply these results to dark matter halos. We establish the general expression of the core mass – halo mass relation $M_c(M_h)$. For a repulsive self-interaction, we show that the core mass M_c is always much below the maximum mass $M_{\rm max}^{\rm GR}$ set by general relativity so the core cannot collapse towards a black hole. For an attractive self-interaction, we show that the core mass M_c can reach in principle the maximum mass $M_{\rm max}^{\rm NR}$ in sufficiently large dark matter halos, leading to core collapse, and we discuss if this situation can happen in practice.

Keywords: Self-gravitating Bose-Einstein condensates; axion stars; maximum mass

1. Introduction

The concept of boson stars was introduced by Kaup[1] and Ruffini and Bonazzola[2] in the 1960s. They considered the $T=0$ limit in which bosons form Bose-Einstein condensates (BECs). In that case, all the bosons are in the same quantum state described by a unique complex wave function $\varphi(x^\mu)$ satisfying the Klein-Gordon-Einstein (KGE) equations. Boson stars can be regarded as macroscopic quantum states that are only prevented from collapsing gravitationally by the Heisenberg uncertainty principle. Kaup[1] and Ruffini and Bonazzola[2] showed that equilibrium states can exist only below a maximum mass $M_{\rm max}^{\rm GR}=0.633M_P^2/m$, where $M_P=(\hbar c/G)^{1/2}$ is the Planck mass, set by general relativity. Above that mass, boson stars are expected to collapse and form a black hole. These results are remarkably similar to those obtained for neutron stars which also display a maximum mass $M_{\rm max}^{\rm GR}=0.384\, M_P^3/m^2$ as found by Oppenheimer and Volkoff.[3] However, there also exist crucial differences between boson and fermion stars. In particular, boson stars are stopped from collapsing by the Heisenberg uncertainty principle while gravitational collapse in fermion stars is avoided by the Pauli exclusion principle. This difference is reflected in the scaling with m of the maximum mass of stable configurations. The maximum mass of boson stars scales as $M_{\rm max}^{\rm GR}\sim M_P^2/m$ instead

of $M_{\rm max}^{\rm GR} \sim M_P^3/m^2$ for fermions. They differ by a factor $m/M_P \ll 1$. This leads to the concept of "mini-boson stars" or "mini-soliton stars" with extremely high densities.

Colpi *et al.*[4] considered the case of bosons stars with a repulsive $\frac{\lambda}{4\hbar c}|\varphi|^4$ ($\lambda > 0$) self-interaction and found that the resulting configurations differ markedly from the noninteracting case. In the Thomas-Fermi (TF) limit, the maximum mass set by general relativity is $M_{\rm max}^{\rm GR} = 0.06\sqrt{\lambda} M_P^3/m^2$ (see Refs.[4,5]). For $\lambda \sim 1$ it exhibits the same scaling as the maximum mass of fermion stars. This leads to much bigger structures than in the noninteracting case, making them much more astrophysically interesting. They are called "massive boson stars". In a sense, the repulsive self-interaction for bosons plays a role similar to the quantum pressure arising from the Pauli exclusion principle for fermions.

The case of bosons with an attractive $\frac{\lambda}{4\hbar c}|\varphi|^4$ ($\lambda < 0$) self-interaction, like the QCD axion with a mass $m \sim 10^{-4}\,{\rm eV}/c^2$ and a negative self-interaction constant $\lambda \sim -7.39 \times 10^{-49}$, was considered by Kolb and Tkachev[6] in a cosmological context. In the early Universe, self-gravity can be neglected. Because of the attractive self-interaction, axions can form miniclusters of mass $M_{\rm axiton} \sim 10^{-12}\,M_\odot$ and size $R_{\rm axiton} \sim 10^9\,{\rm m}$ called axitons. Tkachev[7] took self-gravity into account and considered the possibility to form axion stars by Jeans instability. However, he assumed a repulsive self-interaction ($\lambda > 0$). When the self-interaction between bosons is attractive, there exists a maximum mass $M_{\rm max}^{\rm NR} = 5.073\,M_P/\sqrt{|\lambda|}$ which was first identified by Chavanis.[8] This is the maximum mass of dilute axion stars. This is a purely nonrelativistic result, contrary to the maximum mass of boson and fermion stars discussed above which is due to general relativity. For QCD axion stars, one finds $M_{\rm max}^{\rm NR} = 6.46 \times 10^{-14}\,M_\odot$ and a corresponding radius $(R_{99}^*) = 227\,{\rm km}$ which are of the order of the mass and size of asteroids. This leads to the notion of "axteroids". For $M > M_{\rm max}^{\rm NR}$ there is no equilibrium state and the axion star collapses.[9] This leads to a bosenova[10] or a black hole[11,12] if we take special or general relativity into account, or to the formation of a dense axion star[13] if we take into account higher order terms in the expansion of the self-interaction potential, e.g., a repulsive $|\phi|^6$ self-interaction[14,15] that can stabilize the star against gravitational collapse.[a] The axion star can also fragment into several stable pieces (axion "drops") of mass $M' < M_{\rm max}$, thereby preventing its complete collapse.[19,20]

If bosons are ultralight,[21] with a mass $m \sim 10^{-22}\,{\rm eV/c^2}$, they can form compact objects of galactic size.[b] Therefore, ultralight axions have been invoked in models

[a] Visinelli *et al.*[16] and Eby *et al.*[17] argue that relativistic effects are crucial on the branch of dense axion stars while self-gravity is negligible. As a result, dense axion stars correspond to "pseudobreathers" or "oscillons" which are described by the sine-Gordon equation. For a real scalar field (SF), these objects are known to be unstable and to decay via emission of relativistic axions on a timescale much shorter than any cosmological timescale. This conclusion is, however, contested by Braaten and Zhang.[18]

[b] More massive bosons with a mass $10^{-22}\,{\rm eV/c^2} \leq m \leq 10^{-3}\,{\rm eV/c^2}$ can also form compact objects of galactic size provided that they are self-interacting (with $\lambda \leq 10^{-15}$).[22]

of dark matter (DM) halos. Boson stars or BECDM halos can be formed from a dissipationless relaxation process called gravitational cooling[23] or violent relaxation.[24] By this process, large DM halos acquire a "core-halo" structure with a quantum core (soliton) in its ground state surrounded an extended halo which results from the quantum interferences of the excited states. This "core-halo" structure has been evidenced in numerical simulations of the Schrödinger-Poisson equations.[25–33] The quantum core may solve the core-cusp problem of the cold dark matter (CDM) model and the halo (similar to an isothermal of NFW profile) accounts for the flat rotation curves of the galaxies. A general expression of the core mass-halo mass relation $M_c(M_h)$ in BECDM halos with no, repulsive or attractive self-interaction has been obtained in Refs.[22,34–36]. For an attractive self-interaction, and in sufficiently large DM halos, the core mass can overcome the maximum mass $M_{\rm max}^{\rm NR}$ and collapse. The conditions for this collapse require, however, slightly stronger self-interactions that those commonly allowed by particle physics and cosmology.

In these Proceedings, we review some aspects of our work on self-gravitating BECs. In Sec. 2, we discuss self-gravitating BECs in the nonrelativistic regime described by the Gross-Pitaevskii-Poisson (GPP) equations. In Sec. 3, we discuss the exact mass-radius relation of self-gravitating BECs. In Sec. 4, we obtain an approximation analytical expression of the mass-radius relation of self-gravitating BECs based on a Gaussian ansatz. In Sec. 5, we discuss the maximum mass of dilute axion stars (self-gravitating BECs with attractive self-interaction) and some of its generalizations. In Sec. 6, we apply our results to DM halos and discuss the core mass – halo mass relation and the possibilty or not to have core collapse. In Appendices A and B, we consider general relativistic BECs described by the KGE equations for a complex and a real SF.

2. Self-gravitating BECs

2.1. *Gross-Pitaevskii-Poisson equations*

We assume that DM is made of bosons (like the axion) in the form of BECs at $T = 0$. We use a nonrelativistic approach based on Newtonian gravity. The evolution of the wave function $\psi(\mathbf{r}, t)$ of a self-gravitating BEC is governed by the GPP equations[8,37]

$$i\hbar\frac{\partial\psi}{\partial t} = -\frac{\hbar^2}{2m}\Delta\psi + m\Phi\psi + m\frac{dV}{d|\psi|^2}\psi, \tag{1}$$

$$\Delta\Phi = 4\pi G|\psi|^2, \tag{2}$$

where m is the mass of the bosons, $\Phi(\mathbf{r}, t)$ is the gravitational potential and $\rho(\mathbf{r}, t) = |\psi|^2$ is the mass density of the BEC. The first term in Eq. (1) is the kinetic term which accounts for the Heisenberg uncertainty principle. The second term accounts for the self-gravity of the BEC. The third term takes into account the self-interaction of the bosons. We shall consider a standard $|\psi|^4$ potential of the form

$$V(|\psi|^2) = \frac{2\pi a_s\hbar^2}{m^3}|\psi|^4, \tag{3}$$

where a_s is the scattering length of the bosons. The interaction between the bosons is repulsive when $a_s > 0$ and attractive when $a_s < 0$.

The GPP equations conserve the mass $M = \int |\psi|^2 \, d\mathbf{r}$ and the energy

$$E_{\rm tot} = \frac{\hbar^2}{2m^2} \int |\nabla\psi|^2 \, d\mathbf{r} + \frac{1}{2} \int |\psi|^2 \Phi \, d\mathbf{r} + \int V(|\psi|^2) \, d\mathbf{r}, \tag{4}$$

which is the sum of the kinetic energy Θ, the gravitational energy W, and the internal energy U (i.e. $E_{\rm tot} = \Theta + W + U$).

2.2. *Madelung transformation*

Writing the wave function as

$$\psi(\mathbf{r}, t) = \sqrt{\rho(\mathbf{r}, t)} e^{iS(\mathbf{r},t)/\hbar}, \tag{5}$$

where $\rho(\mathbf{r}, t)$ is the mass density and $S(\mathbf{r}, t)$ is the action, and making the Madelung transformation

$$\rho(\mathbf{r}, t) = |\psi|^2 \qquad \text{and} \qquad \mathbf{u} = \frac{\nabla S}{m}, \tag{6}$$

where $\mathbf{u}(\mathbf{r}, t)$ is the velocity field, the GPP equations (1) and (2) can be written under the form of hydrodynamic equations

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{u}) = 0, \tag{7}$$

$$\frac{\partial S}{\partial t} + \frac{(\nabla S)^2}{2m} + m\Phi + mV'(\rho) + Q = 0, \tag{8}$$

$$\frac{\partial \mathbf{u}}{\partial t} + (\mathbf{u} \cdot \nabla)\mathbf{u} = -\frac{1}{m} \nabla Q - \frac{1}{\rho} \nabla P - \nabla\Phi, \tag{9}$$

$$\Delta\Phi = 4\pi G\rho, \tag{10}$$

where

$$Q = -\frac{\hbar^2}{2m} \frac{\Delta\sqrt{\rho}}{\sqrt{\rho}} = -\frac{\hbar^2}{4m} \left[\frac{\Delta\rho}{\rho} - \frac{1}{2} \frac{(\nabla\rho)^2}{\rho^2} \right] \tag{11}$$

is the quantum potential taking into account the Heisenberg uncertainty principle, and $P(\rho)$ is the pressure arising from the self-interaction of the bosons given by

$$P(\rho) = \rho V'(\rho) - V(\rho). \tag{12}$$

For the standard self-interaction potential (3) we get

$$P = \frac{2\pi a_s \hbar^2}{m^3} \rho^2. \tag{13}$$

This is the equation of state of a polytrope of index $n = 1$. The squared speed of sound is $c_s^2 = P'(\rho) = \rho V''(\rho) = 4\pi a_s \hbar^2 \rho / m^3$. The hydrodynamic equations (7)-(10) are called the quantum Euler-Poisson equations. Equation (7), corresponding to the

imaginary part of the GP equation, is the continuity equation. Equation (8), corresponding to the real part of the GP equation, is the quantum Hamilton-Jacobi (or Bernoulli) equation. Equation (9), obtained by taking the gradient of Eq. (8), is the momentum equation. Equation (10) is the Poisson equation. In the TF limit where the quantum potential can be neglected (formally $\hbar \to 0$ with $4\pi a_s\hbar^2/m^3$ finite), they become equivalent to the classical Euler-Poisson equations for a barotropic gas.

The quantum Euler equations conserve the mass $M = \int \rho\, d\mathbf{r}$ and the energy

$$E_{\rm tot} = \int \rho \frac{\mathbf{u}^2}{2}\, d\mathbf{r} + \frac{1}{m}\int \rho Q\, d\mathbf{r} + \frac{1}{2}\int \rho\Phi\, d\mathbf{r} + \int V(\rho)\, d\mathbf{r}, \tag{14}$$

which is the sum of the classical kinetic energy Θ_c, the quantum kinetic energy Θ_Q, the gravitational energy W, and the internal energy U.

2.3. *Equilibrium states*

The condition of quantum hydrostatic equilibrium, corresponding to a steady state of the quantum Euler equation (9), writes

$$\frac{\rho}{m}\nabla Q + \nabla P + \rho\nabla\Phi = \mathbf{0}. \tag{15}$$

Combining Eq. (15) with the Poisson equation (10), and considering a standard BEC described by the potential (3), we obtain the fundamental differential equation of quantum hydrostatic equilibrium[8,37]

$$\frac{\hbar^2}{2m^2}\Delta\left(\frac{\Delta\sqrt{\rho}}{\sqrt{\rho}}\right) - \frac{4\pi a_s\hbar^2}{m^3}\Delta\rho = 4\pi G\rho. \tag{16}$$

This equation describes the balance between the quantum potential taking into account the Heisenberg uncertainty principle, the pressure due to the self-interaction of the bosons, and the self-gravity. It corresponds to a stationary state of the GPP equations.[8,37] This equation can also be obtained from an energy principle. Indeed, one can show (see Appendix B of Ref.[22]) that an equilibrium state of the GPP equations is an extremum of energy $E_{\rm tot}$ at fixed mass M and that an equilibrium state is dynamically stable if, and only if, it is a minimum of energy at fixed mass.

3. Exact mass-radius relation of self-gravitating BECs

The fundamental equation of hydrostatic equilibrium of self-gravitating BECs, Eq. (16), has been solved numerically (exactly) in Ref.[38] for an arbitrary self-interaction (repulsive or attractive). The nodeless solution describes a compact gravitational quantum object (soliton/BEC) in its ground state. From this solution we have determined the exact mass-radius relation of self-gravitating BECs.

3.1. *Noninteracting bosons*

For noninteracting bosons ($a_s = 0$), the mass-radius relation is given by[38,39]

$$M = 9.95\frac{\hbar^2}{Gm^2R_{99}}, \tag{17}$$

where R_{99} represents the radius containing 99% of the mass (the density profile has not a compact support). The mass decreases as the radius increases. The equilibrium states are all stable.

3.2. *Bosons with a repulsive self-interaction*

For bosons with a repulsive self-interaction ($a_s > 0$), the exact mass-radius relation is represented in Fig. 1. The mass decreases as the radius increases. In the TF limit $M \gg \hbar/\sqrt{Gma_s}$ where the quantum potential can be neglected, the density profile can be obtained analytically since the system is equivalent to a polytrope of index $n = 1$. We get

$$\rho(r) = \frac{\rho_0 R_{\rm TF}}{\pi r}\sin\left(\frac{\pi r}{R_{\rm TF}}\right). \tag{18}$$

The equilibrium states have a unique radius given by[7,8,40–44]

$$R_{\rm TF} = \pi\left(\frac{a_s\hbar^2}{Gm^3}\right)^{1/2}, \tag{19}$$

which is independent of their mass M. This is the minimum radius of self-gravitating BECs with a repulsive self-interaction. In the noninteracting limit $M \ll \hbar/\sqrt{Gma_s}$ and $R \gg R_{\rm TF}$, we recover Eq. (17).

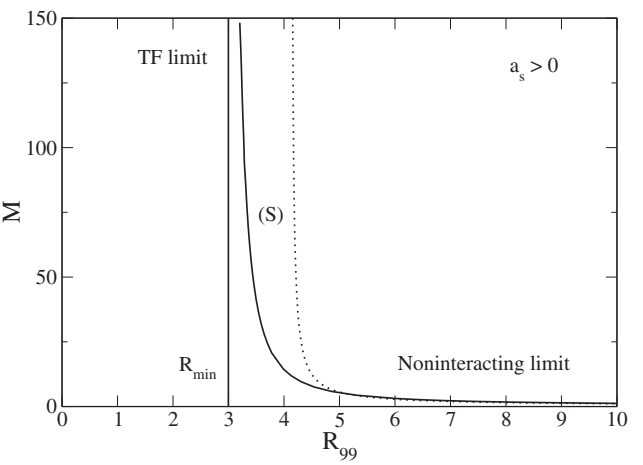

Fig. 1. Mass-radius relation of self-gravitating BECs with $a_s > 0$ (full line: exact;[38] dotted line: Gaussian ansatz[8]). The mass is normalized by $M_a = \hbar/\sqrt{Gma_s}$ and the radius by $R_a = (a_s\hbar^2/Gm^3)^{1/2}$.

3.3. *Bosons with an attractive self-interaction*

For bosons with an attractive self-interaction ($a_s < 0$), the exact mass-radius relation is represented in Fig. 2. It displays a maximum mass[8,38]

$$M_{\rm max}^{\rm NR} = 1.012\,\frac{\hbar}{\sqrt{Gm|a_s|}} \quad \text{at} \quad R_{99}^* = 5.5\,\left(\frac{|a_s|\hbar^2}{Gm^3}\right)^{1/2}. \tag{20}$$

There is no equilibrium state with $M > M_{\rm max}^{\rm NR}$. In that case, the BEC is expected to collapse.[9] The outcome of the collapse (dense axion star, black hole, bosenova, axion drops...) is discussed in Refs.[9–20]. For $M < M_{\rm max}$ there are two possible equilibrium states with the same mass. The equilibrium states with $R > R_{99}^*$ are stable and the equilibrium states with $R < R_{99}^*$ are unstable. This can be shown by using the Poincaré criterion, the Wheeler theorem, or by computing the squared pulsation.[8,9,15,38] In the nongravitational limit $M \ll M_{\rm max}^{\rm NR}$ and $R \ll R_{99}^*$, the mass-radius relation is given by[38]

$$M = 0.275\,\frac{mR_{99}}{|a_s|}. \tag{21}$$

These equilibrium states are unstable. In the noninteracting limit $M \ll M_{\rm max}^{\rm NR}$ and $R \gg R_{99}^*$, we recover Eq. (17). These equilibrium states are stable.

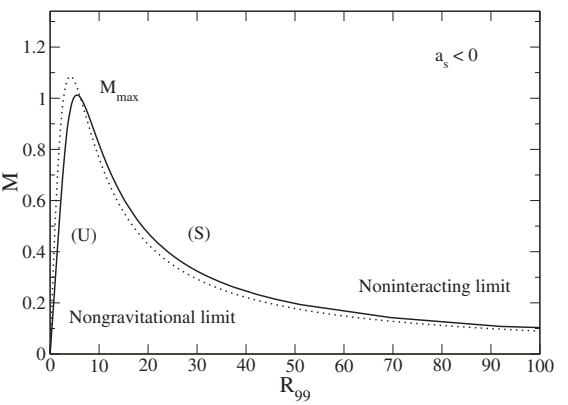

Fig. 2. Mass-radius relation of self-gravitating BECs with $a_s < 0$ (full line: exact;[38] dotted line: Gaussian ansatz[8]). The mass is normalized by $M_a = \hbar/\sqrt{Gm|a_s|}$ and the radius by $R_a = (|a_s|\hbar^2/Gm^3)^{1/2}$.

4. Approximate mass-radius relation of self-gravitating BECs from a Gaussian ansatz

Stable BEC stars correspond to minima of energy $E_{\rm tot}$ at fixed mass M. We can obtain an approximate analytical expression of the mass-radius relation of self-gravitating BECs by making a Gaussian ansatz for the wave function leading to the

density profile[c]

$$\rho(\mathbf{r}) = \frac{M}{R^3}\frac{1}{\pi^{3/2}}e^{-r^2/R^2}. \tag{22}$$

The radius containing 99% of the mass is $R_{99} = 2.38167\,R$. With this ansatz the total energy can be written as[8,37]

$$E_{\rm tot}(R) = \sigma\frac{\hbar^2 M}{m^2R^2} - \nu\frac{GM^2}{R} + \zeta\frac{2\pi a_s\hbar^2M^2}{m^3R^3} \tag{23}$$

with $\sigma = 3/4$, $\nu = 1/\sqrt{2\pi}$ and $\zeta = 1/(2\pi)^{3/2}$. At equilibrium, the condition $E'_{\rm min}(R) = 0$ (extremum of energy) gives the mass-radius relation[8]

$$M = \frac{\frac{2\sigma}{\nu}\frac{\hbar^2}{GmR}}{1-\frac{6\pi\zeta}{\nu}\frac{a_s\hbar^2}{Gm^3R^2}}. \tag{24}$$

A more general expression of the mass-radius relation is given in Eq. (292) of Ref.[37]. The BEC is stable provided that $E''_{\rm tot}(R) > 0$ which corresponds to the requirement that the equilibrium state is a minimum of energy at fixed mass or, equivalently, that the squared pulsation is positive ($\omega^2 > 0$).

For noninteracting bosons ($a_s = 0$), the mass-radius relation from Eq. (24) reduces to

$$M = \frac{2\sigma}{\nu}\frac{\hbar^2}{Gm^2R}. \tag{25}$$

For bosons with a repulsive self-interaction ($a_s > 0$), in the TF limit ($\hbar \to 0$ with fixed $g = 4\pi a_s\hbar^2/m^3$), the mass-radius relation from Eq. (24) reduces to

$$R = \left(\frac{6\pi\zeta}{\nu}\right)^{1/2}\left(\frac{a_s\hbar^2}{Gm^3}\right)^{1/2}. \tag{26}$$

For bosons with an attractive self-interaction ($a_s < 0$), the approximate values of the maximum mass and of the corresponding radius obtained from Eq. (24) are

$$M_{\rm max} = \left(\frac{\sigma^2}{6\pi\zeta\nu}\right)^{1/2}\frac{\hbar}{\sqrt{Gm|a_s|}}, \qquad R_* = \left(\frac{6\pi\zeta}{\nu}\right)^{1/2}\left(\frac{|a_s|\hbar^2}{Gm^3}\right)^{1/2}. \tag{27}$$

In the nongravitational limit, the mass-radius relation from Eq. (24) reduces to

$$M = \frac{\sigma}{3\pi\zeta}\frac{mR}{|a_s|}. \tag{28}$$

5. Generalizations of the maximum mass of axion stars

In this section, we discuss some generalizations of the maximum mass of axion stars.

[c]Here, we restrict ourselves to the equilibrium state, so we just need to make an ansatz for the density profile. See Sec. 8 of Ref.[37] for a more general study.

5.1. *Dimension of space*

The previous results are valid for spherically symmetric systems in $d = 3$ dimensions. It is possible to generalize them in a space of arbitrary dimension d.[46] For an attractive self-interaction, there is a maximum mass when $2 \leq d \leq 4$.[d] Using a Gaussian ansatz we find that

$$M_{\rm max} = (4-d)^{\frac{4-d}{2}}(d-2)^{\frac{d-2}{2}}\frac{\sigma}{\nu^{\frac{d-2}{2}}(d\zeta)^{\frac{4-d}{2}}}\frac{\hbar^{d-2}}{(2\pi|a_s|)^{\frac{4-d}{2}}G^{\frac{d-2}{2}}m^{\frac{3d-8}{2}}}, \tag{29}$$

$$R_* = \left(\frac{d-2}{4-d}\right)^{1/2}\left(\frac{d\zeta}{\nu}\right)^{1/2}\left(\frac{2\pi|a_s|\hbar^2}{Gm^3}\right)^{1/2} \tag{30}$$

with $\sigma = d/4$, $\nu = 1/[\Gamma(d/2)2^{d/2}]$ and $\zeta = 1/(2\pi)^{d/2}$. These equations define $M_{\rm max}(d)$ and $R_*(d)$. In $d = 2$ dimensions, we obtain

$$M_{\rm max} = \frac{\sigma}{2\pi\zeta}\frac{m}{|a_s|}, \qquad R_* = 0, \tag{31}$$

which corresponds to the nongravitational limit ($G = 0$). The prefactor is equal to $1/2$. This expression can be compared with the exact solution $M_{\rm max}^{\rm exact} = 0.465638...\frac{m}{|a_s|}$ associated with the Townes[47] soliton obtained by solving the ordinary GP equation in $d = 2$. In $d = 4$ dimensions, we obtain

$$M_{\rm max} = \frac{2\sigma}{\nu}\frac{\hbar^2}{Gm^2}, \qquad R_* \to +\infty, \tag{32}$$

which corresponds to the noninteracting limit ($a_s = 0$).

5.2. *Central black hole*

The effect of a central black hole, creating an external potential $\Phi_{\rm BH} = -GM_{\rm BH}/r$, on the value of the maximum mass has been investigated in Ref.[48]. It is found that

$$\frac{M_{\rm max}}{M_{\rm max}^{(0)}} = \frac{R_*}{R_*^{(0)}} = -\frac{\mu}{2} + \frac{1}{2}\sqrt{\mu^2+4}, \tag{33}$$

where

$$\mu = \frac{\lambda}{\nu}\frac{M_{\rm BH}}{M_{\rm max}^{(0)}} \tag{34}$$

is the normalized mass of the black hole. These equations define $M_{\rm max}(M_{\rm BH})$ and $R_*(M_{\rm BH})$. In these expressions, $M_{\rm max}^{(0)}$ and $R_*^{(0)}$ denote the maximum mass and the corresponding radius in the absence of a central black hole [see Eq. (27)] and $\lambda = 2/\sqrt{\pi}$.

[d] When $d < 2$ there is a stable equilibrium state for any mass M. When $d > 4$ there is an equilibrium state for any mass M but it is unstable. When $2 \leq d \leq 4$ there is a maximum mass. The equilibrium states with $R < R_*$ are unstable and the equilibrium states with $R > R_*$ are stable. For a repulsive self-interaction there is a minimum mass when $d \geq 4$ given by an expression similar to Eq. (29). The equilibrium states are stable if $R < R_*$ and unstable if $R > R_*$. Noninteracting bosons stars are unstable when $d \geq 4$. These results show that the dimension $d = 3$ of our universe is very special (see also Ref.[45] for fermion stars).

5.3. *Harmonic potential*

The effect of an external harmonic potential $\Phi_{\rm H}=\frac{1}{2}\omega_0^2r^2$ on the value of the maximum mass has been investigated in Ref.[46]. When $\omega_0^2>0$ the potential is confining and can take into account tidal effects from neighboring systems. When $\omega_0^2<0$ the potential mimics a solid rotation $\Omega=\sqrt{-\omega_0^2}$ or the effect of the cosmological constant $\Lambda=-3\omega_0^2$ (dark energy). It is found that

$$M_{\rm max}=\frac{8R_*}{3R_*^2+5},\qquad \omega_0^2=\frac{2(1-R_*^2)}{R_*^4(3R_*^2+5)}, \tag{35}$$

where $M_{\rm max}$ is normalized by $M_{\rm max}^{(0)}$, R_* is normalized by $R_*^{(0)}$, and ω_0 is normalized by the inverse of the dynamical time $t_D=(6\pi\zeta/\nu)(\alpha/\sigma)^{1/2}|a_s|\hbar/(Gm^2)$. These equations define $M_{\rm max}(\omega_0)$ and $R_*(\omega_0)$ in parametric form. In the nongravitational case ($G=0$) and $\omega_0^2>0$ we find that

$$M_{\rm max}^{\rm NG}=\frac{4\sigma}{15\pi\zeta}\left(\frac{2\sigma}{5\alpha}\right)^{1/4}\left(\frac{m\hbar}{\omega_0 a_s^2}\right)^{1/2},\qquad R_*^{\rm NG}=\left(\frac{2\sigma}{5\alpha}\right)^{1/4}\left(\frac{\hbar}{m\omega_0}\right)^{1/2} \tag{36}$$

with $\alpha=3/2$. The prefactor of the maximum mass is equal to 0.6705.... This result can be compared with the exact solution $M_{\rm max}^{\rm NG,exact}=0.573...(m\hbar/\omega_0 a_s^2)^{1/2}$ obtained by numerically solving the ordinary GP equation with a confining harmonic potential.[49]

5.4. *Relativistic corrections*

For boson stars with an attractive self-interaction ($a_s<0$), the relativistic corrections to the maximum mass and the corresponding radius are[46]

$$M_{\rm max}=1.012\,\frac{\hbar}{\sqrt{Gm|a_s|\left(1+2.56\frac{Gm}{|a_s|c^2}\right)}}, \tag{37}$$

$$R_*=5.5\left[\frac{|a_s|\hbar^2\left(1+2.56\frac{Gm}{|a_s|c^2}\right)}{Gm^3}\right]^{1/2}. \tag{38}$$

These formulae interpolate between the exact expressions from Eq. (20) when $|a_s|\to+\infty$ and the exact expression of the maximum mass $M_{\rm max}^{\rm GR}=0.633\,\hbar c/Gm$ set by general relativity when $a_s=0$. We see that relativistic corrections tend to reduce the maximum mass and increase the minimum radius of axion stars with respect to the nonrelativistic limit. Relativistic corrections become important when $|a_s|\sim r_S$, where $r_S=Gm/c^2$ is the effective Schwarzschild radius of the bosons. Relativistic corrections are negligible when $|a_s|\gg r_S$. The transition scale $r_S\sim Gm/c^2$ can be obtained by equating $M_{\rm max}^{\rm NR}\sim\hbar/\sqrt{Gm|a_s|}$ and $M_{\rm max}^{\rm GR}\sim\hbar c/Gm$.

6. Application to DM halos

We now apply the results of the previous sections to DM halos. DM halos typically have a "core-halo" structure made of a quantum core (soliton) in its ground state surrounded by an approximately isothermal atmosphere arising from quantum interferences of excited states.[34,37] This "core-halo" structure results from a process of gravitational cooling[23] and violent relaxation[24] as evidenced in numerical simulations of the Schrödinger-Poisson equations.[25–33] The results of Secs. 2-5 describe the ground state of a self-gravitating BEC,[8] so they apply to the quantum core of DM halos. The "minimum halo" of mass $(M_h)_{\rm min}$ (the smallest halo observed in the universe), which is a purely condensed object without atmosphere, corresponds to the condition $M_c = M_h$. For bigger halos of mass $M_h \geq (M_h)_{\rm min}$, the mass M_c of the quantum core increases with the halo mass M_h. For noninteracting bosons and for bosons with a repulsive self-interaction, we may wonder if the core mass M_c can reach the maximum mass $M_{\rm max}^{\rm GR}$ set by general relativity and collapse towards a supermassive black hole (SMBH). For bosons with an attractive self-interaction, we may wonder if the core mass M_c can reach the maximum mass $M_{\rm max}^{\rm NR}$ of Ref.[8] and collapse. The outcome of the collapse in that case would be a dense axion "star", a black hole, a bosenova, or axion drops.[9–20]

6.1. *Core mass–halo mass relation*

In Refs.[22,34–36], we have derived the core mass–halo mass relation of DM halos (without or with the presence of a central black hole) from a thermodynamic approach. We have obtained a general relation $M_c(M_h)$ valid for noninteracting bosons as well as for bosons with a repusive or an attractive self-interaction (and for fermions not considered here). To obtain this relation, we have proceeded as follows:

(i) Using some approximations, we have calculated the Lynden-Bell entropy $S(M_c)$ as a function of the core mass M_c. The equilibrium core mass is then obtained by maximizing the Lynden-Bell entropy at fixed total mass and total energy. We have shown[34,35] that this maximization problem is equivalent to the "velocity dispersion tracing" relation according to which the velocity dispersion in the core $v_c^2 \sim GM_c/R_c$ is of the same order as the velocity dispersion in the halo $v_h^2 \sim GM_h/r_h$. This relation can be written as

$$v_c \sim v_h \qquad \Rightarrow \qquad \frac{M_c}{R_c} \sim \frac{M_h}{r_h}. \tag{39}$$

(ii) To relate the core radius R_c to the core mass M_c, we have used the analytical expression of the mass-radius relation $M_c(R_c)$ of self-gravitating BECs obtained from the Gaussian ansatz [see Eq. (24)] yielding[8]

$$M_c = \frac{3.76\,\frac{\hbar^2}{Gm^2R_c}}{1-3\frac{a_s\hbar^2}{Gm^3R_c^2}} \tag{40}$$

or, equivalently,

$$R_c = 1.87\,\frac{\hbar^2}{Gm^2M_c}\left(1 \pm \sqrt{1+0.849\,\frac{Gma_sM_c^2}{\hbar^2}}\right). \tag{41}$$

(iii) Assuming that the atmosphere is isothermal, we have shown that the halo mass-radius relation $M_h(r_h)$ is given by[34]

$$M_h = 1.76\,\Sigma_0 r_h^2, \tag{42}$$

where $\Sigma_0 = 141\,M_\odot/\mathrm{pc}^2$ is the universal surface density of DM halos infered from the observations.[e]

Combining Eqs. (39)-(42), we obtain the general expression of the core mass–halo mass relation $M_c(M_h)$ under the form[22,35]

$$M_c = 2.23\,\frac{\hbar\Sigma_0^{1/4}M_h^{1/4}}{G^{1/2}m}\left(1+1.06\,\frac{a_s}{m}\Sigma_0^{1/2}M_h^{1/2}\right)^{1/2}. \tag{43}$$

Writing $M_c = M_h$ for the minimum halo, we obtain

$$(M_h)_{\min}^{3/2} = 4.99\,\frac{\hbar^2\Sigma_0^{1/2}}{Gm^2}\left(1+1.06\,\frac{a_s}{m}\Sigma_0^{1/2}(M_h)_{\min}^{1/2}\right). \tag{44}$$

This equation determines the mass $(M_h)_{\min}$ of the minimum halo as a function of m and a_s. Inversely, for given $(M_h)_{\min}$, it determines a consistency relation between m and a_s (see the universal curve plotted in Fig. 19 of Ref.[35]).

6.2. *Noninteracting bosons*

For noninteracting bosons ($a_s = 0$), the core mass – halo mass relation (43) reduces to[22,35]

$$M_c = 2.23\left(\frac{\hbar^4\Sigma_0 M_h}{G^2m^4}\right)^{1/4}. \tag{45}$$

On the other hand, according to Eq. (44), the mass of the boson is given by $m = 2.23\,(\hbar^4\Sigma_0/G^2(M_h)_{\min}^3)^{1/4} = 2.25\times10^{-22}\,\mathrm{eV}/c^2$ [in the numerical applications we assume that $(M_h)_{\min} = 10^8\,M_\odot$]. For a DM halo of mass $M_h = 10^{12}\,M_\odot$ similar to the one that surrounds our Galaxy, we obtain a core mass $M_c = 10^9\,M_\odot$ and a core radius $R_c = 63.5\,\mathrm{pc}$. The quantum core represents a bulge or a nucleus. It cannot mimic a SMBH because it is too much extended ($Rc^2/GM \sim 10^6 \gg 1$).

The maximum mass and the minimum radius of a noninteracting boson star at $T = 0$ set by general relativity are[1,2]

$$M_{\max}^{\mathrm{GR}} = 0.633\,\frac{\hbar c}{Gm}, \qquad R_{\min}^{\mathrm{GR}} = 9.53\,\frac{GM_{\max}}{c^2}. \tag{46}$$

[e]We note that the halo mass M_h used in our papers[22,34–36] is related to the virial halo mass M_v used in Ref.[26] by $M_h/M_\odot = 6.01\times10^{-6}\,(M_v/M_\odot)^{4/3}$ [see Eq. (146) of Ref.[35]]. As a result, the scalings of the core mass – halo mass relations $M_c(M_h)$ and $M_c(M_v)$ are different.

These scalings can be qualitatively obtained as explained in Appendix B.2 of Ref.[8]. For a boson of mass $m = 2.25 \times 10^{-22}\,\mathrm{eV}/c^2$, we obtain $M_{\rm max}^{\rm GR} = 3.76 \times 10^{11}\,M_\odot$ and $R_{\rm min}^{\rm GR} = 0.171\,\mathrm{pc}$. The maximum mass is much larger than the typical quantum core mass of a DM halo. According to Eq. (45), the mass of the soliton would be equal to the maximum mass ($M_c = M_{\rm max}^{\rm GR}$) in a DM halo of mass $M_h = 6.49 \times 10^{-3} c^4/(G^2\Sigma_0) = 2.01 \times 10^{22}\,M_\odot$ (remarkably, this expression is independent of the boson mass and is of the order of the mass of the Universe[36]). Such a large halo mass is clearly unrealistic (the biggest DM halos observed in the Universe have a mass $M_h \sim 10^{14}\,M_\odot$). Therefore, the soliton present at the center of a noninteracting BECDM halo can never collapse towards a SMBH. This conclusion was first reached in Appendix C of Ref.[36]. Since $M_c \ll M_{\rm max}^{\rm GR}$ in all realistic DM halos, a nonrelativistic approach is justified.

6.3. *Repulsive self-interaction in the TF limit*

For bosons with a repulsive self-interaction in the TF limit, the core mass–halo mass relation (43) reduces to[22,35]

$$M_c = 2.30 \left(\frac{\hbar^2 \Sigma_0 a_s M_h}{G m^3}\right)^{1/2}. \tag{47}$$

On the other hand, according to Eq. (44), the ratio a_s/m^3 is given by $a_s/m^3 = 0.189\,G(M_h)_{\rm min}/\hbar^2\Sigma_0 = 4.35 \times 10^3\,\mathrm{fm}/(\mathrm{eV}/\mathrm{c}^2)^3$. For a DM halo of mass $M_h = 10^{12}\,M_\odot$ similar to the one that surrounds our Galaxy, we obtain a core mass $M_c = 10^{10}\,M_\odot$ and a core radius $R_c = 635\,\mathrm{pc}$. The quantum core represents a bulge or a nucleus. It cannot mimic a SMBH because it is too much extended ($Rc^2/GM \sim 10^6 \gg 1$).

The maximum mass and the minimum radius of a self-interacting boson star at $T = 0$ in the TF limit set by general relativity are[4,5]

$$M_{\rm max}^{\rm GR} = 0.307\,\frac{\hbar c^2 \sqrt{a_s}}{(Gm)^{3/2}}, \qquad R_{\rm min}^{\rm GR} = 6.25\,\frac{G M_{\rm max}}{c^2}. \tag{48}$$

These scalings can be qualitatively obtained as explained in Appendix B.3 of Ref.[8]. For a ratio $a_s/m^3 = 4.35 \times 10^3\,\mathrm{fm}/(\mathrm{eV}/\mathrm{c}^2)^3$, we obtain $M_{\rm max}^{\rm GR} = 2.35 \times 10^{15}\,M_\odot$ and $R_{\rm min}^{\rm GR} = 703\,\mathrm{pc}$. The maximum mass is much larger than the typical quantum core mass of a DM halo. According to Eq. (48), the mass of the soliton would be equal to the maximum mass ($M_c = M_{\rm max}^{\rm GR}$) in a DM halo of mass $M_h = 0.0178 c^4/(G^2\Sigma_0) = 5.51 \times 10^{22}\,M_\odot$ (remarkably, this expression is independent of the ratio a_s/m^3 and is of the order of the mass of the Universe[36]). Such a large halo mass is clearly unrealistic (the biggest DM halos observed in the Universe have a mass $M_h \sim 10^{14}\,M_\odot$). Therefore, the quantum core present at the center of a BECDM halo with repulsive self-interactions can never collapse towards a SMBH. This conclusion was first reached in Appendix C of Ref.[36]. Since $M_c \ll M_{\rm max}^{\rm GR}$ in all realistic DM halos, a nonrelativistic approach is justified.

6.4. *Attractive self-interaction*

For bosons with an attractive self-interaction, the core mass–halo mass relation (see Fig. 3) presents a maximum when the core mass reaches the critical value [see Eq. (27)]

$$(M_c)_{\rm max}=1.085\frac{\hbar}{\sqrt{Gm|a_s|}}=10.9\left(\frac{f^2\hbar}{c^3m^2G}\right)^{1/2} \tag{49}$$

at which it becomes unstable and collapses.[8,9] The collapse of the core, leading to a dense axion "star" (soliton), a black hole, a bosenova or to axion drops,[9–20] occurs in a DM halo of mass[22,35]

$$(M_h)_{\rm max}=0.223\frac{m^2}{a_s^2\Sigma_0}=2255\frac{f^4}{\hbar^2c^6\Sigma_0}. \tag{50}$$

We have expressed these results in terms of the decay constant f (see Appendix B) which is related to the mass m and the scattering length a_s by Eq. (B.13). We note that the maximum halo mass $(M_h)_{\rm max}$ depends only on f while the maximum core mass $(M_c)_{\rm max}$ depends on f and m.

The maximum mass of a self-gravitating BEC made of ultralight axions with mass $m_{\rm th}=2.92\times10^{-22}\,{\rm eV}/c^2$ and scattering length $(a_s)_{\rm th}=-3.18\times10^{-68}\,{\rm fm}$ (corresponding to $f_{\rm th}=1.34\times10^{17}\,{\rm GeV}$ and $\lambda_{\rm th}=-1.18\times10^{-96}$) is $M_{\rm max}=5.10\times10^{10}\,M_\odot$ and the corresponding radius is $R^*_{99}=1.09\,{\rm pc}$. The minimum halo ($(M_h)_{\rm min}=10^8\,M_\odot$, $(r_h)_{\rm min}=1\,{\rm kpc}$) has a mass much smaller than the maximum mass, so it is stable ($(M_h)_{\rm min}<(M_c)_{\rm max}$). The halo mass at which the core mass would become unstable ($M_c=(M_c)_{\rm max}$) and collapse is $(M_h)_{\rm max}=1.01\times10^{20}\,M_\odot$. Since the largest DM halos observed in the Universe have a much smaller mass, of the order of $M_h\sim10^{14}\,M_\odot\ll(M_h)_{\rm max}$, we conclude that the quantum cores of BECDM halos with an attractive self-interaction are always stable ($M_c<(M_c)_{\rm max}$). Furthermore, since $M_h\ll(M_h)_{\rm max}$, the attractive self-interaction is negligible. This corroborates our claims[22,35,36] that the attractive self-interaction of the bosons can be neglected for what concerns the structure of DM halos in the nonlinear regime: Everything happens *as if* the bosons were noninteracting.

Remark: We recall that the theoretical value $f_{\rm th}=1.34\times10^{17}\,{\rm GeV}$ of the decay constant used above comes from the constraints from particle physics and cosmology.[21] It may be interesting to relax these constraints and consider arbitrary values of f. In that case, we find that an attractive self-interaction would be important in realistic DM halos of mass $M_h\leq10^{14}\,M_\odot$, and lead to the collapse of their quantum core when $M_h=(M_h)_{\rm max}$ [corresponding to $M_c=(M_c)_{\rm max}$], if $f<4.22\times10^{15}\,{\rm GeV}$ [the bound corresponds to $(M_h)_{\rm max}=10^{14}\,M_\odot$ in Eq. (50)]. For example, for $f=1.34\times10^{15}\,{\rm GeV}$ and $m=10^{-22}\,{\rm eV}/c^2$, we find that the quantum core of a DM halo of mass $(M_h)_{\rm max}\sim10^{12}\,M_\odot$ reaches its critical mass $(M_c)_{\rm max}\sim10^9\,M_\odot$ [with $R^{99}_*\sim300\,{\rm pc}$] and collapses. The collapse of the quantum

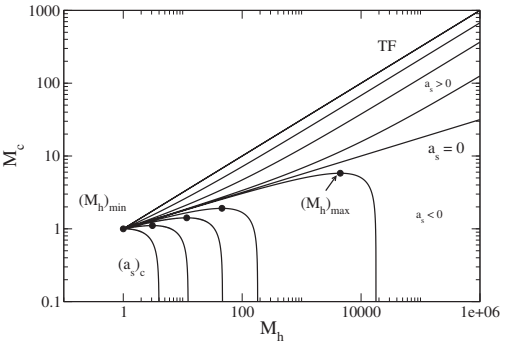

Fig. 3. Core mass M_c as a function of the halo mass M_h for different values of a_s and m such that the minimum halo mass $(M_h)_{\rm min}$ is fixed [see Eq. (44)]. The mass is normalized by $(M_h)_{\rm min}$ (typically $(M_h)_{\rm min} \sim 10^8\, M_\odot$). We have indicated the position of the minimum halo mass $(M_h)_{\rm min}$ (common origin) and the position of the maximum halo mass $(M_h)_{\rm max}$ (bullet) above which the quantum core becomes unstable and collapses (when $a_s < 0$) [see Eqs. (49) and (50)]. We have highlighted the curve corresponding to the noninteracting case $a_s = 0$ [see Eq. (45)] and the curve corresponding to the TF limit $a_s/a_*' \gg 1$ [see Eq. (47)].

core leads to a dense axion "star",[13–15] a bosenova,[10] or axion drops.[19,20f] However, we recall that values of f smaller than $4.22 \times 10^{15}\,$GeV are outside of the range $10^{16}\,{\rm GeV} \leq f \leq 10^{18}\,{\rm GeV}$ predicted by particle physics and cosmology ($10^{16}\,$GeV is the Grand Unified Theory scale and $10^{18}\,$GeV is the Planck scale),[21] so that, according to these constraints, we do not expect the collapse of the core to occur in realistic DM halos of mass $M_h < 10^{14}\, M_\odot$ (as discussed above and in Refs.[22,35,36]).

7. Conclusion

In these Proceedings, we have emphasized the importance of the maximum mass of dilute axion stars (i.e. nonrelativistic self-gravitating BECs with an attractive self-interaction) first identified in Ref.[8]. Above this maximum mass the star collapses leading to a dense axion "star", a black hole, a bosenova, or axion drops.[9–20] We have discussed some applications of these results in relation to DM halos.[22,35,36] Other applications have been discussed in Refs.[50–55].

Appendix A. Relativistic complex scalar field

In this Appendix, we discuss the main properties of a relativistic complex self-interacting SF, establish its hydrodynamic representation, consider the TF approximation, and determine its equation of state $P(\epsilon)$ for an arbitrary self-interaction

[f]It does not lead to a SMBH which would be obtained for much larger values of f (above the reduced Planck mass $10^{18}\,$GeV)[11,12] for which our previous assumptions do not apply.

potential $V(|\varphi|^2)$. For a $|\varphi|^4$ self-interaction, we justify the equation of state introduced by Colpi *et al.*[4] (see also Refs.[56,57]). We also justify the GPP equations (1) and (2) in the nonrelativistic limit.

Appendix A.1. *Klein-Gordon-Einstein equations*

We consider a relativistic complex SF $\varphi(x^\mu) = \varphi(x, y, z, t)$ which is a continuous function of space and time. It can represent the wavefunction of a relativistic BEC.[56,58] The total action of the system, which is the sum of the Einstein-Hilbert action of general relativity + the action of the SF, can be written as

$$S = \int \left(\frac{c^4}{16\pi G} R + \mathcal{L} \right) \sqrt{-g}\, d^4x, \tag{A.1}$$

where R is the Ricci scalar curvature, $\mathcal{L} = \mathcal{L}(\varphi, \varphi^*, \partial_\mu\varphi, \partial_\mu\varphi^*)$ is the Lagrangian density of the SF, and $g = \det(g_{\mu\nu})$ is the determinant of the metric tensor. We consider a canonical Lagrangian density of the form

$$\mathcal{L} = \frac{1}{2} g^{\mu\nu} \partial_\mu\varphi^* \partial_\nu\varphi - V_{\rm tot}(|\varphi|^2), \tag{A.2}$$

where the first term is the kinetic energy and the second term is minus the potential energy. The potential energy can be decomposed into a rest-mass energy term and a self-interaction energy term:

$$V_{\rm tot}(|\varphi|^2) = \frac{m^2c^2}{2\hbar^2}|\varphi|^2 + V(|\varphi|^2). \tag{A.3}$$

The least action principle $\delta S = 0$ with respect to variations $\delta\phi$ (or $\delta\phi^*$), which is equivalent to the Euler-Lagrange equation

$$D_\mu \left[\frac{\partial \mathcal{L}}{\partial(\partial_\mu\varphi)^*} \right] - \frac{\partial \mathcal{L}}{\partial \varphi^*} = 0, \tag{A.4}$$

yields the KG equation

$$\Box\varphi + 2\frac{dV_{\rm tot}}{d|\varphi|^2}\varphi = 0, \tag{A.5}$$

where $\Box = D_\mu\partial^\mu = \frac{1}{\sqrt{-g}}\partial_\mu(\sqrt{-g}\, g^{\mu\nu}\partial_\nu)$ is the d'Alembertian operator. For a free massless SF ($V_{\rm tot} = 0$), the KG equation reduces to $\Box\varphi = 0$.

The least action principle $\delta S = 0$ with respect to variations $\delta g^{\mu\nu}$ yields the Einstein field equations

$$R_{\mu\nu} - \frac{1}{2} g_{\mu\nu} R = \frac{8\pi G}{c^4} T_{\mu\nu}, \tag{A.6}$$

where $R_{\mu\nu}$ is the Ricci tensor and $T_{\mu\nu}$ is the energy-momentum (stress) tensor of the SF given by

$$T^\nu_\mu = \frac{\partial \mathcal{L}}{\partial(\partial_\nu\varphi)}\partial_\mu\varphi + \frac{\partial \mathcal{L}}{\partial(\partial_\nu\varphi^*)}\partial_\mu\varphi^* - g^\nu_\mu \mathcal{L}. \tag{A.7}$$

For the Lagrangian (A.2), we get

$$T_{\mu\nu} = \frac{1}{2}(\partial_\mu\varphi^*\partial_\nu\varphi + \partial_\nu\varphi^*\partial_\mu\varphi) - g_{\mu\nu}\mathcal{L}. \tag{A.8}$$

Equations (A.5) and (A.6) with Eq. (A.8) form the KGE equations. The conservation of the energy-momentum tensor $D_\mu T^{\mu\nu} = 0$ is automatically included in the Einstein equations through the contracted Bianchi identities.

Appendix A.2. *Hydrodynamic representation*

We can write the KG equation (A.5) under the form of hydrodynamic equations by using the de Broglie transformation (see, e.g., Refs.[56,58]). To that purpose, we write the SF as

$$\varphi = \frac{\hbar}{m}\sqrt{\rho}e^{im\theta/\hbar}, \tag{A.9}$$

where ρ is the pseudo rest-mass density[g] and $\theta = S_{\rm tot}/m$ is the action by unit of mass ($\sim$ phase). They satisfy

$$\rho = |\psi|^2 = \frac{m^2}{\hbar^2}|\varphi|^2 \quad \text{and} \quad \theta = \frac{\hbar}{2mi}\ln\left(\frac{\varphi}{\varphi^*}\right). \tag{A.10}$$

Substituting Eq. (A.9) into the Lagrangian density (A.2), we obtain

$$\mathcal{L} = \frac{1}{2}g^{\mu\nu}\rho\partial_\mu\theta\partial_\nu\theta + \frac{\hbar^2}{8m^2\rho}g^{\mu\nu}\partial_\mu\rho\partial_\nu\rho - V_{\rm tot}(\rho) \tag{A.11}$$

with

$$V_{\rm tot}(\rho) = \frac{1}{2}\rho c^2 + V(\rho). \tag{A.12}$$

The Euler-Lagrange equations for θ and ρ, resulting from the least action principle, are

$$D_\mu\left[\frac{\partial\mathcal{L}}{\partial(\partial_\mu\theta)}\right] - \frac{\partial\mathcal{L}}{\partial\theta} = 0, \quad D_\mu\left[\frac{\partial\mathcal{L}}{\partial(\partial_\mu\rho)}\right] - \frac{\partial\mathcal{L}}{\partial\rho} = 0. \tag{A.13}$$

They yield the equations of motion[56,58]

$$D_\mu\left(\rho\partial^\mu\theta\right) = 0, \tag{A.14}$$

$$\frac{1}{2}\partial_\mu\theta\partial^\mu\theta - \frac{\hbar^2}{2m^2}\frac{\Box\sqrt{\rho}}{\sqrt{\rho}} - V'_{\rm tot}(\rho) = 0. \tag{A.15}$$

The same equations are obtained by substituting the de Broglie transformation from Eq. (A.9) into the KG equation (A.5), and separating the real and the imaginary parts. Equation (A.14) can be interpreted as a continuity equation $D_\mu J^\mu = 0$ accounting for the conservation of the charge (or boson number) and Eq. (A.15)

[g]We stress that ρ is *not* the rest-mass density. It is only in the nonrelativistic regime $c \to +\infty$ that ρ coincides with the rest-mass density.

can be interpreted as a quantum relativistic Hamilton-Jacobi (or Bernoulli) equation with a relativistic covariant quantum potential

$$Q_{\rm dB} = \frac{\hbar^2}{2m}\frac{\Box\sqrt{\rho}}{\sqrt{\rho}}. \tag{A.16}$$

Appendix A.3. *TF approximation*

In the classical limit or in TF approximation ($\hbar \to 0$), the Lagrangian from Eq. (A.11) reduces to

$$\mathcal{L} = \frac{1}{2}g^{\mu\nu}\rho\partial_\mu\theta\partial_\nu\theta - V_{\rm tot}(\rho). \tag{A.17}$$

The Euler-Lagrange equations (A.13) yield the equations of motion

$$D_\mu\left(\rho\partial^\mu\theta\right) = 0, \tag{A.18}$$

$$\frac{1}{2}\partial_\mu\theta\partial^\mu\theta - V'_{\rm tot}(\rho) = 0. \tag{A.19}$$

The same equations are obtained by making the TF approximation in Eq. (A.15), i.e., by neglecting the quantum potential. Equation (A.18) can be interpreted as a continuity equation and Eq. (A.19) can be interpreted as a classical relativistic Hamilton-Jacobi (or Bernoulli) equation.

Assuming $V'_{\rm tot} > 0$, and using Eq. (A.19), we introduce the fluid quadrivelocity

$$u_\mu = -\frac{\partial_\mu\theta}{\sqrt{2V'_{\rm tot}(\rho)}}c, \tag{A.20}$$

which satisfies the identity $u_\mu u^\mu = c^2$. The energy-momentum tensor is given in the hydrodynamic representation, by

$$T^\nu_\mu = \frac{\partial\mathcal{L}}{\partial(\partial_\nu\theta)}\partial_\mu\theta + \frac{\partial\mathcal{L}}{\partial(\partial_\nu\rho)}\partial_\mu\rho - g^\nu_\mu\mathcal{L}. \tag{A.21}$$

For the Lagrangian (A.17) we get

$$T_{\mu\nu} = \rho\partial_\mu\theta\partial_\nu\theta - g_{\mu\nu}\mathcal{L}. \tag{A.22}$$

This expression can also be obtained from Eq. (A.8) by using the de Broglie representation (A.9) and making the TF approximation. Using Eq. (A.20), we get

$$T_{\mu\nu} = 2\rho V'_{\rm tot}(\rho)\frac{u_\mu u_\nu}{c^2} - g_{\mu\nu}\mathcal{L}. \tag{A.23}$$

The energy-momentum tensor (A.23) can be written under the perfect fluid form

$$T_{\mu\nu} = (\epsilon + P)\frac{u_\mu u_\nu}{c^2} - Pg_{\mu\nu}, \tag{A.24}$$

where ϵ is the energy density and P is the pressure, provided that we make the identifications

$$P = \mathcal{L}, \qquad \epsilon + P = 2\rho V'_{\rm tot}(\rho). \tag{A.25}$$

Therefore, the Lagrangian plays the role of the pressure of the fluid. Combining Eq. (A.17) with the Bernoulli equation (A.19), we get

$$\mathcal{L} = \rho V'_{\rm tot}(\rho) - V_{\rm tot}(\rho). \tag{A.26}$$

Therefore, according to Eqs. (A.25) and (A.26), the energy density and the pressure derived from the Lagrangian (A.17) are given by[56,59]

$$\epsilon = \rho V'_{\rm tot}(\rho) + V_{\rm tot}(\rho) = \rho c^2 + \rho V'(\rho) + V(\rho), \tag{A.27}$$

$$P = \rho V'_{\rm tot}(\rho) - V_{\rm tot}(\rho) = \rho V'(\rho) - V(\rho), \tag{A.28}$$

where we have used Eq. (A.12) to get the second equalities. Eliminating ρ between Eqs. (A.27) and (A.28), we obtain the equation of state $P(\epsilon)$. On the other hand, Eq. (A.28) can be integrated into[56]

$$V(\rho) = \rho \int \frac{P(\rho)}{\rho^2}\, d\rho. \tag{A.29}$$

Equation (A.28) determines $P(\rho)$ as a function of $V(\rho)$ while Eq. (A.29) determines $V(\rho)$ as a function of $P(\rho)$.

Appendix A.4. *Nonrelativistic limit*

In the weak-field gravity limit of general relativity $\Phi/c^2 \ll 1$, using the simplest form of the Newtonian gauge, the line element is given by

$$ds^2 = c^2\left(1 + 2\frac{\Phi}{c^2}\right)dt^2 - \left(1 - 2\frac{\Phi}{c^2}\right)\delta_{ij}dx^i dx^j, \tag{A.30}$$

where $\Phi(\mathbf{r}, t)$ is the Newtonian potential. Making the Klein transformation (see, e.g., Ref.[58])

$$\varphi(\mathbf{r}, t) = \frac{\hbar}{m} e^{-imc^2 t/\hbar}\psi(\mathbf{r}, t) \tag{A.31}$$

in the KGE equations (A.5) and (A.6), where ψ is the pseudo wave function satisfying $\rho = |\psi|^2$, we obtain after simplification the general relativistic GP equation[58,60]

$$i\hbar c\,\partial^0\psi - \frac{\hbar^2}{2m}\Box\psi + \frac{1}{2}mc^2(g^{00} - 1)\psi + i\frac{\hbar c^2}{2}\Box t\,\psi - m\frac{dV}{d|\psi|^2}\psi = 0, \tag{A.32}$$

coupled to the Einstein equations expressed in terms of ψ. We note that $\Box t$ can be written as $\Box t = -\frac{1}{c}g^{\mu\nu}\Gamma^0_{\mu\nu}$, where $\Gamma^\sigma_{\mu\nu}$ are the Christoffel symbols.[58] Taking the nonrelativistic limit $c \to +\infty$ of these equations with the Newtonian gauge (A.30), we obtain the GPP equations (1) and (2) [see Refs.[58,61,62] for the details of the derivation]. For a complex SF, the potential $V(|\psi|^2)$ which occurs in the GP equation (1) coincides with the potential $V(|\varphi|^2)$ which occurs in the KG equation (A.5) with Eq. (A.3) up to the change of function from Eq. (A.31) leading to

$$|\varphi|^2 = \frac{\hbar^2}{m^2}|\psi|^2. \tag{A.33}$$

Appendix A.5. $|\varphi|^4$ *potential*

We consider a $|\varphi|^4$ (quartic) potential of the form

$$V(|\varphi|^2) = \frac{\lambda}{4\hbar c}|\varphi|^4, \tag{A.34}$$

where λ is the dimensionless self-interaction constant. For nonrelativistic BECs, the potential that occurs in the GP equation (1) is usually written as in Eq. (3). Substituting Eq. (A.33) into Eq. (3), we get

$$V(|\varphi|^2) = \frac{2\pi a_s m}{\hbar^2}|\varphi|^4. \tag{A.35}$$

Comparing Eqs. (A.34) and (A.35), we obtain[9]

$$\frac{\lambda}{8\pi} = \frac{a_s mc}{\hbar} = \frac{a_s}{\lambda_C}, \tag{A.36}$$

where $\lambda_C = \hbar/mc$ is the Compton wavelength of the bosons. For the $|\varphi|^4$ model the KG and GP equations can be written as

$$\Box\varphi + \frac{m^2c^2}{\hbar^2}\varphi + \frac{8\pi a_s m}{\hbar^2}|\varphi|^2\varphi = 0, \tag{A.37}$$

$$i\hbar\frac{\partial\psi}{\partial t} = -\frac{\hbar^2}{2m}\Delta\psi + m\Phi\psi + \frac{4\pi a_s\hbar^2}{m^2}|\psi|^2\psi = 0. \tag{A.38}$$

In terms of the pseudo rest-mass density [see Eqs. (A.9) and (A.10)], the potential (A.35) reads

$$V(\rho) = \frac{2\pi a_s\hbar^2}{m^3}\rho^2. \tag{A.39}$$

Substituting Eq. (A.39) into Eqs. (A.27) and (A.28) we obtain

$$\epsilon = \rho c^2\left(1 + \frac{6\pi a_s\hbar^2}{m^3c^2}\rho\right), \tag{A.40}$$

$$P = \frac{2\pi a_s\hbar^2}{m^3}\rho^2. \tag{A.41}$$

Eliminating ρ between these two equations, we get

$$P = \frac{m^3c^4}{72\pi a_s\hbar^2}\left(\sqrt{1 + \frac{24\pi a_s\hbar^2}{m^3c^4}\epsilon} \mp 1\right)^2. \tag{A.42}$$

This relativistic equation of state $P(\epsilon)$ was introduced by Colpi *et al.*[4] in the context of boson stars. It was studied in detail by Chavanis and Harko[5] in connection with general relativistic BEC stars and by Li *et al.*[63] and Suárez and Chavanis[59] in a BECDM cosmological context. This equation of state reduces to that of an $n = 1$ polytrope [see Eq. (A.41) with $\epsilon \sim \rho c^2$] at low densities $\rho \ll m^3c^2/|a_s|\hbar^2$

(nonrelativistic limit) and to the linear law $P \sim \epsilon/3$ similar to the equation of state of the radiation at high densities (ultrarelativistic limit).

Remark: Sometimes, a $|\varphi|^4$ self-interaction potential is written as

$$V(|\varphi|^2) = \frac{m^2}{2\hbar^4}\lambda_s|\varphi|^4, \tag{A.43}$$

where λ_s is the dimensional self-interaction constant. Comparing Eq. (A.43) with Eqs. (A.34) and (A.35) we get

$$\lambda_s = \frac{4\pi a_s\hbar^2}{m} = \frac{\lambda\hbar^3}{2m^2c}. \tag{A.44}$$

Appendix B. Relativistic real scalar field

In this Appendix, we discuss the main properties of a relativistic real SF, consider the instantonic potential of axions, take the nonrelativistic limit, and justify the GPP equations (1)-(3) with $a_s < 0$.

Appendix B.1. *Klein-Gordon-Einstein equations*

For a real SF described by a canonical Lagrangian, the KGE equations write

$$\Box\varphi + \frac{m^2c^2}{\hbar^2}\varphi + \frac{dV}{d\varphi} = 0, \tag{B.1}$$

$$R_{\mu\nu} - \frac{1}{2}g_{\mu\nu}R = \frac{8\pi G}{c^4}T_{\mu\nu}, \tag{B.2}$$

where the energy-momentum tensor is given by

$$T_{\mu\nu} = \partial_\mu\varphi\partial_\nu\varphi - g_{\mu\nu}\left[\frac{1}{2}g^{\rho\sigma}\partial_\rho\varphi\partial_\sigma\varphi - \frac{m^2c^2}{2\hbar^2}\varphi^2 - V(\varphi)\right]. \tag{B.3}$$

Appendix B.2. *Nonrelativistic limit*

In the nonrelativistic limit $c \to +\infty$ where the SF displays rapid oscillations, the KGE equations can be simplified by averaging over the oscillations. To that purpose, we write

$$\varphi(\mathbf{r},t) = \frac{1}{\sqrt{2}}\frac{\hbar}{m}\left[\psi(\mathbf{r},t)e^{-imc^2t/\hbar} + \psi^*(\mathbf{r},t)e^{imc^2t/\hbar}\right], \tag{B.4}$$

where the complex wave function $\psi(\mathbf{r},t)$ is a slowly varying function of time (the fast oscillations $e^{imc^2t/\hbar}$ of the SF have been factored out). This transformation allows us to separate the fast oscillations of the SF with pulsation $\omega = mc^2/\hbar$ caused by its rest mass from the slow evolution of $\psi(\mathbf{r},t)$. Using the simplest form of the Newtonian gauge [see Eq. (A.30)], substituting Eq. (B.4) into the KGE equations (B.1)-(B.3), averaging over the oscillations and taking the nonrelativistic limit

$c \to +\infty$, we obtain the GPP equations (1) and (2) [see Secs. II and III of Ref.[15] and Appendix A of Ref.[64] for the details of the derivation]. For a real SF, the (effective) potential $V(|\psi|^2)$ that occurs in the GP equation (1) is obtained from the potential $V(\varphi)$ that occurs in the KG equation (B.1) by first substituting Eq. (B.4) into $V(\varphi)$, then averaging over the oscillations. It is different from the potential obtained by directly replacing φ^2 by $(\hbar/m)^2|\psi|^2$ in the potential $V(\varphi)$.

Remark: General relativistic boson stars decribed by a real SF have a naked singularity at the origin and are always unstable.[65h] It is possible to construct regular solutions which are periodic in time[66,67] when $M < M_{\rm max}^{\rm GR} = 0.606\, M_P^2/m$ but, on a long timescale (which can exceed the age of the universe), these "oscillatons" are unstable and disperse to infinity or form a black hole. Their instability is basically due to the fact that the charge (boson number) is not conserved for a real SF. However, in the nonrelativistic limit, particle number conservation is approximately restored and Newtonian boson stars (like axion stars) can be stable (see Sec. 3).

Appendix B.3. *Instantonic potential of axions*

Axions are hypothetical pseudo-Nambu-Goldstone bosons of the Peccei-Quinn phase transition associated with a $U(1)$ symmetry that solves the strong charge parity (CP) problem of quantum chromodynamics (QCD). The axion is a spin-0 particle with a very small mass $m = 10^{-4}\,{\rm eV}/c^2$ and an extremely weak self-interaction (with a decay constant $f = 5.82 \times 10^{10}\,{\rm GeV}$) arising from nonperturbative effects in QCD. Axions have huge occupation numbers so they can be described by a classical relativistic quantum field theory with a real SF $\varphi(\mathbf{r}, t)$ whose evolution is governed by the Klein-Gordon-Einstein (KGE) equations. The instantonic potential of axions is

$$V(\varphi) = \frac{m^2 c f^2}{\hbar^3}\left[1 - \cos\left(\frac{\hbar^{1/2}c^{1/2}\varphi}{f}\right)\right] - \frac{m^2c^2}{2\hbar^2}\varphi^2, \tag{B.5}$$

where m is the mass of the axion and f is the axion decay constant. For this potential, the KG equation (B.1) takes the form

$$\Box\varphi + \frac{m^2 c^{3/2} f}{\hbar^{5/2}} \sin\left(\frac{\hbar^{1/2}c^{1/2}\varphi}{f}\right) = 0. \tag{B.6}$$

This is the general relativistic sine-Gordon equation. Considering the dilute regime $\varphi \ll f/\sqrt{\hbar c}$ (which is valid in particular in the nonrelativistic limit $c \to +\infty$)[i] and expanding the cosine term of Eq. (B.5) in Taylor series, we obtain at leading order the φ^4 potential

$$V(\varphi) = -\frac{m^2c^3}{24 f^2 \hbar}\varphi^4. \tag{B.7}$$

[h] This result is in agreement with the cosmic censorship conjecture which excludes spacetimes with naked singularities.

[i] According to Eq. (B.10), the axion decay constant f scales as $c^{3/2}$.

In that case, the KG equation (B.1) takes the form

$$\Box\varphi + \frac{m^2c^2}{\hbar^2}\varphi - \frac{m^2c^3}{6f^2\hbar}\varphi^3 = 0. \tag{B.8}$$

In the nonrelativistic limit, the effective potential $V(|\psi|^2)$ appearing in the GP equation (1) is given by[14,15]

$$V(|\psi|^2) = \frac{m^2cf^2}{\hbar^3}\left[1 - \frac{\hbar^3 c}{2f^2m^2}|\psi|^2 - J_0\left(\sqrt{\frac{2\hbar^3 c|\psi|^2}{f^2m^2}}\right)\right], \tag{B.9}$$

where J_0 is the Bessel function of zeroth order. If we keep only the first term in the expansion of Eq. (B.9), we obtain the $|\psi|^4$ potential

$$V(|\psi|^2) = -\frac{\hbar^3c^3}{16f^2m^2}|\psi|^4. \tag{B.10}$$

This approximation is valid for dilute axion stars satisfying $|\psi|^2 \ll f^2m^2/\hbar^3c$. We note that $V(|\psi|^2) \equiv \overline{V(\varphi)}$ is different from the expression that one would have naively obtained by directly substituting $\varphi^2 = (\hbar/m)^2|\psi|^2$ into Eq. (B.5). The difference is already apparent in the first term of the expansion of the potential which involves a coefficient $-1/16$ [see Eq. (B.10)] instead of $-1/24$ [see Eq. (B.7)]. They differ by a factor 2/3. This is because φ is a real SF. Therefore, substituting φ (exact) from Eq. (B.4) into $V(\varphi)$, *then* averaging over the oscillations, is different from substituting $\varphi^2 = (\hbar/m)^2|\psi|^2$ (already averaged over the oscillations) into $V(\varphi)$.

In general, a quartic potential is written as

$$V(\varphi) = \frac{\lambda}{4\hbar c}\varphi^4, \tag{B.11}$$

where λ is the dimensionless self-interaction constant. Comparing Eqs. (B.7) and (B.11), we find that

$$\lambda = -\frac{m^2c^4}{6f^2}. \tag{B.12}$$

On the other hand, comparing Eq. (B.10) with Eq. (3), we obtain

$$a_s = -\frac{\hbar c^3 m}{32\pi f^2}. \tag{B.13}$$

Equations (B.12) and (B.13) then yield

$$\frac{\lambda}{8\pi} = \frac{2a_s mc}{3\hbar}. \tag{B.14}$$

We note that the relation between λ and a_s is different for a real SF and for a complex SF (see Appendix A). They differ by a factor 2/3 for the reason indicated previously.

We note that the self-interaction constant λ or the scattering length a_s is negative, so that the φ^4 self-interaction term for axions is *attractive*. This attraction

is responsible for the collapse of dilute axion stars above the maximum mass from Eq. (20).[8,9] The next order φ^6 term in the expansion of the potential (B.5) has been considered in Refs.[14,15] and turns out to be repulsive. This repulsion, that occurs at high densities and which has a relativistic origin, may stop the collapse of dilute axion stars and lead to the formation of dense axion stars[13] (see, however, footnote a concerning their possible instability with respect to relativistic decay).

A dark matter solution for the XENON1T electron excess and the galactic center 511 keV line

Yasaman Farzan

School of Physics, Institute for Research in Fundamental Sciences (IPM)
P.O.Box 19395-5531, Tehran, Iran
E-mail: yasaman@theory.ipm.ac.ir
http://physics.ipm.ac.ir/

The excess of the 511 keV line from the Milky Way galactic bulge, confirmed by the INTEGRAL detector, is a longstanding mystery. The morphology of the line appears to be proportional to the square of the dark matter density, hinting towards a dark matter origin. On the other hand, in 2020, XENON1T has reported an excess of electrons with a recoil energy of $2-4$ keV. We present a model based on a dark matter of a few MeV mass that decays into a pair of pico-charged particles with a lifetime much larger than the age of the Universe. The magnetic field of the galaxy accumulates these relativistic pico-charged particles whose scattering on the electrons can explain the signal reported by XENON1T. The annihilation of the pico-charged particles in the galactic bulge leads to e^-e^+ production and therefore to an excess of the 511 keV line. We review the present observational bounds and the strategies to test the model.

Keywords: Dark matter, pico-charged particles, XENON1T electron excess, 511 keV line, galactic bulge

1. Introduction

Various observations such as galactic rotation curves, structure formation, dynamics of the galaxy clusters, collision of bullet clusters and anisotropies of Cosmic Mircrowave Background (CMB) point towards existence of a new form of matter all over the universe known as Dark Matter (DM). The constituent particles of DM should be either electrically neutral or their electric charge should be much smaller than the electron electric charge. Otherwise, they will emit photons and will not remain dark. The dark matter lifetime should be much longer than the age of the Universe. The observation of bullet clusters constrain the self-interaction of the dark matter particles indicating that they cannot have strong interactions. Last but not least, at the onset of structure formation, the dark matter should be non-relativistic. None of the Standard Model (SM) elementary particles satisfies these conditions. As a result, the observational hints for dark matter opens a window towards new physics beyond the standard model by introducing a new neutral (meta)stable massive particle that can play the role of dark matter.[a]

[a]The primordial blackholes as dark matter candidates have received popularity after observation of gravitational waves by LIGO and VIRGO. We will not however pursue this idea in this letter.

The models for dark matter candidates are quite diverse. Depending on the details of the model, different strategies for dark matter detection have been developed. In a wide class of models known as WIMP, where dark matter has a mass in the wide range of MeV to 100 TeV and it weakly interacts with the Standard Model (SM) particles[b], there are three approaches to dark matter detection: (1) direct dark matter detection, (2) indirect dark matter detection and (3) dark matter production in colliders. No conclusive evidence for dark matter detection has been reported from any of these experiments so far but every now and then, a signal is reported by indirect search experiments which may be interpreted as dark matter. Some of these signals disappear by collecting more data or are eventually proved to be artifacts. There are however signals that pass the test of time but after some period of time simply go out of fashion because the simplistic dark matter models developed to explain them become ruled out by independent observations. However, the dark sector does not need to be simplistic. Indeed, judging from the rich and dazzling structure of the SM, simplicity and minimalism is not the taste of the physics of the elementary particles. Going beyond simplistic dark matter models, it may be possible to resurrect dark matter explanation for the signal.

One example of the signals that has survived the test of time is the 511 keV line observed from galactic center which must come from the positronium (the e^-e^+ atom) decay: $e^- + e^+ \to \gamma + \gamma$. The intensity of the line indicates an excess of e^+ in the galactic center. Although the excess may come from the SM sources such as pulsars but entertaining a DM origin is too tantalizing to dismiss, especially that the morphology of the intensity of the line follows a ρ_{DM}^2 distribution, further pointing towards DM pair annihilation as the origin of the excess. In Ref.[1], it had been shown that dark matter with mass of a few MeV can explain the excess of the 511 keV line observed from the galactic center by pair annihilation into pairs of electron positron with a cross section of $\langle \sigma(\mathrm{DM} + \mathrm{DM} \to e^-e^+)v \rangle \sim O(10^{-38})$ cm^2 . This model implies huge energy pump into the plasma at the era of recombination when the DM density is high, through annihilation into e^-e^+. Such entropy pump can distort the CMB fluctuation pattern. The Planck data therefore rules this solution out.[2] Moreover, this model is disfavored by the lack of observation of the 511 keV line from dwarf galaxies.[3]

Ref.[4] proposes a dark matter model for the 511 keV line from the center of the Milky Way (MW) that can avoid the bounds from CMB and explain the lack of the 511 keV line from satellite dwarf galaxies. In this model, dark matter is composed of a scalar particle, X, with a mass of a few MeV which can be identified with the SLIM particle.[5,6] X decays into a pair of pico-charged particle $(C + \bar{C})$ with a lifetime much longer than the age of Universe: $\Gamma(X \to C + \bar{C})t_0 \ll 1$ in which t_0 is the age of the Universe. The magnetic field of the MW accumulates the C and

[b]Here, by weak interactions, we do not necessarily mean nuclear weak interaction, characterized by the SM W and Z gauge boson exchange.

$\bar{C}$ particles. The $C\bar{C}$ pairs eventually annihilate with each other producing e^-e^+ pairs. At the recombination and during the dark ages, the density of $C\bar{C}$ would be too small to pump energy to the plasma so the CMB bound can be avoided. Moreover, the magnetic field in the dwarf galaxies may be too weak to accumulate $C\bar{C}$ so the lack of the 511 keV line from them can be explained.

Ref.[4] predicted a signal at direct dark matter search experiments with low energy threshold. The relativistic C particles wandering around can impart a recoil energy of a few keV via Coulomb interaction to the electrons. In 2020, XENON1T reported an excess of electrons with recoil energy of 2–4 keV.[7] In Ref.[8], we discussed the parameter space where the model can explain both signals. Refs.[9] have also attempted to explain the XENON1T signal via DM.

This paper is organized as follows. In Sect. 2, we describe the model and the bounds that constrain its parameter space. In Sect. 6, we show how the model can explain the 511 keV line from the galactic bulge. In Sect. 4, we describe how the model can explain the XENON1T data. We show that the XENON1T electron recoil spectrum can also set the strongest upper bound on $f = \Gamma(X \to C\bar{C})t_0$. A summary is given in Sect. 5. In Sect. 5, we also discuss how the model can be tested with further collection of the 511 keV data from satellite galaxies and studying the correlation of the intensity with the magnetic field of the host [dwarf] galaxy. We also discuss the signatures in diffuse gamma ray background from the inflight annihilation of positron. We also comment on the positron flux to be detected by Voyager.

2. The model and its constraints

As mentioned in the introduction, the model is based on a scalar dark matter, X with a mass of a few MeV which decays into a pair of pico-charged particles, $C\bar{C}$. The X particle can be identified with the SLIM particle introduced in Ref.[5]. In the SLIM scenario, the DM is thermally produced via interaction with neutrinos and its abundance is set *a la* freeze-out scenario through lepton number violating annihilation into neutrino or antineutrino pair, $\langle\sigma(X+X \to \nu+\nu)v\rangle = \langle\sigma(X+X \to \bar{\nu}+\bar{\nu})v\rangle \sim pb$. Within the SLIM scenario, the annihilation to neutrino or antineutrino pair takes place via the t-channel exchange of a new Majorana neutrino which has a Yukawa coupling with the SM neutrino and X. A Z_2 symmetry, under which only the new Majorana neutrino and X are odd, guarantees the stability of X which is the lightest among the Z_2 odd particles. The same Z_2 symmetry forbids Yukawa coupling between the leptons, the Higgs and the new Majorana fermions and as a result, neutrinos cannot obtain a Dirac mass at the tree level. The SM neutrinos obtain a Majorana mass at one loop level within the SLIM scenario. The smallness of the neutrino mass is explained, thanks to the loop suppression despite a relatively large Yukawa coupling between, X and neutrinos of order of 10^{-3}. The model is testable by searching for the three body decay of Kaon and pion where along with the charged leptons, these new particles are emitted and

appear as missing energy.[10] Ref.[6] shows how the SLIM scenario can be embedded within a UV complete model. Combining the condition $\langle\sigma(X+X)v\rangle \sim pb$ (to obtain the required DM relic abundance via the freeze-out mechanism) with the one-loop contribution to the neutrino mass to be equal to $\sim \sqrt{\Delta m^2_{atm}}$ sets an upper bound of $\sim$ 10 MeV on the dark matter mass. On the other hand, X, being in thermal equilibrium with neutrinos at the time of the neutrino decoupling, cannot be lighter than a few MeV;[11] otherwise, it will lead to too many extra relativistic degrees of freedom. If X is not the SLIM and its production is not thermal, these lower and upper bounds on its mass can be relaxed.

Taking the pico-charged particles C and $\bar{C}$ to be scalars, the decay $X \to C\bar{C}$ can take place via a soft Z_2 symmetry breaking trilinear term of form $AX\bar{C}C$ with a very small A making X metastable. Let us now discuss how C and $\bar{C}$ acquire their minuscule electric charge. For this purpose, we need a new Abelian gauge symmetry such that the C and $\bar{C}$ are charged under the new $U_X(1)$ gauge symmetry. We denote the new gauge boson with A_μ. The kinetic and mass mixings between A_μ and the SM hypercharge gauge boson B_μ lead to a small electric charge for the C and $\bar{C}$ particles. We follow the notation of Ref.[12] and write

$$-\frac{A_{\mu\nu}A^{\mu\nu}}{4} - \frac{B_{\mu\nu}B^{\mu\nu}}{4} - \frac{\delta}{2}A_{\mu\nu}B^{\mu\nu} - \frac{1}{2}\left(\partial_\mu\sigma + M_1 A_\mu + \epsilon M_1 B_\mu\right)^2 \ , \qquad (1)$$

where $\delta, \epsilon \ll 1$. In the kinetic and mass basis, the three neutral gauge bosons are the SM γ, Z bosons and a new gauge boson A'_μ which we shall call dark photon. To the first approximation in ϵ and δ, the mass of A' is decoupled from m_Z and is equal to M_1. Up to $O(\epsilon^2, \delta^2)$, the coupling between the SM charged fermions, f and A' can be written as the following:

$$q' \bar{f}\gamma^\mu f A'_\mu \qquad \text{where} \qquad q' = e\cos\theta_W(\epsilon - \delta)Q_f, \qquad (2)$$

in which θ_W is the weak (Weinberg) mixing angle. The coupling of $C\bar{C}$ to A' is given by $g_X J^\mu_C A'_\mu$ where J^μ_C is the current of the C particles. Then, the C particle obtains an electric charge of

$$q_C = -g_X \epsilon \cos\theta_W .$$

From Eq. (2), we observe that in the limit $\epsilon \to \delta$, the SM fermions do not couple to A'. In this limit, if A' is lighter than the $C\bar{C}$ pair with a mass of order of a few keV, it will become metastable with a lifetime much greater than the age of the Universe.[4] This means the A' particles produced in the early universe remain as relics today and contribute as a subdominant DM component. In Ref.[8], we do not however consider this limit and allow for a faster decay of A'. As shown in Ref.[8], the $U_X(1)$ symmetry can be identified with the $L_\mu - L_\tau$ symmetry with a gauge coupling of $g_{\tau-\mu}$ which opens up the possibility of fast decay $A' \to \bar{\nu}_\mu\nu_\mu, \bar{\nu}_\tau\nu_\tau$. The decay can relax the bound from supernova cooling, opening up the window $m_{A'} \sim 100$ keV, $q' \sim 10^{-10} - 10^{-9}$ and $g_{\tau-\mu} \sim 10^{-9}$. Such values of coupling are too small to produce A' with significant abundance in the early universe so the bounds on the

extra relativistic degrees of freedom from CMB and BBN can be relaxed. On the other hand, the A' particles produced in the supernova core decay into neutrino and antineutrino pairs in the outer layers of supernova. This process can severely change the supernova evolution. It can even facilitate the shock revival. Thus, in future with better observation of supernovae and more advanced simulations, this part of the parameter range of the model can be tested. For the time being, however, this range of the parameter space is accepted within the uncertainties. The A' particles escaping the core decay into $\nu\bar{\nu}$ pairs so similarly to the standard picture, the binding energy of the star will be emitted in the form of neutrinos to be observed by detectors on the Earth such as Super-Kamiokande.

The C particles produced by the X decay will be relativistic at the production with a velocity far exceeding the escape velocity from the galaxy. They are kept in the galactic disc by the magnetic field. To accumulate the C and $\bar{C}$ particles, their Larmour radius,

$$r_c = (100\text{ pc})\frac{3\times 10^{-11}}{q_C}\frac{m_X}{10\text{ MeV}}\frac{1\ \mu\text{Gauss}}{B}$$

should be smaller than the thickness of the galactic disc. This requirement sets a lower bound on q_C: $q_C > 10^{-11}$, see Refs.[4,8]. The strongest upper bound on q_C in this mass range comes from supernova cooling consideration and is $q_C < 10^{-9}$, see Ref.[13].

As shown in Ref.[14], expanding supernova remnants can pump energy to the charged particles, enhancing their Larmor radius and expelling them from the galactic disc with a rate of $(100\text{ M}yr)^{-1}$ unless there is an efficient mechanism for energy loss for the charged particles. As discussed in Ref.[4], in the limit $\delta \to \epsilon$ where A' is (meta)stable, the relic background of A' can behave as a coolant. That is the C and $\bar{C}$ particles can scatter off the background A', losing energy. As discussed in Ref.[8], in general case $\delta \neq \epsilon$ where there is no A' background, another coolant should be introduced. Following Ref.[8], we denote the coolant with Y and take $10\text{ eV} < m_Y < 10\text{ keV}$, $n_Y|_{local} = (\rho_{DM}|_{local}/\langle\rho_{DM}\rangle)\langle n_Y\rangle$ with a coupling of g_Y to the C particles leading to the scattering cross section of $\sigma_S \sim g_Y^4/(4\pi E_C^2)$. The energy loss at each collision can be written as $\Delta E_C = m_Y v^2 (E_C/m_C)^2$.

The energy of the C particle at the production from $X \to C\bar{C}$ is equal to $m_X/2$. In the absence of energy pump from supernova, the time scale for the energy loss from $m_X/2$ to $m_C(1+v_f^2/2)$ is

$$\tau_E = \int_{m_C(1+v_f^2/2)}^{m_X/2} \frac{dE_C}{\Delta E_C}\frac{1}{\sigma_S v n_Y} \sim \frac{4\pi m_C^3}{g_Y^4 n_Y m_Y}\left(\frac{1}{v_f}-\frac{1}{v_i}\right). \tag{3}$$

Equating τ_E with the time scale of the energy gain from expanding supernova remnants (*i.e.,* 100 Myr), we find

$$v_f = 0.08\left(\frac{0.25}{g_Y}\right)^4\left(\frac{m_C}{3\text{MeV}}\right)^3\frac{0.1\times\rho_{DM}|_{local}}{n_Y m_Y}. \tag{4}$$

Let us now discuss the bounds on $\Gamma_X = \Gamma(X \to C\bar{C})$ or equivalently on $f = \Gamma_X t_0$. A rather strong bound comes from the requirement that annihilation $C\bar{C} \to A'A'$ does not deplete the C abundance of the galactic disc: That is $\sigma(C\bar{C} \to A'A')n_C v_f t_0 < 1$ which leads to

$$f < 10^{-2} \frac{m_X}{10 \text{ MeV}} \left(\frac{0.15}{g_X}\right)^4 \left(\frac{m_C}{5 \text{ MeV}}\right)^2 \frac{0.06}{v_f}.$$

A stronger bound comes from the requirement that the process of cooling during the history of the galaxy does not repel all the coolants. We should bear in mind that the coolant is a subdominant DM component which contributes less than 10 % to the whole dark matter content. Ref.[8] shows that this requirement implies

$$f < 10^{-3} \frac{m_X}{10 \text{ MeV}} \frac{m_Y}{10 \text{ keV}} \frac{10\rho_Y}{\rho_{DM}}.$$

As we shall see in Sect. 4, the bound from XENON1T detector on f is much stronger.

In order to produce e^-e^+ from $C\bar{C}$ annihilation yet another interaction is required. We will discuss this coupling in Sect. 6.

3. Explaining the 511 keV line

The 511 keV photon line has been detected from the galactic bulge of the MW for more than 40 years.[21] The INTErnational Gamma-Ray Astrophysics Laboratory (INTEGRAL) is a space telescope launched in 2002. The data from the SPI spectrometer at INTEGRAL over the years has confirmed the 511 keV signal at 56 σ C.L. The narrow photon line peaked at 511 keV, whose energy coincides with the rest mass of electron or positron, should come from the annihilation of the electron positron pairs at rest which form positronium atoms. The source of such large positron abundance in the bulge of MW is subject to debate. An intriguing possibility can be annihilation of DM leading to the e^-e^+ production. Astrophysical sources such as pulsars or X-ray binaries may also contribute to the positron flux but their characteristic spectral shapes do not fit the observations.[15] Moreover, the morphology of the observed 511 keV line is better compatible with the ρ^2_{DM} ditribution than what is predicted from these point sources, hinting further toward a DM annihilation origin.[16]

Ref.[1] proposes DM with mass of few MeV annihilating to e^-e^+ as a solution to the 511 keV line. With an annihilation $\langle\sigma(DM + DM \to e^- + e^+)v\rangle \sim 10^{-2}$ pb, MeVish DM can account for the intensity of the 511 keV line. However, if the annihilation to e^-e^+ is a S-wave process, the reioinzing energy dump at recombination will cause delayed recombination which is in tension with the CMB data.[2] If the annihilation is P-wave, at the freeze-out temperatures, the annihilation cross section will be $\sim$10 pb, washing out the relic density of DM. Thus, we should go beyond this minimal scenario. In the following, we show that the model described in Sect. 2 can provide a reliable explanation.

The X DM particles in the galaxy decay into $C\bar{C}$ with a rate of Γ_X. If these C particles are accumulated close to their production point, their number density after t^0 will be

$$n_C = \frac{\rho_X}{m_X} f \quad \text{with} \quad f = \Gamma_X t^0 \tag{5}$$

in which f is the fraction of X particles that have decayed. According to the INTEGRAL findings,[21] the intensity of 511 keV line from galactic center is $\Phi_{511} = (0.96 \pm 0.07) \times 10^{-3}$ph cm^{-2} sec^{-1}. If each $C\bar{C}$ annihilation produces N_{pair} pairs of e^-e^+ and subsequently N_{pair} pairs of photons, the flux from the galaxy bulge will be

$$\Phi_{511} \simeq 2N_{pair} \frac{\int_0^{r_b} (n_X(r))^2 f^2 \langle \sigma_{C\bar{C}} v \rangle 4\pi r^2 dr}{4\pi r_{sol}^2} \tag{6}$$

where $r_{sol} \simeq 8$ kpc is the distance between us and the center of MW, $r_b \simeq 1$ kpc is the galactic bulge radius and $n_X = \rho_X(r)/m_X$. In the minimalistic dark matter scenario in which the dark matter pair annihilates directly into e^-e^+, the flux is given by the formula in Eq. (6), replacing $N_{pair}f^2$ with 1 and $\sigma_{C\bar{C}}$ with $\sigma(\mathrm{DM} + \mathrm{DM} \to e^-e^+)$. In this scenario, the cross section should be of order of $10^{-39} - 10^{-38}$ cm^2 to account for the 511 keV line intensity which implies that in our model:

$$\sigma_{C\bar{C}} \sim 2\ nb \left(\frac{1.5 \times 10^{-4}}{f} \right)^2 \left(\frac{m_X}{5\ \mathrm{MeV}} \right)^2 \frac{1}{N_{pair}}. \tag{7}$$

Let us now discuss the couplings that leads to the e^-e^+ production from the $C\bar{C}$ annihilation. Taking effective coupling $(\bar{e}e)(\bar{C}C)/\Lambda$, the cross section of 2 nb implies $\Lambda < 100$ GeV which would be within the reach of the LEP collider and other accelerator experiments. We therefore invoke the possibility of intermediate light neutral particles, ϕ, to avoid the bounds from the LEP. Then, the production of e^-e^+ takes place in two steps: First, $C\bar{C} \to \phi\bar{\phi}$ and subsequently $\phi \to e^-e^+$. As a result, $N_{pair} = 2$. The $\phi \to e^-e^+$ decay can take place through

$$g_\phi \phi \bar{e} e. \tag{8}$$

As long as $g_\phi < 10^{-11}$, the ϕ production in the supernova core will be negligible. We need $g_\phi > 10^{-15}$ in order for the ϕ decay length to be shorter than 10 pc. If ϕ travels less than ∼100 pc in the bulge (i.e., of order of the resolution of the INTEGRAL observatory) before decay, the n_{DM}^2 dependence of the 511 keV line morphology will be maintained, as favored by observation. Thus, $0.3 \times 10^{-15} < g_\phi < 10^{-11}$. ϕ is mainly an electroweak singlet mixed with the SM Higgs via

$$a_\phi \phi |H|^2$$

Then,

$$g_\phi = \sqrt{2} \frac{a_\phi v}{m_h^2} Y_e \tag{9}$$

in which Y_e is the Yukawa coupling of the SM Higgs to the electron. Fortunately, the hierarchy between the H and ϕ masses does not require unnatural fine tuned cancellation at tree level because $a_\phi \lesssim m_\phi$. In the early universe, ϕ can be produced via $e^-e^+ \to \phi\gamma$ with a number density $n_\phi \sim \langle\sigma_\phi v\rangle n_e^2 H^{-1}|_{T=m_\phi}$ where $\sigma_\phi = e^2 g_\phi^2/8\pi m_\phi^2$. Thus, during the period between $T = m_\phi$ and Γ_ϕ^{-1}, we can write $n_\phi/n_\gamma = 8\times10^{-8}(g_\phi/10^{-11})^2$. As a result, n_ϕ at $T \sim 1$ MeV would be small enough to satisfy the BBN bounds. In the range of g_ϕ in which we are interested, the decay of the ϕ particles takes place long before the recombination. For more details, see Ref.[4].

4. Direct detection of the C particles in the galaxy

The C particles, having a tiny electric charge, can have Coulomb interaction with the electrons and protons. It can also interact with matter fields by the t-channel exchange of dark photon, A'. The velocity of C arriving at the detector is larger than the typical velocity of the DM particles (*i.e.,* velocity of $C \gg 10^{-3}$). As a result, the recoil energy imparted by the C collision can be much larger than that expected from the collision of a DM particle of mass of MeV. This rises the hope to search for C particles by the direct dark matter search experiments, despite C being light. In this section, we shall show how the electron excess with recoil energy of $2-4$ keV at XENON1T can be explained within our model. We will then show that XENON1T sets strongest upper bound on the fraction of the X particle decaying into $C\bar{C}$, f.

According to Eq. (4), the velocity of C particles around us is $v_f \sim 0.08$. The Larmor radius in the Earth magnetic field is 5×10^8 km$(10^{-11}/q_C)(m_C/3$ MeV). Since the Larmor radius is much larger than the Earth radius, the Earth magnetic field cannot accumulate the C particles so their density around the Earth will be similar to anywhere in the solar system (i.e., anywhere in a distance of 8 kpc from the MW galactic center): $(\rho_{DM}|_{local}/m_X)f$ in which $\rho_{DM}|_{local} \sim 0.4$ GeV/cm^3.

Consider a C particle with a velocity of v_f scattering off a non-relativistic particle of mass, m. Up to corrections of $O(v_f^4)$, the maximum recoil energy, which corresponds to the backward scattering, can be written as

$$E_{max} = 2mv_f^2 \frac{m_C^2}{(m+m_C)^2}. \tag{10}$$

For $m_C \sim 1-5$ MeV, $v_f = 0.08$ and $m = m_e$, $E_{max} = 3-5.5$ keV which is tantalizingly within the range of electron recoil excess observed by XENON1T.[7] Taking m equal to the mass of Xenon or of Argon, E_{max} turns out to be much below the detection energy threshold of the experiments such as XENON1T,[17] DarkSide[18] and even the CRESST detector.[19]

The spectrum of recoiled electrons per detector mass will be

$$\frac{dN}{dE_r} = \frac{Z_{out}}{m_N}\left(2f\frac{\rho_X}{m_X}\right)\int f_C(v)\frac{d\sigma}{dE_r}vdv$$

where m_N is the mass of the nuclei inside the detector; *i.e.,* $m_N = 131$ GeV for the Xenon. Z_{out} denotes the number of the electrons in the outer orbitals of the detector atoms whose binding energies are smaller than E_r. Ref.[20] shows that to a reasonable approximation, the binding energy can be treated with a step function in computing the scattering cross section. For Xenon, $Z_{out} = 44$ which is the number of the electrons in the $n = 3, 4, 5$ orbitals. These outer electrons have velocities smaller than v_f so we neglect their velocity in our analysis. The velocity distributions of the C and $\bar{C}$ particles are given by $f_C(v)$. In our computation, we take $f_C(v) = \delta(v - v_f)$ for simplicity. As far as $|\epsilon|/2m_eE_r \gg |\epsilon - \delta|/(2m_eE_r + m_{A'}^2)$, the t-channel photon exchange gives the dominant contribution to the C particles scattering off the electrons. The differential cross section can be written as[24]

$$\frac{d\sigma}{dE_r} = \frac{e^2 q_C^2}{8\pi m_e v^2} \frac{1}{E_r^2} \left(1 + \frac{2m_eE_r}{2m_eE_r + m_{A'}^2} \frac{\delta - \epsilon}{\epsilon}\right)^2 \tag{11}$$

where $E_r < E_{max} = 2m_e v^2 \left(\frac{m_C}{m_C + m_e}\right)^2$. The first (second) term in the parenthesis comes from the contribution from t channel photon (dark photon, A') exchange.

Analyzing the XENON1T data, we take $v_f = 0.08$, $q_C = 10^{-11}$ and $m_X = 10$ MeV and use the data presented in Fig. 4 of Ref.[7]. Let us define χ^2 as follows

$$\chi^2 = \sum_{bins} \frac{[N_i^{obs} - N_i^{pred}]^2}{\sigma_i^2} \tag{12}$$

where N_i^{obs} is the observed number of events at bin i and N_i^{pred} is the prediction for the sum of the background and the signal from the C scattering in the ith bin. The values of the uncertainty (σ_i), the background and N_i^{obs} are obtained from Fig. 4 of Ref.[7]. We only focus on the first seven bins because the excess appears only at $E_r < 8$ keV. The variation of χ^2 with m_C seems to be only mild.

In Sect. 2, we discussed that for 100 keV $< m_{A'} <$ few MeV, identifying the $U_X(1)$ with the $L_\mu - L_\tau$ gauge symmetry, the bounds on $q' \propto (\delta - \epsilon)$ from supernova cooling can be relaxed because A' can decay into neutrino pairs relatively fast. For $m_{A'} \sim$ few MeV, $2m_eE_r \ll m_{A'}^2$ and we can treat $(\delta - \epsilon)/(\epsilon m_{A'}^2)$ and f as two free parameters to be fitted with the data. Taking $m_C = 5$ MeV, we find that the minimum of χ^2 lies at $f = 10^{-7}$ and $(\delta - \epsilon)/\epsilon = -2 \times 10^3 (m_{A'}/\text{MeV})^2$. For $\epsilon = -q_C/(g_X \cos\theta_W) \sim 10^{-11}/(g_X \cos\theta_W)$, this corresponds to $q' \sim (10^{-8}/g_X)(m_{A'}/\text{MeV})^2$. At this point, $\chi^2 = 4.7$ with $5 = 7 - 2$ degrees of freedom which corresponds to a one-sided goodness of fit of 45 %. The results are shown in Fig. 1 with a red curve. In the first bin, contribution from the dark photon and the SM photon cancel each other. In case of the green curve shown in Fig. 1, we have taken $2m_eE_r(\delta/\epsilon - 1)/m_{A'}^2 \to 0$ so there is no cancellation between dark and SM photons. As seen in the figure, in this case the spectrum diverges for small E_r.

For $m_{A'} \sim 100$ keV, $2m_eE_r$ is comparable to $m_{A'}^2$ and we should use the whole formula to fit the data. Taking $m_C = 5$ MeV and $m_{A'} = 100$ keV ($m_{A'} = 200$ keV),

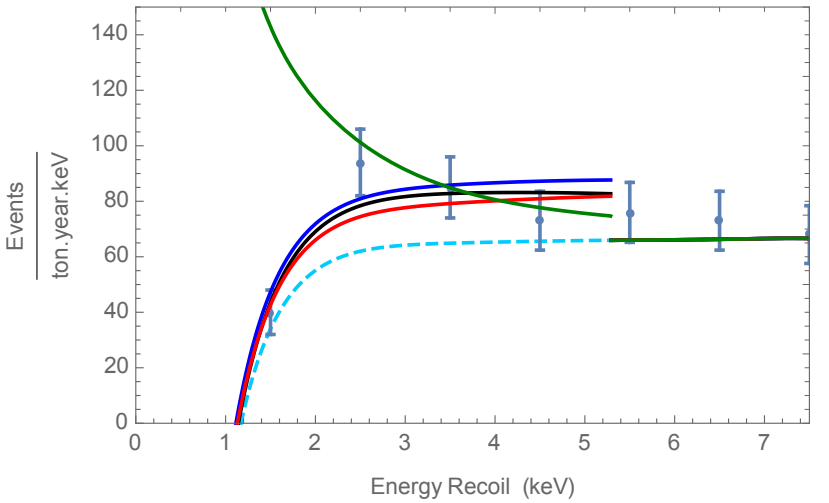

Fig. 1. XENON1T datapoints superimposed on our predictions. We have set $m_C = 5$ MeV corresponding to $E_{max} = 5.3$ keV. The red curve shows the prediction for $m_{A'} > 1$ MeV, $f = 10^{-7}$ and $(\delta-\epsilon)/\epsilon = -2\times10^3(m_{A'}/\text{MeV})^2$. The black curve depicts the prediction for $m_{A'} = 0.1$ MeV, $(\delta-\epsilon)/\epsilon = -13.9$ and $f = 6.6\times10^{-7}$. The blue curve illustrates the prediction for $m_{A'} = 0.2$ MeV, $(\delta-\epsilon)/\epsilon = -76$ and $f = 2\times10^{-7}$. The green curve shows the SM photon dominant regime with $f = 5\times10^{-6}$. The SM background is shown by the cyan dashed curve.

the best fit will correspond to $(\delta-\epsilon)/\epsilon = -13.9$ and $f = 6.6\times10^{-7}$ ($(\delta-\epsilon)/\epsilon = -76$ and $f = 2\times10^{-7}$) and to the minimum $\chi^2 = 4.11$ ($\chi^2 = 4.5$). From Fig. 1, we observe that both fits result in very close prediction. At this fit, q' is right above the supernova bound ($q' \sim 10^{-10} - 10^{-9}$) which can be ruled in by opening the possibility of decay of A' into neutrino pairs in the outer layers of the supernova as discussed in Sect. 2. The effects of such couplings can be tested by studying the flavor composition, the neutrino energy spectrum and the duration of the neutrino emission. The q' coupling can lead to the production of the A' particles in the early universe, contributing to the extra relativistic degrees of freedom, $\delta N_{eff} < 1$. More accurate δN_{eff} determination by future CMB and BBN studies can test this model with $q' \sim 10^{-10} - 10^{-9}$.

Let us now discuss the bound that can be derived on f from the XENON1T data. To do so, we consider the bins with energy less than 8 keV. Fig. 2 shows χ^2 as a function of f. Since the first bin is close to the detection threshold and it suffers from large uncertainty in the evaluation of the background from ^{214}Pb, we present results both including and excluding the first bin. We have taken $m_C = 4$ MeV, but the results are rather insensitive to the value of m_C. To draw the blue and green lines, we have set $\delta = \epsilon$ which means the dark photon decouples and does not contribute to the scattering. Drawing the orange line, we have chosen the value of $2m_e(\delta-\epsilon)/(m_{A'}^2\epsilon)$ such that the contributions from SM photon and dark photon cancel each other at $E_r = 1.5$ keV. From the figure we find an upper bound of

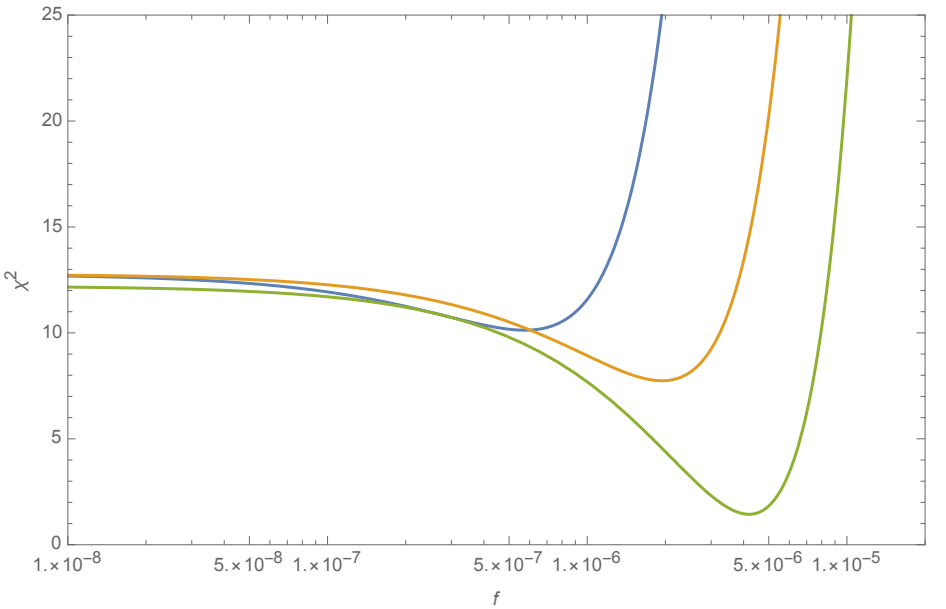

Fig. 2. χ^2 vs. f. We have taken $v_f = 0.08$, $q_c = 10^{-11}$, $m_X = 10$ MeV and $m_C = 4$ MeV. The blue and orange curves (the green curve) show χ^2 for the seven (six) bins between 1 keV$< E_r <$ 8 keV (2 keV$< E_r <$ 8 keV). To draw the blue and green curves, we have assumed that the photon exchange gives the dominant contribution to the scattering, $(m_e E_r/m_{A'}^2)[(\delta-\epsilon)/\epsilon] \ll 1$. To draw the orange curve we have set $(2m_e/m_{A'}^2)[(\delta-\epsilon)/\epsilon] = -1/(1.5\text{ keV})$.

1.5×10^{-6} on f at 3 σ, taking all the bins with $E_r < 8$ keV:

$$f < 1.5 \times 10^{-6} \quad \text{at } 3\sigma.$$

Excluding the first energy bin relaxes the bound to 10^{-5}. Notice that these bounds are much stronger than the constraints discussed in Sect. 2. Since $f = \Gamma_X t_0$, the upper bound on f is equivalent to a lower bound on the dark matter lifetime. The lifetime of X should be larger than $10^{15} - 10^{16}$ years.

Let us revisit the explanation for the 511 keV line taking into account this very stringent upper bound on f. To explain the intensity of the 511 keV line from the galactic bulge, the annihilation cross section of $C\bar{C} \to \phi\bar{\phi}$ should be $\text{mb}(10^{-7}/f)^2(m_X/5\text{ MeV})^2$. Taking a quartic coupling between these scalars of form $\lambda_{\phi C}|\phi|^2|C|^2$, we need $\lambda_{\phi C} \sim 0.02$ to obtain an annihilation cross section of mb.

5. Conclusion and discussion

We have presented a dark matter model that can simultaneously explain the 511 keV line from the galactic bulge and the electron excess with recoil energy of $2-4$ keV reported by XENON1T. The model is based on introducing a dark matter particle with a mass of $O(1-10)$ MeV that decays into a pair of pico-charged particles.

Although the velocities of the C and $\bar{C}$ particles are much larger than the escape velocity from the galaxy, the galactic magnetic field can accumulate them inside the galactic disk. The C particles with velocities of order of $0.08c$ can scatter off the electrons of the direct dark matter search experiments, imparting a recoil energy of a few keV which can explain the electron excess at the low energy bins reported by XENON1T. Moreover, the $C\bar{C}$ accumulated in the galactic bulge can annihilate with each other, giving rise to the excess of the 511 keV line. We have shown that the XENON1T data also sets strong upper bound of 10^{-6} on the fraction of X particles that have decayed into $C\bar{C}$ since early universe until today, $f < 10^{-6}$. The density of $C\bar{C}$ at the time of recombination and during the dark ages would be too low to pump any significant energy and ionize the atoms so the bounds from the CMB on the minimalistic DM explanation for the 511 keV line do not apply here.

The model enjoys a rich phenomenology and can be tested by a myriad of methods. Most obvious test is further data from upcoming direct dark matter search experiments, especially the XENONnT detector which is an upgrade of XENON1T. The XENONnT detector is in the construction phase.

The C particles obtain their electric charge through the mixing of the photon and the dark photon, A' which is the gauge boson of a new $U_X(1)$ symmetry under which C and $\bar{C}$ are charged. Simultaneous explanation for the excess of events with recoil energy between $2-4$ keV and for the absence of an excess at the 1 keV bin requires a cancellation between the contributions from the t-channel exchanges of the photon and A'. Such a cancellation is possible with a light A' with a mass of 100 keV–1 MeV. We have shown that by identifying the $U_X(1)$ symmetry with the $L_\mu - L_\tau$ symmetry and therefore allowing for $A' \to \nu_\mu \bar{\nu}_\mu, \nu_\tau \bar{\nu}_\tau$, it is possible to avoid the present bounds from the supernova cooling consideration. The A' decaying to $\nu\bar{\nu}$ in the outer layers of supernova can however alter the evolution of supernova, leaving its imprint on the duration of neutrino emission, flavor composition, energy spectrum and shock revival. All these signatures provide alternative methods to test the model.

The intensity of the 511 keV line from dwarf galaxies is proportional to the product of the number of C and $\bar{C}$ particles. As a result, there should be a correlation between the magnitude of the magnetic field in dwarf galaxies and the intensity of the 511 keV photon line emitted from them which can be tested in the future.

The positrons from the $C\bar{C}$ annihilation at the production are relativistic. A fraction of these positrons may annihilate in flight giving rise to a continuous γ ray spectrum on which there is a bound, implying that the C particles should be lighter than $6-15$ MeV depending on the models for ionization fraction in the galaxy.[21–23] In future with more data, lighter C can be probed by this consideration. Moreover, there will be an excess cosmic positron at few MeV range. At these energies, the solar wind renders measurements of cosmic positron flux in the MeV range obsolete within the solar system. Fortunately, there are detectors on board the Voyager spacecraft that have set an upper bound on the cosmic positrons outside the solar

system. The bound can be interpreted as $m_C < 20$ MeV. Further data from Voyager can test smaller values of m_C or hopefully detect a positron excess which will be a hint in favor of the present model.

Acknowledgments

The article is prepared for the proceedings of the sixteenth Marcel Grossmann meeting (MG16). The author would like to thank the organizers and conveners of this meeting for the kind invitation. She is also grateful for ICRANET whose support made this participation possible.

Preliminary results of the investigation of the properties of 13 clusters of galaxies from CfA2 redshift survey are discussed in the presented article. The distributions on absolute magnitude and luminosity represent two areas for clusters ##88, 1101, 1046, 142, 933, 1242, 1652, 107, 150, 316, 317, 961, 977. Redshifts of these clusters are in the region 0.002 – 0.032. The distributions on groups members position, absolute magnitude and luminosity represent two areas for these clusters. Galaxies from these areas are paired accordingly its spectral characteristics and position. Also several anomalies of spatial dynamic of galaxies in these clusters were separated. Such structure could be caused by dark matter presence inside cluster in configuration similar to Zeldovich pancake or gravitational lensing on compact object or dark matter blob located between galaxy cluster and observer. Several peculiarities have found on the spatial distributions of galaxies in clusters ##933, 142, 1046, and 1652. Moreover, these groups reveals associations with high-energy gamma-emission sources on Fermi/LAT 10-Year Point Source Catalog 4FGL DR2 data (4FGLJ1144.9+1937, 4FGLJ0152.2+3714, 4FGLJ1230.8+1223 and 4FGLJ1653.8+3945 correspondingly).These sources are active galaxies 3C 264, B2 0149+37, M87 and MRC 501. Furthermore, 3C 264 and M87 observed in subTeV energy band by VERITAS data. Joint observations of such clusters by orbital gamma-ray observatories with high angular resolution and ground-based Cherenkov air-shower experiments could possibly clarify the type of gravitational lensing and processes of particle acceleration in these objects especially highest energy of emitted gammas. Thus we propose including these and similar clusters in the programs of observations of the planned experiment GAMMA-400 (Gamma Astronomical Multifunctional Modular Apparatus) with angular resolution $\sim 0.01^\circ$ at $E_\gamma = 100\,GeV$ and several TeV upper energy band. Also now it is discussed coordination of multiwavelength observations program of Cherenkov Telescope Array (CTA) and GAMMA-400 objects list for observations.

Keywords: Clusters of galaxies; CfA2 redshift survey.

1. Introduction

Galaxy clusters are the biggest gravitationally bound systems[1,2] reveal an independent approach to the problems related to the distribution of matter at various redshift ranges – particulars given in Ref. 4 and Ref. 5. It possible to use the results of its characteristics investigation to understand processes of formation of such systems and galaxies contained its possibly connecting dark matter halos (DMH) and to constrain cosmological models – see, for example Ref. 6 and Ref. 5. The differences of galaxies were identified by their luminosity, morphology, colour, etc. Moreover, following to Ref. 3 and Ref. 2, it allowed studying the relation between the topology and properties of galaxies at the large-scaling structure and concluding both cosmological parameters and galaxy formation mechanisms. Also the investigation of galaxies clusters relates to the dependence of the characteristics of galaxies on the surrounding medium properties, and the large-scale structure formation. Thus the cluster system dynamic investigation also should estimate possible DM presence due to analysis of several catalogues – for instance, CfA2 Redshift Survey.[8,14,17] Therefore, the large-scale distribution of matter in the Metagalaxy will be described by analysing quantities of galaxies to various limiting magnitudes and the redshift surveys – see, for example Ref. 5 and Ref. 16.

2. The Second CfA Redshift Survey data analysis

Preliminary results of the investigation of the properties of clusters of galaxies from The Second CfA Redshift Survey are discussed in the presented article.

The second CfA redshift survey was started between 1985 and 1995 due measurements of relative distances via redshifts for about 18000 bright galaxies in the northern sky. It contain data of 1971 galaxies groups (totally 6787 members) at galactic latitudes $b \geq 20^\circ$ – see Ref. 17.

Early data from this catalogue were analysed in Ref. 15 and Ref. 14 and it were found several peculiarities for clusters ##933, 1242, 88, 142, 1046, 1101 in distributions of group members on absolute magnitude, angular velocity, etc.

The results of additional analysis of these clusters characteristics are discussed in the presented article. The mean values of it's characteristics are listed in the Table 1 (rows 1 – 5). Several additional peculiarities have found on the distributions of galaxies inside these clusters on magnitude and absolute magnitude on CfA2 data. The examples of such distributions for clusters of galaxies #142 and #88 are presented at figures Fig. 1(a), Fig. 1(b) and Fig. 2(a), Fig. 2(b) correspondingly. Dual structure was separated at distributions of galaxies inside cluster on magnitude and absolute magnitude for these two clusters. Bifurcation points are $m_{142} = 14.5 \pm 0.2$ and $M_{142} = 19.5 \pm 0.2$ for group #142, also $m_{88} = 14.5 \pm 0.2$ and $M_{88} = 19.0 \pm 0.2$ for one #88.

Than we have separate clusters of galaxies contain more than 20 members for subsequent analysis. The mean values of characteristics for other 8 clusters from this subsample are listed in the Table 1 (rows 6 – 13). Fig. 3(a), Fig. 4(a) and

Galaxies from these areas are paired accordingly its spectral characteristics and position. Unfortunately direct data analysis not allow understanding of reality of such dual structure because it could be caused by several selection effects.

Let's try to investigate dynamic of these systems using Nonlinear Time Series Analysis methods – see, for instance, Ref. 9. Unfortunately real time variables are absent in the analysed systems. But dynamic behavior of cluster's members strongly depend of its velocities and distances to cluster centre.[10] We have construct phase space cluster of galaxies #88 using values of redshift, coordinates, magnitude,

absolute magnitude and distance to centre. We have use ratio between distance to centre and tangential velocity as time similar variable in the presented article and constructed simple attractors in this phase space for first attempt of investigation of dynamic of system. Let's separate basins of attractors correspondingly to bifurcation points on the analysable distributions. Accordingly to preliminary results of analysis we have obtained two attractors in the phase space of cluster #88 which concludes real dual structure of this system. Figure 16 represents three dimension projection of obtained attractors.

3. Conclusions

Preliminary results of the properties of 13 clusters of galaxies from CfA2 redshift survey (##88, 1101, 1046, 142, 933, 1242, 1652, 107, 150, 316, 317, 961, 977) are presented. Redshifts of these clusters are in the region 0.002 – 0.032. The distributions on magnitude, absolute magnitude and angular velocity, etc represent two areas for these clusters. Galaxies from these areas are paired accordingly its spectral

characteristics and position. Also several anomalies of spatial dynamic of galaxies in these clusters were separated.

The presence of such structure allows conclude two alternatives. In the first one dark matter presence inside cluster in configuration similar to Zeldovich pancake. Second case is gravitational lensing on compact object or dark matter blob located between galaxy cluster and observer.

Also several peculiarities have found on the spatial distributions of galaxies in clusters##933, 142, 1046, and 1652. Moreover, groups ##933, 142, 1046, and 1652 reveals associations with high-energy gamma-emission sources on Fermi/LAT 10–Year Point Source Catalog 4FGL DR2 data (4FGLJ1144.9+1937, 4FGLJ0152.2+3714, 4FGLJ1230.8+1223 and 4FGLJ1653.8+3945 correspondingly).

Furthermore, 4FGLJ1144.9+1937 and 4FGLJ1230.8+1223 observed in subTeV energy band by VERITAS data.

Joint observations of such clusters by orbital gamma-ray observatories with high angular resolution and ground-based Cherenkov air-shower experiments could possibly clarify the type of influence to groups characteristics (gravitational lensing or object inside cluster) and processes of particle acceleration in these objects especially highest energy of emitted gammas. Thus we propose including these and similar clusters in the programs of observations of the planned experiment GAMMA-400 (Gamma Astronomical Multifunctional Modular Apparatus) with angular resolution $\sim 0.01^\circ$ at $E_\gamma = 100\,GeV$ and upper energy band boundary about several TeV. Also now the coordination of multiwavelength observations program of Cherenkov Telescope Array (CTA) and GAMMA-400 is discussed.

Probing the nature of dark matter with Milky Way subhaloes

M. R. Lovell

E-mail: lovell@hi.is

The nature of dark matter is one of the most pressing questions in modern physics. Efforts to answer this question have centred on observations that determine its impact on the properties of galaxies plus attempts to detect rare events in which the dark matter indirectly generates photons. In this talk I presented work on using the properties of Milky Way satellite galaxies to constrain models of self-interacting dark matter (SIDM) and warm dark matter (WDM). First I used N-body simulations of an SIDM model with a very large self-interaction at low relative velocities ($\sigma > 100$ cm^{2}gr^{-1}) to demonstrate that subhaloes in such models undergo gravothermal collapse and increase the diversity of satellite matter distributions in line with inferences from observations. Second, I considered the radial distribution of subhaloes in WDM simulations from the point-of-view of stellar stream gap constraints. I showed that the subhalo population within 50 kpc of the host halo centre is comprised of massive satellites that have sunk under dynamical friction. Given that the abundance and structure of massive satellites in WDM is very similar to the fiducial cold dark matter (CDM) model, the differences between the subhalo populations in the two models in the inner halo are much smaller than for the halo as a whole, and therefore the stellar stream gaps statistics, which are only available out to 30 kpc, are not as powerful at discriminating between the models as previously anticipated. I ended with a brief presentation of estimates for the production rate of X-ray photons in dark matter decay, and predicted that the velocity dispersion of X-ray decay lines to be probed in nearby galaxy clusters will have values in the range [500,800] kms^{-1}.

Keywords: Dark matter

1. Introduction

Observations of a wide variety of astrophysical objects have returned evidence for the existence of an invisible substance that constitutes $\sim 82\%$ of the mass of the Universe. These observations include the anisotropies of the cosmic microwave background radiation (CMB)[1] and the rotation curves of galaxies (e.g. Ref 2). All of these observations are consistent with the presence of matter that is dynamically cold, at least on the scales of massive galaxies and larger, and does not interact with light; this material is therefore dubbed cold dark matter (CDM).

The CMB and rotation curves studies probe the properties of dark matter on scales typically larger than 10 kpc. However, on scales of dwarf galaxies, the close match between observations on the one hand and predictions for gwalaxy abundance and structure from CDM N-body simulations start to break down.[3–5] In part, such discrepancies can be explained by astrophysical processes that change the properties

of dark matter haloes, through reionisation[6,7] and supernova feedback.[8,9] However, it is not clear that astrophysics alone provides the best match to observations.[10–12] In the context of the non-detection of CDM-type dark matter candidates with either direct detection[13,14] or γ-ray indirect detection experiments,[15,16] it is important to consider dark matter candidates that behave somewhat differently, both in their astrophysical impact on structure formation and in their detection abilities.

In this talk I covered three topics: two in the properties of Milky Way (MW) satellites and a third on the potential for detection of dark matter decay in X-rays. The two MW subhaloes topics concern very different dark matter models: first, an extreme velocity dependent self-interacting dark matter (SIDM) model in the context of MW satellite densities, and second, the effect of the warm dark matter (WDM) model consequences on the spatial distribution of both satellites and non-luminous subhaloes. The dark matter decay results are applicable to any model in which dark matter undergoes two-body decay that does not affect the galaxy kinematics significantly.

These proceedings are organised into three sections. I describe the SIDM work in Section. 2, the WDM work in Section. 3, and the dark matter decay results in Section. 4. The papers from which these three sections were derived are Ref. 17, Ref. 18 and Ref. 19 respectively.

2. Gravothermal collapse in SIDM and the densities of Milky Way satellites

The masses of MW satellites have been a popular probe of dark matter and astrophysics models for at least 10 years. Refs. 5, 20 showed that, at least at a first glance, CDM simulations predicted the existence of satellites more massive and dense than any of the observed MW satellites at the same time that other studies reported evidence for cored dark matter density profiles.[21] A successful dark matter model will have to explain both of these observations simultaneously. Ref. 22 argued that cored SIDM dark matter profiles were insufficiently dense to explain the very high reported masses of the MW's ultrafaint dwarf galaxies, and therefore in order for these models to be viable a fraction of SIDM subhaloes below a given mass scale would need to undergo the process of gravothermal collapse, by which material starts rapidly flowing towards the halo centre and creates a density profile much steeper than in CDM.[23]

For Ref. 22 we had run an extreme model of SIDM that would cause gravothermal collapse to occur in MW satellites within a Hubble time. It featured a strong cross section-velocity dependence: a cross section $\sigma \sim 100$ cm^{2}g^{-1} at interactions velocities < 30 kms^{-1}. This cross-section was chosen in order to induce gravothermal collapse without relying on stripping of the satellite outskirts[24] and to avoid violating published bounds on high velocity interaction cross-sections from cluster mergers;[25] we do not attempt to match the reported measurements of ~ 1 cm^{2}g^{-1} cross-sections at $\sim$1500-2000 kms^{-1} by Refs. 26, 27. Our goal in Ref. 17 was to

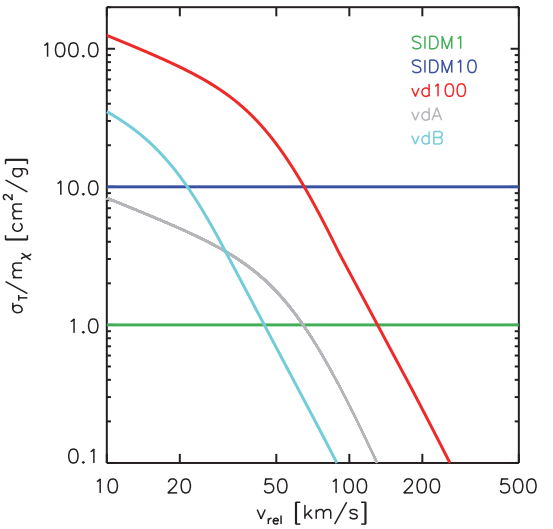

Fig. 1. Self-interaction cross section as a function of particle relative velocity for five SIDM models. The primary model of interest in our study was vd100, which is shown in red. We also show two further velocity-dependent SIDM models, labelled vdA (grey) and vdB (cyan), plus two velocity independent models with cross-sections ~ 1 cm^{2}g^{-1} (SIDM1, green) and ~ 10 cm^{2}g^{-1} (SIDM10, blue). Reproduced from Ref. 17.

investigate the abundance and density of subhaloes in this model, which we dubbed 'vd100'. We present the velocity dependence of the cross section for this model and other SIDM models in Fig. 1.

We explored the properties of the vd100 model using the same simulation that we ran for Ref. 22. This was zoomed resimulation of the Aquarius Aq-A3 MW halo-analogue[28] using the same initial conditions as for the original CDM simulation but with the inclusion of vd100 model self-interactions. The simulation was run with the Arepo code.[29] The host halo virial mass $M_{200} = 1.9 \times 10^{12}$ M$_\odot$, the simulation particle mass was 4.9×10^4 M$_\odot$, and the gravitational softening length $\epsilon = 120.5$ pc. The cosmological parameters were consistent with the WMAP first year results.[30] The same code, simulation parameters and cosmological parameters were used in the other four SIDM simulations.

We looked for evidence of gravothermal collapse through the following methodology. We computed circular velocity curves for subhaloes within each of these simulations that were located within 300 kpc of the centre of the host halo, and parametrised the structure of velocity curves with two numbers: the maximum value of the circular velocity, $V_{\rm max}$, and the radius $r_{\rm max}$ at which $V_{\rm max}$ is attained. $V_{\rm max}$ is often interpreted as a proxy for the subhalo mass, and $r_{\rm max}$ as a measure of concentration at fixed $V_{\rm max}$, with larger $r_{\rm max}$ corresponding to a less concentrated halo. We present contour plots for the $V_{\rm max} - r_{\rm max}$ distributions of haloes in the CDM, SIDM10, vdB, and vd100 simulation subhaloes in Fig. 2.

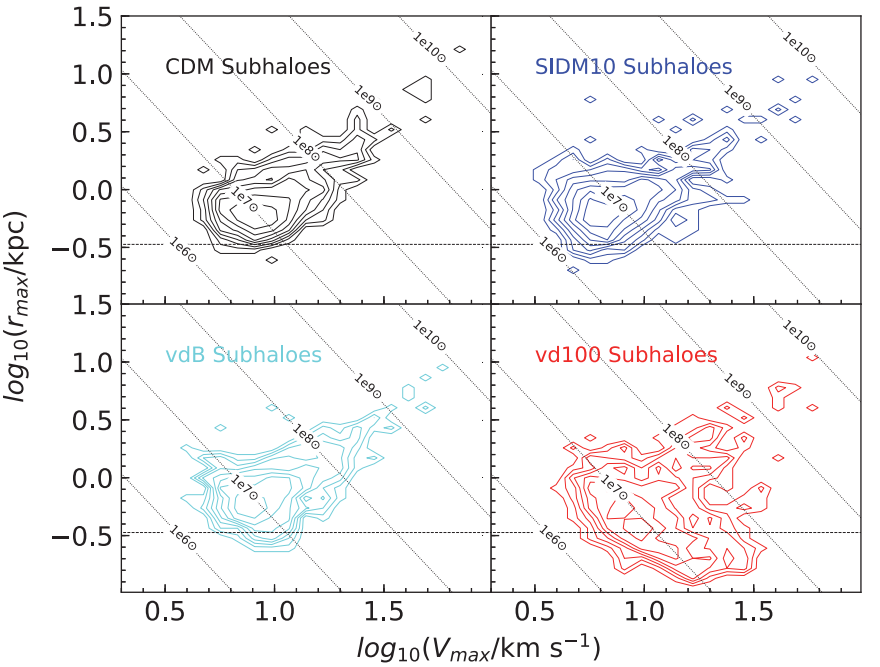

Fig. 2. Contour plots of $V_{\rm max}$ - $r_{\rm max}$ values for subhaloes in four models: CDM (top left panel), SIDM10 (top right), vdB (bottom left) and vd100 (bottom right). Diagonal lines denote parameter space along which the mass enclosed with $r_{\rm max}$ is constant. The horizontal lines denote the radius corresponding to 2.8× the softening length of the simulation and therefore marks the hard resolution limit. Reproduced from Ref. 17.

The vdB subhaloes follow the same relation in $V_{\rm max}$ - $r_{\rm max}$ as their CDM equivalents despite their very high cross-sections at low velocities, > 20 cm^{2}gr^{-1}. By contrast, a large population of vd100 subhaloes have $r_{\rm max}$ well below the CDM relation: the subhaloes are therefore denser than CDM and have undergone gravothermal collapse. We explore this trend further for a sample of subhalo circular velocity curves that have $V_{\rm max}$ values in the range $V_{\rm max} = [25, 35]$ kms^{-1} from the CDM and vd100 runs, which we present in Fig. 3.

The number of vd100 subhaloes with $r_{\rm max} > 1$ kpc is approximately the same as the number of CDM subhaloes in the same $V_{\rm max}$ bin, since the implementation of velocity-dependent SIDM has only a minor impact on the halo mass function[a]. From radii < 2 kpc these vd100 subhaloes' circular velocity profiles decline much faster than their CDM counterparts as a consequence of their cored profiles. However, there also exists a population of approximately twice as many vd100 subhaloes with $r_{\rm max} < 1$ kpc. The accurate values of $r_{\rm max}$ and $V_{\rm max}$ for these subhaloes

[a]In models for which the cross-section is large at high velocities, as is common for velocity independent models, interactions between subhaloes and the host can evaporate subhaloes and suppress the mass function.[11,17]

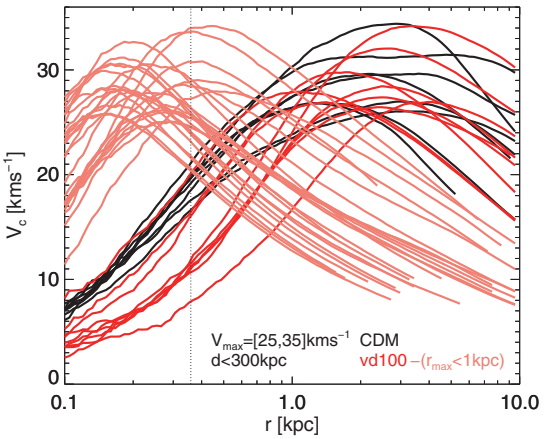

Fig. 3. Circular velocity curves for subhaloes in the CDM and vd100 simulations that have $V_{\rm max}$ =[25, 35] kms^{-1}. CDM subhaloes are shown in black. vd100 subhaloes that have $r_{\rm max} >$ 1 kpc are shown in red, and vd100 subhaloes with $r_{\rm max} < 1$ kpc are shown in pink. Reproduced from Ref. 17.

are unknown because the circular velocity curves are still rising at the softening resolution limit; we therefore just state that these haloes have indeed undergone collapse and are concentrated enough to explain the ultrafaint dwarf masses at the same time that the uncollapsed cored haloes can fit the brighter satellites.[22] We also show in Ref. 17 that the density profiles of these objects is a power law of slope -3.

3. The WDM subhalo distribution and implications for gaps in streams studies

For the second part of the talk I switched to MW satellites in the WDM cosmology. The motivation for this model arises from clues that it might, under some circumstances, be a better match to observations than CDM[12] and also that its primary particle physics candidate, the sterile neutrino[31,32] may have been detected in X-ray decay.[33,34] This model suppresses the number of dwarf mass haloes[35] and lowers their concentrations[10] relative to CDM. The WDM model can therefore be constrained by observations that measure the number and concentration of dwarf haloes, especially dark matter haloes so small that they never form stars.

One such method is to attempt to detect gaps in stellar streams. Globular clusters and satellite galaxies experience stripping of their outer layers as they orbit within the gravitational field of their host galaxies, leaving behind a smooth stream of stars. The structure of the stream will be disturbed by interactions with other structures, such as dark matter subhaloes. The effect of dark matter physics on the abundance and density of subhaloes can therefore be inferred from the presence of the gaps in streams.[36–38]

Several studies have claimed strong limits on WDM in particular from the apparent detection of such gaps in streams,[37,38] although the nature of dark matter substructures as a cause is disputed. For the paper from which this talk section was derived, I examined the subhaloes that populate the region where streams can be probed for gaps given current observational constraints, i.e. $\lesssim$30 kpc from the MW centre, in CDM and in WDM and analysed the difference between these inner-host subhaloes on the one hand and subhaloes at all radii on the other.

For this project, we estimated the subhalo population properties using two N-body simulations, one of CDM and one of a WDM . Our two companion simulations were CDM and WDM variations of the COCO volume;[39,40] a zoomed simulation of a spherical region $\sim$28 Mpc in radius with a dark matter simulation particle mass of $\sim 2 \times 10^5$ $M_\odot$. The WDM model was a 3.3 keV thermal relic; this was chosen to be consistent with a set of Lyman-α forest constraints[41] and is also a reasonable approximation to the matter power spectrum of the sterile neutrino that could explain the reported 3.55 keV line.[12] We identified 26 MW-halo analogues: these we selected to be in the mass range $[1.0, 1.5] \times 10^{12}$ $M_\odot$, and also to be isolated in that the distance to any larger halo was > 1 Mpc[b].

We first considered the abundance of subhaloes in two mass bins: $[10^7, 10^8]$ $M_\odot$ and $[10^8, 10^9]$ $M_\odot$. We computed the number of subhaloes in these mass bins for CDM and WDM in two radius bins: < 40 kpc from the halo centre to represent stream gap-generating subhaloes and < 300 kpc for the subhalo population at large. Any changes in these quantities will be driven by two factors: the larger number of haloes generated in CDM plus the additional stripping of subhaloes in WDM due to their lower concentrations. In order to ascertain the contribution of these two factors we therefore performed a 'hybrid' calculation, in which for each CDM subhalo we selected a WDM subhalo with the same infall mass and infall time and assigned this WDM subhalo final time mass to the CDM subhalo. This was equivalent to the mass that the CDM subhalo may have had if it had experienced a WDM stripping rate. Our hybrid calculation therefore factors out the contribution to CDM–WDM differences from the change in infall mass function and retains the differences from stripping.

With these results we compute the ratio of WDM-to-CDM subhalo abundances in the two mass bins plus the ratios of the hybrid measurements and present the results in the left-hand set of panels in Fig. 4. Beginning with the $[10^7, 10^8]$ $M_\odot$ bin, we find strong differences in the relative properties of the models between radius bins. Within the full 300 kpc distance from the host halo centre the number of WDM subhaloes is suppressed to 10% of the CDM value on average, whereas for the 40 kpc bin it is instead 30% in the median, with a much larger scatter. We argue in the paper that this result is due to the inner halo being dominated by the remnants of

[b]The MW is located only 750 kpc from the more massive Andromeda galaxy; we expect that this will not affect the results.

massive haloes that have sunk under dynamical friction; the abundance of massive haloes is much more similar between the two models than the mass function down to 10^7 $M_\odot$, therefore the value of this ratio is much closer to 1. A similar result is found for the more massive bin, where the suppression is a median 40% of CDM for the < 300 kpc bin but 60% of CDM.

One possible complication to this picture is the issue of extra stripping in WDM subhaloes as discussed above, and we can tease out the contributions of changes in stripping and changes in the mass function by comparing the hybrid calculation results to the full WDM results: if the hybrid results are the same as the full WDM then the change between WDM and CDM is entirely due to extra stripping, whereas if the hybrid results instead straddle the ratio = 1 line then the change was entirely due to the input mass function. In the lower mass bin the < 300 kpc hybrid ratio is much closer to a ratio of 1 than to 0.1, therefore the change in mass function drives the difference, whereas in the < 40 kpc radius the hybrid suppression ratio is lower than at < 300 kpc as per the switch from unstripped low-infall mass subhaloes to high-mass stripped ones.

The difference in subhalo infall mass at different radii will also have an impact on the concentration–mass relations at these radii, with the subhaloes in the central region more likely to be the dense cores of massive progenitors. The concentration of these objects will also have an effect on the gaps in streams measurements. Obtaining an accurate concentration–mass relation for subhaloes close to the host halo centre with N-body simulations is challenging for a number of reasons, including the possibility that mass from the subhalo is inaccurately ascribed to the host halo and that the mass distribution of the host will be strongly impacted by the presence of the stellar disc, both from the disc itself and from the contraction of the halo. We therefore developed an estimate for the mass and size of subhaloes in the centre using the infall mass / structure plus a measurement of the observed MW mass profile. We used the measured MW mass profile of Ref 42 to calculate the tidal radius of a subhalo at a distance of 20 kpc from the halo centre based on its infall mass and infall density profile, then assumed that the halo layers outside the tidal radius were removed while the mass inside the tidal radius was not affected. We thus calculated a new mass based on the mass interior to the tidal radius, and a new size as the half-mass radius of the remaining (unstripped) material. We computed median mass–radius relations for subhaloes within 50 kpc of the host centre using these estimates of stripped mass and size, and also median relations across the subhalo using the infall mass and infall size. We present these results in the right hand panel of Fig. 4.

Beginning with the whole subhalo population, the CDM and WDM sizes are identical at $6 \times 10^9\,M_\odot$ but quickly diverge towards lower masses, with WDM subhaloes of mass $6 \times 10^7\,M_\odot$ on average 50% larger than CDM subhaloes of the same mass. The subhaloes in the inner halo instead show much smaller sizes, such that

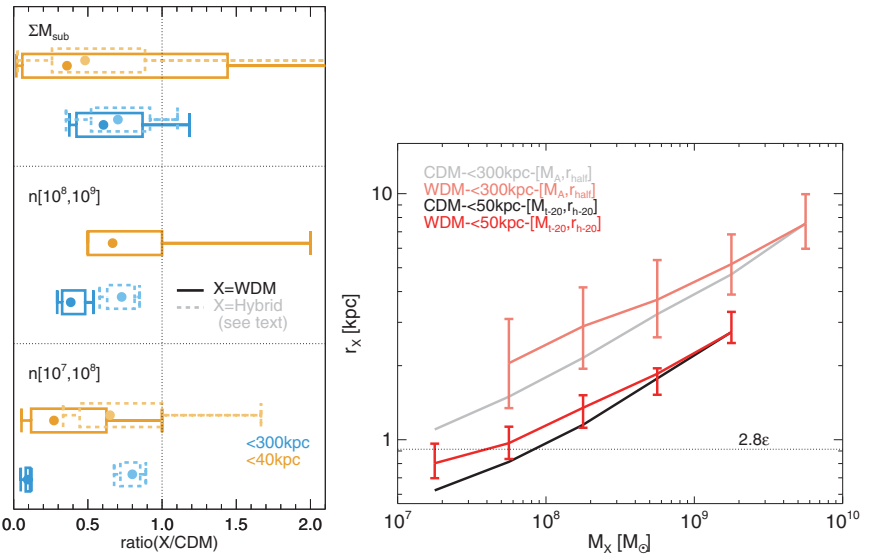

Fig. 4. *Left-hand panels:* ratio of quantities between WDM and CDM versions of the 24 volumes. In the top panel we show the ratio of the mass in WDM and CDM; in the middle panel the fraction of the number of subhaloes in the mass bin $[10^8, 10^9]$ $M_\odot$, and in the bottom panel the ratio of $[10^7, 10^8]$ $M_\odot$ subhalo number. Ratios for subhaloes within 40 kpc of the host centre are shown in orange and within 300 kpc in blue. Filled dots denote median ratios, boxes 68% of the data and error bars 95% of the data. Solid lines are used for the measured WDM subhalo fractions and dashed lines for the hybrid calculation as described in the text; the hybrid calculation is omitted for the mass= $[10^8, 10^9]$ $M_\odot$, distance< 30 kpc bin due to poor statistics. *Right-hand panel:* the mass–radius relation for subhaloes in two radius bins. Data for subhaloes within 300 kpc are shown using infall masses and sizes in grey (CDM) and pink (WDM); data for subhaloes in the < 50 kpc bin are calculated using estimates for the stripping radius at 20 kpc as discussed in the text, and are shown in black (CDM) and red (WDM). Error bars on the WDM relations denote 58% of the data; error bars are omitted for CDM on clarity grounds, and are of the same size as for WDM. Reproduced from Ref. 18.

the WDM subhaloes within 50 kpc are more concentrated the CDM subhalo population. The difference in ratio between the stripped estimates for these inner-host subhaloes is approximately 20% at $10^8\,M_\odot$, and the majority of such WDM subhaloes are less than 2 kpc in size. We therefore argue that the subhaloes likely to generate stream gaps would have to have stream impact parameters less than 2 kpc in order for the difference in concentrations to be imprinted on the gap properties.

In conclusion, I showed in this part of the talk that the properties of the subhaloes that generate gaps are very different to the properties of subhaloes generally, in that they are the stripped, concentrated remnants of massive haloes. Therefore the ability of stream-gap analyses to discern between CDM and WDM is weaker than one would infer from the subhalo population at large.

4. Predictions for the X-ray emission signal from decaying dark matter in galaxy clusters

For the final part of the talk I shifted to indirect detection opportunities for dark matter decay, and presented a prediction for the decay to be measured in nearby galaxy clusters by the XRISM X-ray experiment.

Decay is possible for dark matter particles that have a lifetime much longer than the age of the Universe but are never the less not completely stable. Such particles are typically light and therefore decay in the X-ray band. The prime dark matter particle candidate that has a mass in this range is the resonantly produced sterile neutrino, which in addition to dark matter explains baryogenesis and the oscillations of standard model neutrinos;[31,32,43] it also behaves as WDM,[44,45] and is thus accessible to the constraints from the previous section. The decay of this

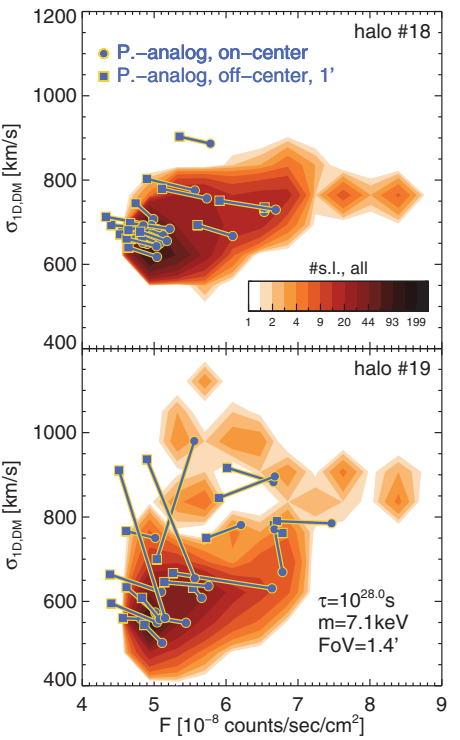

Fig. 5. Predictions for the properties of a putative dark matter X-ray decay line in the Perseus cluster to be measured by the XRISM experiment. We use simulations of two Perseus-mass clusters, and each cluster is represented in one panel and is subject to 500 sightlines. We show contours of the one dimensional velocity dispersion versus the total line flux: the velocity dispersion is independent of the particle physics properties, and the flux assumes $\tau = 10^{28}$ s and $m = 7.1$ keV. The blue circles denote on-centre sightlines for which the velocity dispersion of the cluster member galaxies is the measured velocity dispersion of Perseus cluster members, and the attached blue squares offset 1 arcminute from the centre. Reproduced from Ref. 19.

particle takes the form of a monochromatic X-ray line at an energy half the sterile neutrino rest mass energy. The width of the line is determined by the macroscopic dark matter one dimensional velocity dispersion, and is therefore independent of the particle physics parameters.

The XRISM experiment, to be launched in 2023, will have sufficient spectral resolution to measure the width of the claimed dark matter decay line in nearby clusters of galaxies. I therefore used the C-EAGLE simulations[46,47] of galaxy clusters to perform mock observations with the XRISM field-of-view of dark matter decay lines in Perseus-mass clusters.[19] The flux calculation assumed a particle lifetime $\tau = 10^{28}$ s and mass $m = 7.1$ keV, as inferred from the claimed detections of the 3.55 keV line.[33,34] We identified two of the 30 C-EAGLE clusters as having same mass as Perseus within some tolerance, and computed 500 sightlines through the halo centre from randomized viewing angles. The results are shown in Fig. 5.

The flux of the line can vary by a factor of 50%, with most of the sightlines bunching up towards lower fluxes in the allowed range. The velocity dispersion is concentrated in the [500,800] kms^{-1} range, and exceptionally at [400,1000] kms^{-1}. This velocity dispersion is significantly narrower than the measured velocity dispersion of the member stars, which is typically 1300 kms^{-1}, and is still much broader than astrophysical emission lines (< 200 kms^{-1}). Given that the velocity dispersion is also independent of the particle physics parameters for the sterile neutrino model, the XRISM observatory offers arguably the best opportunity to detect dark matter within the next five years.

5. Conclusions

In this talk I summarised three leads for constraining and identifying the dark matter: the density of the Milky Way (MW) ultrafaint satellites, the properties of subhaloes that carve gaps in stellar streams, and the parameters of X-ray decay lines in galaxy clusters.

First, I investigated how the distribution of ultrafaint satellite densities could be explained by a velocity-dependent self-interacting dark matter model (SIDM) in which the self-interaction cross-section is of order 100 $\mathrm{cm}^2\mathrm{gr}^{-1}$ for relative velocities below 20 kms^{-1}. I showed that this model induces gravothermal collapse in a fraction of the dark matter subhaloes. The density profiles of these collapsed subhaloes exhibit a power law of index -3. The combination of collapsed and cored SIDM subhaloes can potentially explain the diversity of MW satellites masses, in which bright satellites could be hosted in massive, cored satellites whereas ultrafaint dwarfs are hosted in less massive, gravothermally collapsed subhaloes.[17]

For the second part of the talk I switched to comparing the subhaloes that carve gaps in stellar streams between cold dark matter (CDM) and warm dark matter (WDM), for which I extracted subhaloes from the COCO simulations that are located within the same region of configuration space that stream gaps can be detected (< 30 kpc from the host centre). I showed that these central-region

subhaloes are the remnants of massive progenitors that have sunk to the halo centre under dynamical friction. I therefore argued that, since the differences between CDM and WDM massive subhaloes are small, the discriminating power of stream gaps as a dark matter probe is weaker than one would infer from comparing all subhaloes associated with each host.[18]

I ended the talk with a brief presentation of work on dark matter indirect detection. I showed calculations for the expected width of putative lines from dark matter decay in a series of nearby galaxy clusters. Given the uncertainty between viewing angles, I showed that the line velocity dispersion would have a value in the range $[500, 800]$ kms^{-1}, which is narrower than the velocity dispersion of the member galaxies but crucially still significantly broader than X-ray emission lines from hot gas.[19] The upcoming XRISM observatory will therefore have an excellent opportunity to determine whether the line detected at 3.55 keV in galaxies and clusters[33,34] is from an astrophysical source or is indeed from dark matter decay.

Addressing classical cosmological back-reaction with multiple scales

Yonadav Barry Ginat
Faculty of Physics, Technion – Israel Institute of Technology, Haifa, 3200003, Israel
E-mail: ginat@campus.technion.ac.il

This is a summary of my talk at the 16th Marcel Grossmann conference, given on-line in July 2021. Various aspects of the averaging problem – the problem of finding an effective large-scale cosmological solution of the Einstein field equations, when small-scale perturbations are present — are discussed, and treated with the multiple-scales technique of singular perturbation theory. This allows one to show that a split between a background metric that varies only on large scales, and perturbations to it, is consistent, provided certain conditions are met. I finish by giving an explicit example of the back-reaction of a perturbation consisting of a single small-scale mode, and point at possible future directions.

Keywords: Cosmological perturbation theory; gravity.

1. Introduction

The Universe is usually described, on large scales, by a Friedmann-Lemaître-Robertson-Walker (FLRW) metric[1]

$$\mathrm{d}s^2 = a^2(\eta)\left(-\mathrm{d}\eta^2 + \gamma_{ij}\mathrm{d}x^i\mathrm{d}x^j\right), \tag{1}$$

which is a solution of the Einstein equations

$$R_{ab}(g_{ab}) - \Lambda g_{ab} = 8\pi G\rho_{ab} \equiv 8\pi G\left(T_{ab} - \frac{1}{2}Tg_{ab}\right), \tag{2}$$

for a homogeneous and isotropic energy-momentum tensor T_{ab}. However, in reality, the matter distribution is inhomogeneous on small scales, and becomes homogeneous and isotropic only on scales of about[2] $\sim$ 100 Mpc so an averaging procedure is required, to find a homogeneous $\overline{\rho}_{ab}$. Such averaging does not, for a general metric, commute with the non-linear operation of computing the Ricci tensor from the metric, so $\overline{R}_{ab} \neq R_{ab}(\overline{g}_{ab})$. Hence, the equation, whose solution is the FLRW metric, does not, strictly speaking, correspond to a realistic universe. An averaged equation should rather be

$$\overline{R}_{ab} - \Lambda\overline{g}_{ab} = 8\pi G\overline{\rho}_{ab}. \tag{3}$$

This discrepancy is a consequence of the averaging, or back-reaction problem.[3–6]

Another instance of the same problem arises in the context of splitting the space-time metric g_{ab} into an FLRW 'background' piece, g^{FLRW}_{ab} and a perturbation, h_{ab}, *viz.*

$$g_{ab} = g^{\mathrm{FLRW}}_{ab} + h_{ab}, \tag{4}$$

where in standard cosmological perturbation theory, h_{ab} is taken to be small.[1] However, its magnitude depends on scale and, in general, on the co-ordinate system one uses;[7] this calls into question the very validity of such a background-perturbation split, which rests on the consistency of even defining a large-scale background.

Several proposals were put forward in the past to address this problem, including special averaging techniques[8] or special perturbative expansions,[9] and here I wish to describe another proposal, laid down in Ginat (2021),[10] which can address some of the problems with less assumptions than the other techniques.

Below I choose units such that $c = 8\pi G = 1$. The entire discussion here is classical, and quantum aspects of back-reaction are not discussed at all.

2. Multiple-Scales Treatment of the Einstein Equations

2.1. *The Multiple-Scales Method*

The multiple-scales technique consists in treating small scales and large scales as separate variables, interacting via the non-linearity in the dynamical equations that one wishes to study.[11] If ε denotes a certain small parameter involved in the equations, and x denotes the independent variable, then one defines $X = x/\varepsilon$, and changes

$$\frac{\partial}{\partial x^a} \mapsto \frac{\partial}{\partial x^a} + \frac{1}{\varepsilon}\frac{\partial}{\partial X^a} \tag{5}$$

in the dynamical equations; then, one treats x and X as independent variables. This split is done in conjunction with an asymptotic expansion of the dependent variable, the metric $g_{ab}(x, X, \varepsilon)$, in our case, in ε, as $g_{ab}(x, X) \sim g^0_{ab} + \varepsilon g^1_{ab} + \ldots$, and a similar one for the energy-momentum tensor (with the convention that any X-independent terms enter into ρ^0_{ab}). This expansion is consistent, of course, only if the condition $\varepsilon^n \left|g^n_{ab}\right| \gg \varepsilon^{n+1} \left|g^{n+1}_{ab}\right|$ is satisfied.

The addition of an independent variable, without changing the dynamics, implies that there aren't enough equations to determine the solution fully, leaving certain integration constants, or solutions of homogeneous equations, free. However, in the general case, small-scale resonances yield diverging large-scale behaviour, which potentially violates the above-mentioned consistency requirement. To ensure that it is not, one imposes additional consistency conditions, which determine the undetermined functions or integration constants, in precisely such a manner as to remove the resonances, and ensure the asymptoticity of the expansion. This adds exactly enough equations to fix the solution fully.

2.2. *Application to The Einstein Equations*

Working in harmonic co-ordinates renders the Einstein equations hyperbolic,[12] *viz.*

$$R_{ab} \equiv R^{(h)}_{ab} = -\frac{1}{2} g^{cd} \partial^2_{cd} g_{ab} + P^{cdefgh}_{ab}(g) \partial_c g_{ef} \partial_d g_{gh}, \tag{6}$$

where $P_{ab}^{cdefgh}(g)$ is some function of the metric g, and not of its derivatives. Let us now set x as the cosmological scale and X as some small scale, e.g. a galactic scale; then ε is the ratio between these two scales, and indeed $\varepsilon \ll 1$.

The Einstein equations are second order, so, upon expanding them in ε, the leading order is ε^{-2}, i.e., in harmonic co-ordinates,

$$-\frac{1}{2}g_0^{cd}\partial^2_{X^cX^d}g^0_{ab} + P_{ab}^{cdefgh}(g_0)\partial_{X^c}g^0_{ef}\partial_{X^d}g^0_{gh} = \rho^{-2}_{ab}. \tag{7}$$

Here we can already address the question of the existence of a consistent background-perturbation split for the metric: if $\rho^{-2}_{ab} \neq 0$, i.e. if there are small-scale, relativistic sources, like black holes, then necessarily g^0_{ab} is X *dependent*, and therefore any good definition of a large-scale background is impossible. On the other hand, if one only considers small-scale, 'Newtonian' sources, for which the gravitational potential is $\ll 1$, then ρ^{-2}_{ab} does vanish, and the solution to equation (7) is an X-independent g^0_{ab}, a true background.

2.3. *Consistency Conditions*

To establish the background-perturbation split, all that's left to do is to establish the consistency condition for εg^1_{ab}, that is, to show that it remains small relative to g^0_{ab}. The order ε^{-1} equation is

$$\rho^{-1}_{\mathrm{rel},ab} + \rho^{-1}_{\mathrm{nr},ab} = -\frac{1}{2}g_0^{cd}\partial^2_{X^cX^d}g^1_{ab}, \tag{8}$$

where the subscript 'rel' ('nr') is there, to remind one that this is a relativistic (Newtonian) contribution to the energy-momentum tensor, one which arises, upon Fourier transforming in X, from matter modes which have a relativistic (non-relativistic) dispersion relation. In fact, because $\partial_X g^0 = 0$, in-so-far-as the X-co-ordinates are concerned, the space-time over which g^1_{ab} is defined *qua* a tensor-valued function, is flat: equation (8) is a wave equation for g^1_{ab}, with an X-independent metric $g^0_{ab}\mathrm{d}X^a\mathrm{d}X^b$, so its solutions are waves in flat space-time, parameterised by the large-scale co-ordinate x. This also means that a Fourier transform in X is unambiguous.

Since $\rho^{-1}_{\mathrm{rel},ab}$ is in resonance with the wave-equation operator, the consistency of the asymptotic expansion requires that, in fact, it vanish. If it does, then εg^1_{ab} remains smaller than g^0_{ab}.[10] So far there have been two non-trivial consistency conditions, which limit the applicability to Newtonian sources. Relativistic ones are allowed, though, at all orders, from ε^0 and above. One can generalise this to conclude that whenever $\rho^n_{\mathrm{rel},ab} \neq 0$, one needs an X-dependent g^{n-1}_{ab}, that will precisely cancel the resonances that arise. For example, at $n = 2$, this is the case, and after a few manipulations, one finds, for $k^2 = 0$ (where k is the Fourier conjugate of X)

the following consistency condition:

$$-k^c\partial_{x^c}\hat{g}^1_{\mathrm{hom},ab}(x,k)+P^{cdefgh}_{ab}(g_0)\left(k_c\hat{g}^1_{\mathrm{hom},ef}(x,k)\partial_{x^d}g^0_{gh}+k_d\hat{g}^1_{\mathrm{hom},gh}(x,k)\partial_{x^c}g^0_{ef}\right)$$
$$-\mathrm{i}\int \mathrm{d}^4X e^{\mathrm{i}k\cdot X}\left\{P_{ab}(g_0)\partial_X g_1\partial_X g_1-\frac{1}{2}g_1^{cd}\partial^2_{X^cX^d}g^1_{ab}\right\}_{\mathrm{osc}}=-8\pi\mathrm{i}G\hat{\rho}^0_{ab}(x,k), \quad (9)$$

where a circumflex denotes a Fourier transform in X, a subscript 'osc' means that one removes the X average of the term in the curly brackets from it, and $g^1_{\mathrm{hom},ab}$ is the homogeneous part of the solution of equation (8).

This is the key element of the multiple-scales expansion: the additional degrees of freedom, that are created by treating x and X separately, are fixed by requiring the asymptoticity of the expansion in ε – by removing resonances order-by-order. Indeed, as there is an un-fixed homogeneous part in g^1_{ab}, relativistic sources in ρ^0_{ab} are not a problem.

The X-independent part of the Einstein equation at order ε^0 also gives an effective Einstein equation, governing the large-scale dependence of g^0_{ab}:[10]

$$-\frac{1}{2}g_0^{cd}\partial^2_{x^cx^d}g^0_{ab}+P_{ab}(g_0)\partial_x g_0\partial_x g_0-\Lambda g^0_{ab}-B_{ab}=8\pi G\langle\rho^0_{ab}\rangle_X. \quad (10)$$

When computed in a co-ordinate system of a freely-falling observer in the x-spacetime, the back-reaction tensor B_{ab} corresponds, roughly, to the X-averaged Newtonian gravitational potential energy of the sources in $\rho^{-1}_{\mathrm{nr},ab}$. The averaged equation agrees with the one derived by Green & Wald (2011)[9] under different assumptions.

2.4. *Single Short Mode*

Let me also give a simple example of a situation where $B_{ab}\neq 0$. Consider a cosmological setting, where, in addition to the uniform matter density $\mu_0(\eta)$, the matter distribution has a component $\delta\mu(\eta,\mathbf{x})=2\varepsilon\mu_0(\eta)\rho_0\cos(\mathbf{k}\cdot\mathbf{x}/\varepsilon)$, where $\mathbf{k}$ is a constant of order one, and $\rho_0\mu_0$ is much smaller than the critical density of the Universe.[a] Here, η, $\mathbf{x}$ are conformal, co-moving co-ordinates. The back-reaction tensor, in this case, is given by[10]

$$B^{ij}=\frac{\mu_0^2\rho_0^2}{2a^2k^4}\left(k^ik^j+k^2\delta_{ij}\right), \quad (11)$$

with all other components equal to zero, to leading order in ρ_0. This back-reaction, albeit small, introduces, unsurprisingly, anisotropic stress perturbations.

3. Conclusions

In conclusion, the multiple-scales technique enables one to show that there is a well-defined background metric that depends only on the large-scale, as well as to derive an effective Einstein equation where small-scale gravitational potential

[a]This latter assumption is not strictly necessary, but simplifies matters considerably, in that it allows one to expand in $\rho_0\mu_0/\rho_{\mathrm{crit}}$, which is an expansion in large-scale cosmological perturbations, and then proceed as one would do for standard cosmological perturbation theory.

energy acts as a source of gravity on the large scale. Additionally, one can determine the consistency conditions under which these conclusions obtain, and, in particular, that they do obtain when small-scale over-densities are chiefly due to non-relativistic matter, to leading order in ε.

In the future it would be worthwhile to try to expand this technique from asymptoticity to a convergence property, e.g. two-scale convergence,[13] and also, perhaps more importantly for practical applications, to attempt to include small-scale relativistic objects, such as neutron stars or black holes, perhaps by utilising some extension of Birkhoff's theorem.[14] It is plausible that this theorem would allow one to include isolated black holes in the multiple-scales framework, by relaxing the requirement $\varepsilon \left|g^1_{ab}\right| \ll \left|g^0_{ab}\right|$, and allowing g^1_{ab} to take extremely large values in some very restricted areas of space-time. This should enable one to conclude from Birkhoff's theorem or something similar that an observer far from any isolated black holes will not observe any more back-reaction than if these black holes were normal stars with the same masses.

Imaging formation process for DM profiles

Omar de J. Cabrera-Rosas* and Tonatiuh Matos

Departamento de Física, Centro de Investigación y de Estudios Avanzados del IPN, México Distrito Federal, A.P. 14-740, 07000, México

**E-mail: omar.cabrera@cinvestav.mx*

The imaging formation process in halos for some dark matter profiles is studied. Approaching these models on a small scale, we analyze the images generated on the lens plane by obtaining the analytical surface mass densities $\Sigma(x)$ and their corresponding deflection angles $\alpha(x)$. We identify the presence of Einstein rings, by mapping fringes that represent possible sources (such as other galaxies), placed on the source plane. We approach the simplest case, where lines parallel to the x axis are mapped onto the lens plane, to find out how are the solutions of the $\mathbf{X}$ vector field, which is in this case, the geometrical equivalent to the usual lens mapping.

Keywords: Dark Matter, Gravitational Lensing

1. Introduction

The dynamics of galaxies is a topic of great interest in cosmology. In recent years, this dynamic has been studied with the observation and analysis of the rotation curves of several samples of galaxies. From these observations an acceleration has been measured, and the presence of Dark Matter (DM) is necessary to explain their dynamics.[1,2]

The restrictions belonging to the central surface density of the halo, determine the value of the quantity μ_{DM} which is always a constant, that it seems to be an universal invariant, and there are evidences of this restriction in spiral, dwarf irregulars and ellipticals galaxies to name some types.[3–6] It is important to observe that μ_{DM} is constructed as the product of the characteristic length r_s and the central density value ρ_s of each galaxy, and this is related with the *soliton* region (the core of the galaxy). This is an important zone, because the extra galactic components do not alter this region and the invariant objects present there, are very helpful to understand the complete behavior of the galaxy.[7] In fact, certain models for Scalar Field Dark Matter (SFDM) have predicted that the total mass of these systems is $M_{DM}(300\text{pc}) \sim 10^7 M_\odot$ with a characteristic size $r_s = 300\text{pc}$; that is, the soliton region is perfectly delimited for its analysis, and it is very important for eventual tests that improves the physics interpretation of the data. Therefore, to study the dynamical process for translating this information to the imaging information, this soliton zone must be analyzed, with the corresponding considerations for that region.

In fact, the universal DM profile (the Navarro-Frenk-White profile NFW) has been exhaustively studied, because it fits properly with observational data[8,9];

however, it presents problems on a small scale, which implicates that there must be another models, that explain the core zone.

For the above reasons, a complete optical analysis of this region is in order, using the proper data that comprehends all the physical information encoded in each model, but at the same time with a simplification of the studied equations. Hence, we use the usual gravitational lensing formalism,[10] that contains all the mathematical restrictions to fully understand such optical processes. Hence, we compute the images on the lens plane, as functions of the positions of the sources, the source plane and the redshift, which is encoded into the critical surface mass density Σ_{cr}, that appears in the volumetric density $\rho(r)$ (and thus, into the deflection angle $\alpha(r)$ generated in each physical situation). Therefore, the principal goal for using this approach, is to describe the images generated for recent models of DM, and test which of them behave like the observed data. In this stage of the work, we only study the images generated by objects (fringes) very near to the observation axis, by finding the roots of the equation that represents the mapping in that zone (see Eq. 13 below). This eventually means to translate the optical information obtained from the corresponding images, and link it with the information of the galactic dynamics.

This work is organized as follows. In section 2 we set the basic equations for gravitational lensing, and we obtain the surface mass density and the deflection angle analytically for each profile. In section 3, we establish the $\mathbf{X}$ vector field that describes the ray tracing of the optical process; later we use the method provided in,[11] to study the images that will appear on the lens plane. Finally in section 4, we present the conclusions of this work.

2. Basics equations for gravitational lensing

The configuration for gravitational lensing is as usual[10] , where the source plane, the lens plane and the observer are shown. D_s, D_l and D_{ls} are the distances between observer and source, observer and lens and between lens and source planes, respectively.[10] Now, assume that the DM density profile is given in the form $\rho(x) = \rho_s f(x)$, with ρ_s, r_s and $x = r/r_s$ are the characteristic density, the characteristic radius and the scale radius, respectively; $f(x)$ is any given function of its argument.[2] Hence, it is necessary to find the deflection angle in each case, and because the systems considered here are axially symmetric, the surface mass density and the deflection angle are given by[10]

$$\begin{aligned} \Sigma(\xi) &= \int_{-\infty}^{\infty} \rho(\xi, z) dz, \\ \alpha(x) &= \frac{m(x)}{x}, \end{aligned} \tag{1}$$

Name	$f(x)$	$\Sigma(x)$	$\alpha(x) = m(x)/x$
(1)	(2)	(3)	(4)
Burkert	$\frac{1}{(1+x)(1+x^2)}$	$\beta_B F(x)_B$	$\frac{\sigma_B}{x} g(x)_B$
M-SFDM	$\frac{\sin^2 x}{x^2}$	$\beta_{MsT} F(x)_{MSt}$	$\sigma_{MsT}\left[J_1(2x) + \frac{x^3}{3}\right]$
PI	$\frac{1}{1+x^2}$	$\frac{\beta_{PI}}{\sqrt{1+x^2}}$	$\frac{\sigma_{PI}}{x}(\sqrt{x^2+1} - 1)$
Spano	$\frac{1}{(1+x^2)^{3/2}}$	$\frac{\beta_{Sp}}{1+x^2}$	$\frac{\sigma_{Sp}}{x}\ln(1+x^2)$
Wave DM	$\frac{1}{(1+x^2)^8}$	$\frac{\beta_W}{(x^2+1)^{15/2}}$	$\frac{\sigma_W}{x}\left(1 - \frac{1}{(x^2+1)^{13/2}}\right)$
NFW	$\frac{1}{x(1+x)^2}$	$\frac{2\mu_{DM}}{x^2-1} F(x)_{NFW}$	$\frac{4\kappa_s}{x}\left(\ln\frac{x}{2} + \frac{2}{\sqrt{1-x^2}}\operatorname{arctanh}\sqrt{\frac{1-x}{1+x}}\right)$

where the radial coordinate r is related to cylindrical polar coordinates by $r = \sqrt{\xi^2 + z^2}$ and $m(x)$ is the dimensionless mass defined by

$$m(x) = 2\int_0^x \kappa(\xi)\xi d\xi. \tag{2}$$

The shear of the system is

$$\kappa(x) = \Sigma(x)/\Sigma_{cr} \tag{3}$$

and $\Sigma_{cr} = c^2 D_s/(4\pi G D_l D_{ls})$ is the critical surface mass density.

Using Eqs. (1) and (2), it is obtained the above table, by using the Burkert, Multistate-SFDM, PI, Spano, Wave DM and NFW dark matter profiles given in,[2,7] where β and σ are constants that determine the scaling of such core, and they depend on the values of μ_{DM} and κ_s.

For the Burkert profile the $F(x)_B$ function for the surface mass density is given by

$$\begin{aligned} F(x)_B &= \frac{1}{\sqrt{1+x^2}}\left[\frac{\pi}{2} + \operatorname{arctanh}\left(\frac{1}{\sqrt{1+x^2}}\right)\right] \\ &-2\begin{cases} \frac{1}{\sqrt{1-x^2}}\operatorname{arctanh}\sqrt{\frac{1-x}{1+x}} & (x<1), \\ \frac{1}{\sqrt{x^2-1}}\arctan\sqrt{\frac{x-1}{x+1}} & (x>1), \end{cases} \\ &= \frac{1}{\sqrt{2}}\left[\frac{\pi}{2} + \operatorname{arctanh}\left(\frac{1}{\sqrt{2}}\right)\right] - 1 \quad (x=1), \end{aligned} \tag{4}$$

and the $g_B(x)$ function for the deflection angle is

$$g(x)_B = \frac{1}{2}\left[x^2\left(\frac{\pi}{2} + \operatorname{arctanh}\left(\frac{1}{\sqrt{1+x^2}}\right)\right) + \sqrt{1+x^2}\right] + \ln x$$
$$+2\begin{cases} \sqrt{1-x^2}\operatorname{arctanh}\sqrt{\dfrac{1-x}{1+x}} & (x<1), \\ -\sqrt{x^2-1}\arctan\sqrt{\dfrac{x-1}{x+1}} & (x>1), \end{cases} \tag{5}$$
$$= \frac{\pi}{4} + \frac{1}{\sqrt{2}} + \frac{1}{2}\operatorname{arctanh}\frac{1}{\sqrt{2}} \quad (x=1).$$

For the Multi-State profile, the F_{MSt} function for the surface mass density is given by

$$F(x)_{MSt} = J_0(2x) + \frac{\pi}{2}[J_1(2x)\mathbf{H}_0(2x) - J_0(2x)\mathbf{H}_1(2x)], \tag{6}$$

where J_ν are the Bessel functions of the first kind of ν-th order and $\mathbf{H}_\mu$ the Struve functions of μ-th order[12,13]; the F_{NFW} function and the corresponding deflection angle for the NFW profile are given in.[8,9]

3. Imaging formation

Knowing the deflection angle for each case, it is possible to develop the imaging formation process. It will be helpful to express the quantities for describing the optical process, in a cylindrical coordinate basis $\{\hat{\boldsymbol{\varrho}}, \hat{\boldsymbol{\phi}}, \hat{\boldsymbol{z}}\}$. From this information, the imaging mapping is given by the vector field

$$\mathbf{X} = \mathbf{r} + l\hat{\mathbf{R}}_G, \tag{7}$$

where $\hat{\mathbf{R}}_G$ is the gravitational refraction ray given by[11]

$$\hat{\mathbf{R}}_G = \cos\alpha\hat{\boldsymbol{z}} - \sin\alpha\hat{\boldsymbol{\varrho}}, \tag{8}$$

and l is the length from the lens plane $z=0$, to a point on a given deflected light ray.

Using Eq. (7) the deflected light rays are

$$\mathbf{X} = (\varrho - l\sin\alpha)\hat{\boldsymbol{\varrho}} + l\cos\alpha\hat{\boldsymbol{z}}. \tag{9}$$
